Propylene oxide is important product in chemistry industry, because it is used in the productions of glycols, polyurethanes and different type of plastics. Currently there are two main industrial methods for propylene oxide production. Organic hydroperoxide process and chlorhydrin process have been used for commercially produce propylene oxide [1, 2]. However, these methods are not appropriate from the view of "green chemistry". Recently, considerable progress has been made in the epoxidation of propene with molecular oxygen over coinage metal catalysts such as Au and Ag [3, 4]. However, both gold and silver catalysts have some problems in propene epoxidation. Thus, use of silver in reaction has been difficult because of the low conversation of propylene and a low selectivity towards propylene oxide. Some features of mechanism using a silver catalyst have not been established. In the case of gold catalysts, gold supported on TiO_2 or titanium silicate zeolites converts propene to propylene oxide with a high selectivity (≈90%), but selectivity of gold particles is sensitive to their size and shape [4].

The main goal of this study was to investigate of the structure of the active centre of the silver and gold-doped silver clusters on the reaction mechanism.

2 Methodology

Geometry optimizations were performed within the spin-polarized approach (PBE functional) [5]. The Priroda program [6] was used for the all-electron calculations within the scalar-relativistic approach, which was based on the full four-component one-electron Dirac equation with separation of the spin–orbit effects. The initial coordinates of the tetrahedral Ag_{20} cluster were taken from previous studies [7]. Mono-doped $Ag_{n-1}Au$ clusters have been generated by substituting one Ag atom with a Au atom in the Ag_{20} clusters at relatively low-coordinated sites. The true TS structures were determined according to the Berny algorithm [8]. Calculations of the intrinsic reaction coordinate through the single imaginary mode of the TS were performed to validate the TS structures.

3 Results and discussion

A key step of oxidation process is the interaction of molecular oxygen with catalysts and the formation of active oxygen (superoxide O_2^-, peroxide O_2^{2-}, and atomic $O_{(ad)}$). The type of adsorbed oxygen species affects the rate and the mechanism of the catalytic reactions, and in the beginning of our research the quantum chemical analysis of the structure and electronic properties of $Au_{20-x}Ag_x$ (x = 0, 1) and influence of heteroatoms in Ag_{20} on the oxygen adsorption and dissociation was performed. The oxygen activation was determined by such parameters as heat of adsorption (Q_{ads}), metal−oxygen distance, oxygen-oxygen distance and vibration frequency ω(O-O). We calculated all these parameters and identified that increase of distance O-O and decrease vibration frequency occur with increasing oxygen activation on metal. According to quantum chemical calculation oxygen interacts with atoms with low coordination number [9].

The next step was to investigate mechanism of reaction of propylene oxidation on silver and

bimetallic $AuAg_{19}$ clusters. Before the search of the reaction mechanism, we calculated propylene adsorption on oxidized complexes $Ag_{20}O_2$ and $AuAg_{19}O_2$. Than we selected the most stable structures (Figure 1): (a) where propylene bonds with defect silver atom with adsorption energy (E_{ads}) about -110 kJ/mol and (b) where propylene bonds with not defect silver atom with E_{ads}=-70 kJ/mol. Modeling of the oxidation reaction has shown that the reaction goes through the formation of a five-membered oxametallacycle consisting of two metal atoms and a −O−C−C− fragment and four-membered oxametallacycle including a single metal atom and −O−C− fragment, that results agree with experiment data.

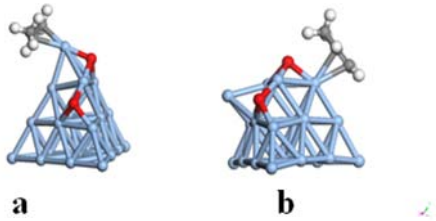

Fig. 1. Optimized structures of $Ag_{20}O_2C_3H_6$

4 Conclusions

Three type of oxygen adsorption was observed: molecular, bridge, and dissociation. The most oxygen activation was observed in case of dissociative adsorption. Oxygen adsorption leads to marked deformation of the clusters as compared to the bare neutral structure.

Simulation the pathway of propylene oxidation has shown that the reaction goes through the formation of a five-membered oxametallacycle consisting of two metal atoms and a −O−C−C− fragment and four-membered oxametallacycle including a single metal atom and −O−C− fragment.

A Comparative Study of Methanol Conversion to Light Olefins over SAPO-34 Prepared via Conventional and Ultrasound Assisted Hydrothermal Methods

Ibragimov H.J.[1], Babaeva F.A.[1], Ahmadova R.H.[1], Rodemerck U.[2], Kondratenko E.V.[2*]

* rena_ax@rambler.ru

Keywords: SAPO-34, hydrothermal, ultrasound, methanol, light olefins

1 Introduction

Because of growing demand for light olefins and the shortage of petroleum resources in the future, the methanol-to-olefin (MTO) technology, regarded as an alternative process for the production of light olefins from nonpetroleum sources, has received strong significant academic and industrial attention [1]. Silicoaluminaphosphate molecular sieves (SAPOs), with CHA framework, have been widely used in many chemical processes, especially in methanol-to-olefin (MTO) process. The SAPO-34 catalyst shows higher selectivity for lower olefins and the complete conversion of methanol in the MTO reaction. Chemical and structural properties of SAPO-34 can affect the methanol conversion and product distribution in MTO process. Thus, optimization of effective parameters in catalyst synthesis is very important steps for development of MTO process [2]. In this study we investigated influence of synthesis method of catalyst to its activity.

2 Experimental/methodology

The SAPO-34 catalyst was synthesized via conventional (HT) and ultrasound assisted hydrothermal (SONO) methods. For synthesis of HT-SAPO-34 the final gel was stirred for 25 h, for synthesis of SONO-SAPO-34 the gel was sonicated for 30 min. In the case of HT-SAPO-34 the synthesis was accomplished at two temperatures for 12 h – 120^0C with further increasing to 200^0C, but in the case of SONO-SAPO-34 at 200^0C for 48 h. Then samples were centrifugated and washed followed by-drying at 110^0C for 12 h and calcination at 550^0C for 12 h. Catalytic tests were conducted at 450^0C-, and 0.125 MPa-, for 5 h on stream using $CH_3OH:N_2$=60:40 feed with a contact time of 2.05 $mg_{cat}\cdot min\cdot ml^{-1}$ with respect to methanol.

3 Results and discussion

C_2-C_4 low olefins were main products of reaction, while C_1-C_4 alkanes were formed in a low amount. Methanol conversion was complete during the process. Figure 1 shows the yield of C_2-C_4 olefins as function of time on stream. Difference in catalytic activity of HT-SAPO-34 and SONO-SAPO-34 was observed during catalytic tests.A short glance on the figure confirms the positive effect of ultrasound pretreatment of gel on catalyst activity and stability. Perfect crystalline structure of SONO-SAPO-34 makes it stable catalyst with longer life time. This conclusion is supported by the fact based on XRD analysis (the average crystallite size calculated for HT-SAPO-34 and SONO-SAPO-34 are 33 and 27 nm, respectively). The effectiveness factor of SONO-SAPO-34 can be explained with less crystal size. The low stability of HT-SAPO-34 can be addressed by its improper crystallinity.

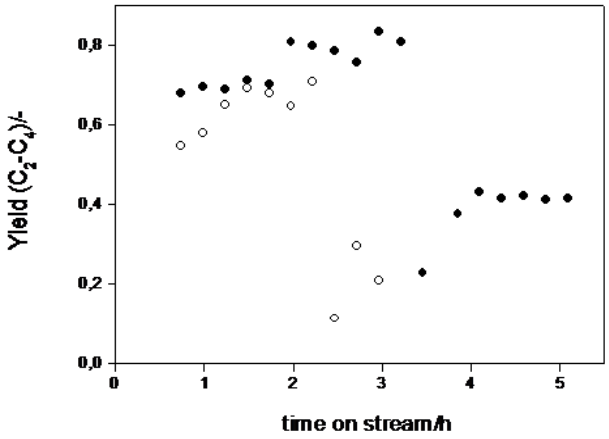

Fig. 1. Time-on-stream yield of C_2-C_4 olefins over HT-SAPO-34- ○ and SONO-SAPO-34- ●

In both cases, with rapidly deactivation of catalysts dimethyl ether is formed in high amounts.

4 Conclusions

The catalytic performance study reveals that SONO-SAPO-34 is a suitable catalyst for MTO process due to its high activity and stability in comparison to HT-SAPO-34.

Keywords: layered double hydroxide (LDH), hydrotalcite, unstable oxidation, state, nickel

1 Introduction

Layered double hydroxides (LDHs) of the hydrotalcite family are layered materials of the general formula $\left[M^{2+}_{1-x} M^{3+}_{x} (OH)_2 \right]^{x+} (A^{n-})_{x/n} \cdot mH_2O$. Interest in LDHs is due to the presence of a number of unique properties typical forgiven class of compounds: magnetic, optical, redox properties, etc. The papers discussing the synthesis and properties of LDHs with cations of different nature and rather complicated mixtures of cations are rather common [1, 2]. However the papers are mainly focused on the introduction of those cations, for which valences 2 and 3 are the most stable ones (iron, copper, zinc, chromium, bivalent nickel, cobalt, gallium, and others). Attempts of stabilization of unstable valence states of the cations in the lattice of LDH are poorly described. At the same time such systems may exhibit unusual redox, catalytic and other properties therefore their synthesis might be of interest. The present article is concerned with the study of systems of co-precipitated hydroxides of magnesium (II), aluminum (III) and nickel (III).

2 Experimental

LDHs containing Ni^{3+} ions in the structure of metal hydroxide layers were synthesised by co-precipitation from the aqueous solutions of mixtures of magnesium, aluminium and nickel salts in oxidizing media. Sodium hypochlorite was used as the oxidizing agent. After synthesis the samples were transformed to carbonate form by ion exchange. The phase composition of samples were studied by X-ray diffraction (XRD) using Rigaku diffractometer (CuK_α - radiation with scanning step 2θ 0,5°). Chemical analysis of the samples was performed using scanning electron microscope QUANTA 3D equipped with a detector of the characteristic X-ray dispersive energy photons (20 kV). Content of Ni^{3+} in the samples was determined by iodometric titration.

3 Results and discussion

Atomic ratio Al^{3+}:Ni^{3+}in the co-precipitated samples was varied in a wide range. Fig. 1 displays XRD patterns for the samples prepared. In the absence of aluminum hydrotalcite-like phase is not formed, only the formation of individual brucite and nickel (III) hydroxide with the structure of brucite was observed. In the systems Mg/AlNi-1:3 and Mg/AlNi-1:1 the coexistence of brucite, Ni (III)-containing layered hydroxide and nickel (III) hydroxide was proved. Only a product obtained from a solution with cations ratio Mg:Al:Ni = 12:3:1is represented by a single phase with a structure similar to hydrotalcite. The formula of synthesized LDH was calculated on the base of the results of chemical analysis: $Mg_6Al_{1,52}Ni_{0,48}(OH)_{15,97}Cl_{0,03}CO_3 \cdot 3{,}5H_2O$. The

presence of chlorides not replaced by carbonate anions is probably due to the fact that in the course of synthesis Cl^- is able to substitute some OH^--groupsin metal hydroxide layers in the structure [3].

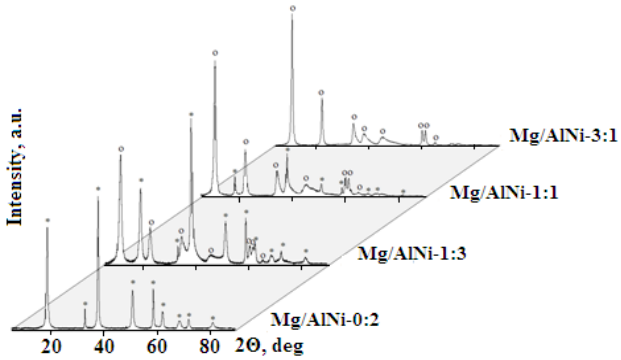

Fig.1. X-ray diffraction of the synthesized samples (* - brucite, o - hydrotalcite)

The content of Ni^{3+} in LDH sample was monitored for 12 months (Fig. 2). For comparison Ni^{3+}content was determined in the synthesized sample of nickel hydroxide ($Ni_2O_3 \cdot xH_2O$). The values of m_t/m_0(the ratio of mass fractions of Ni^{3+}in the sample after the storage and the as-precipitated samples) for the samples demonstrate that $Ni^{3+}$is much more stable in the matrix LDH than in the nickel (III) hydroxide.

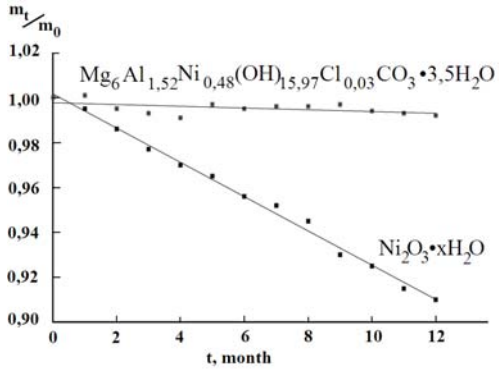

Fig.2. Decrease of Ni^{3+}content in the samples

4 Conclusions

LDH containing Ni^{3+} ions in the structure of metal hydroxide layers was synthesised. The formation of single phase product was shown to be possible with a substitution of up to 25% aluminium ions for nickel in the structure of hydrotalcite. Thus the introduction of cations in the structure of hydrotalcite allows to stabilize them in unstable oxidation state.

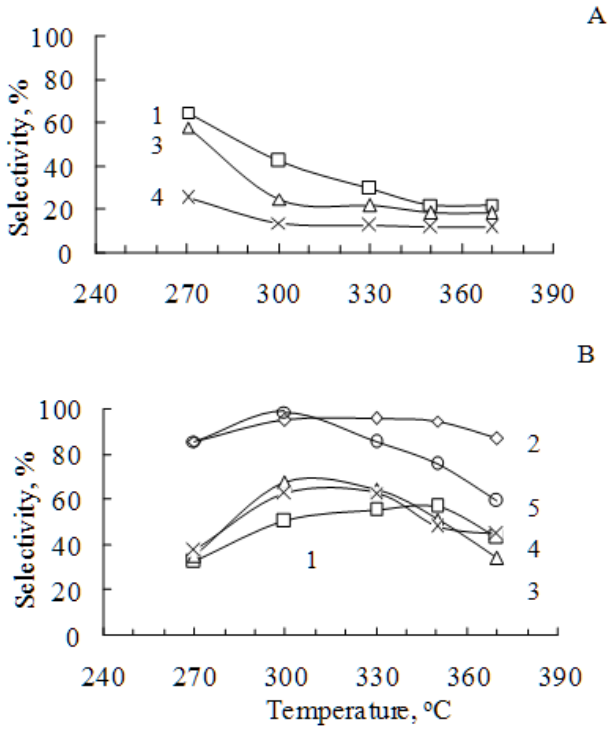
Keywords: oxidation, catalyst, vanadia, 4-methylpyridine, cluster approach, modeling

1 Introduction

Heterogeneous vapor phase catalytic oxidation of 4-methylpyridine is a new efficient and ecology friendly technology of isonicotinic acid, feedstock for the synthesis of a number of antituberculosis drugs. [1]

2 Experimental

Maximum selectivity of isonicotinic acid is 57% on vanadia at a temperature of 350°C. Pyridine-4-carbaldehyde is contained in the reaction products together with isonicotinic acid. Vanadia catalyst promotion of additives of metal oxides of groups IV-VI of the Periodic System reduces the content of pyridine-4-carbaldehyde in the reaction products and increases selectivity of isonicotinic acid (Fig.) .



Volumetric feed rate of 4-methylpyridine-35 г·л$^{-1}_{кат.}$·ч$^{-1}$. molar ratio 4-methylpyridine:O_2:H_2O=1:14:26.
Catalysts: 1 – V_2O_5, 2 – V_2O_5-TiO_2, 3 – V_2O_5-Al_2O_3, 4 – V_2O_5-Fe_2O_3, 5 – V_2O_5-ZrO_2.
Fig. Dependence of selectivity of pyridine-4-aldehyde (A) and isonicotinic acid (B) formation from temperature of 4-methylpyridine oxidation on various catalysts

During oxidation of 4-methylpyridine corresponding aldehyde is formed with a higher yield than during oxidation of 3-methylpyridine. The reason for this is the lower the basicity of the pyridine-4-carbaldehyde compared to 3-isomer. Pyridine-4-carbaldehyde kept weaker on the acid sites surface, it does not have time to oxidize into isonicotinic acid and therefore desorbed into the gas phase. Quantum chemical calculations of the basicity of the pyridine-3- and pyridine-4-aldehydes in the gas phase and experimental data on the influence of water on kinetics of oxidation of 4-methylpyridine confirm this hypothesis (table). At a chemisorption on a catalyst surface water creates the new acid centers capable to interact with heteroatom of nitrogen of a substratum.

Table. Effect of water concentration on the rate constants of stages of 4-methylpyridine oxidation on the V-Ti-Zr-oxide catalyst at a temperature of 245°C. The initial concentrations: [4-methylpyridine] = 1,1 • 10-4, [O2] = 9,4 • 10-3 mol • L-1

Stage №	Stage of reaction	k_i, c^{-1}					
		$[H_2O] \cdot 10^3$, mol/l					
		0	1,3	2,45	5,1	8,9	15,2
1	4-Methylpyridine→ 4-PyCHO	1,788	1,970	2,799	3,891	4,269	4,241
2	4-PyCHO → 4-PyCOOH	1,713	1,968	3,790	6,249	6,389	9,571
3	4-PyCOOH →Py	0,290	0,126	0,080	0,088	0,078	0,056
4	4-Methylpyridine → CO_2	0,084	0,276	0,485	0,316	0,118	0,161
5	4-PyCOOH → CO_2	0	0	0	0,667	0,434	0,514
6	4-PyCHO → 4-PyCN	0,164	0,597	0,814	1,079	0,862	0,650

3 Results and discussion

Kinetic calculations show that isonicotinic acid arise via stage of forming 4-pyridine carbaldehyde. At the stage 3 part of the acid is decarboxylated until pyridine.
When water concentration increases the velocity constant of the aldehyde conversion into acid dramatically rises. 4-cyanopyridine is present in the reaction products. Nitrogen donor for the pyridine-4-aldehyde conversion to 4-cyanopyridine in the stage number 6 are nitrogen moieties of deep oxidation initial 4-methylpyridine (stage number 4) and isonicotinic acid (stage number 5) [2].

4 Conclusion

The cluster approach and the program Gaussian-09 W were used to model both the 4-methylpyridine chemisorption on the vanadia and vanadium binary catalysts surface. It is shown that the promotional effect of the modifier oxide on the vanadia catalytic activity is caused with increasing of nucleophilicity (proton affinity) of vanadium bonded oxygen and reduction enthalpy of deprotonation of the oxidized methyl group of the chemisorbed 4-methylpyridine. An interesting fact is that the avulsion of a proton from the methyl group and its transfer to the vanadyl oxygen of cluster to form a new bond ≡V-O-H requires less energy than heterolytic breaking C-H bond of the methyl group chemisorbed substrate. This can be explained by the fact that "when moving along the reaction path the energy required to break the old bonds, compensated by the energy released in the formation of new" [3].

Keywords: pyrophosphate, phosphate, TiP_2O_7, ODH, n-butane, nano-catalyst

1 Introduction

Titanium pyrophosphates (TiPO) are used in the conversion of n-butane. TiPO catalysts were prepared, by used several methods [1-3] then characterized and tested in ODH of n-butane. Catalyst were characterized by means of X-ray diffraction (XRD), Fourier transformed infrared (FT-IR), Thermal gravimetric analysis (TGA), Brunner-Emmett-Teller surface area measurement (BET) and temperature-programmed desorption of ammonia (NH_3-TPD), Field Emission Scanning Electron Microscopy (FE-SEM) to characterise and describe structural and textural surfaces properties. The effect of the preparation method in conversion of n-butane into butenes and butadiene has been investigated.

2 Experimental

Catalysts preparation:

1. Method A: precipitation-concentration A: done in two steps, 1) is to synthesize titanium oxide TiO2 by coprecipitation of $Ti(OH)_4$ hydroxides. 2) Titanium dioxide and stoichiometric amount of phosphoric acid (85%) are agitated at 80°C, then dried, crushed and calcined [1].

2. Method B: Method coprecipitation B: A sodium pyrophosphate $Na_4P_2O_7$ 0.1M is added in Drop Count in stoichiometric ratios to a 0.1M solution of titanium chlorides $TiCl_4$ in hydrochloric acid 6M (HCl 37%). The precipitate is filtered and washed then dried overnight. Then crushed and calcined too [2].

3. Method S: Solid phase method S: Titanium dioxide TiO2 is mixed in stoichiometric amounts with diammonium hydrogen phosphate $(NH_4)_2HPO_4$. The mixture is grind vigorously and then dried at 120 ° C for one a week, then calcined [3].

Characterization:

The TGA analysis was carried out on a Perkin Elmer Thermal Analyzer. Powder X-ray diffraction patterns were recorded employing CuKα radiation (λ = 1.5418 Å). FTIR analyses were determined using KBr method. The specific surface area of the catalyst sample was measured by BET method. The TPD-NH_3 analysis was done. The acidity and the acidic strength distribution of the catalyst were studied. The morphology surface images of nanostructures of TiPO catalysts were acquired by using (FE-SEM).

Catalytic activity:

The catalytic tests were performed in a fixed bed reactor in the reaction temperature range of 400-500°C, Gas feeds: air/butane= 5/1. The reaction products were analyzed by gas chromatography.

3 Results and discussion

The P:Ti ratios obtained from chemical analysis were close to the theoretical ones for both solids. The specific areas and porosities are shown in Table1. The FTIR spectrum shows titanium pyrophosphate frequencies observed in similar compounds are examined [1-2].

Table 1. Physico-chemical properties of bismuth pyrophosphate catalysts.

Catalyst	Specific surface area ($m^2.g^{-1}$)	Pore volume (10^{-2} cm3.g^{-1})	Particle size* (nm)	Acidity (mmol.g^{-1})	Conv (%)	Sel (%)	Yield
TiPO-2-A	6.51	3.46	41.23	0.38	**25.2**	**45.59**	11.47
TiPO-2-B	6.46	1.8	51.8	1.71	**46.3**	**10.6**	4.9
TiPO-2-S	3.20	2.12	56.42	0.15	**28.1**	**42.95**	**12.07**

***** FE-SEM calculated particle size.

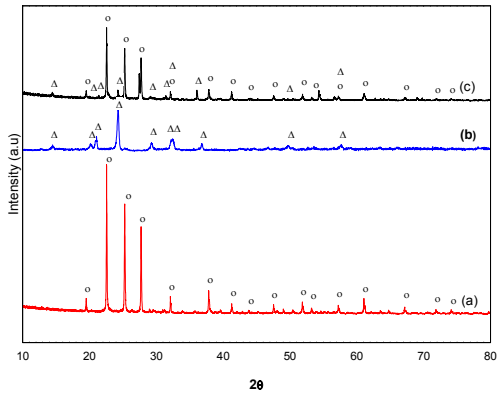

Fig.1. X-ray diffraction patterns of TiPO samples:
a) TiPO-2-A, b) TiPO-2-B, c) TiPO-2-S

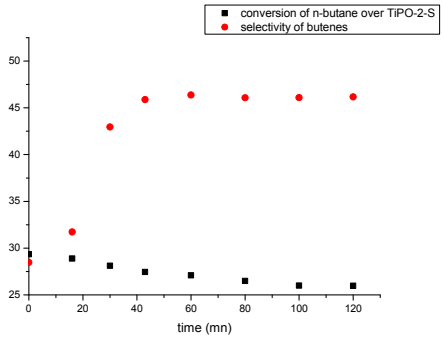

Fig. 2. Conversion of n-butane and butenes selectivity of TiPO-2-S catalyst

In XRD spectra (Fig.1) we identify the phase TiP_2O_7 (JCPDS 00-038-1468) in samples TiPO-2-A and TiPO-2-S. The DTA/TG curves show that samples are stable up 600°C. FE-SEM showed condensed nanoparticles. The major product under this reaction condition is trans-2-butene. The ODH reaction of n-butane gives the best yield (12.07) obtained over TiPO-2-S catalyst, with a conversion of 28.12% and selectivity of 42.95%; which is inversely related to the acidity of the catalyst.

4 Conclusions

The conversion of n-butane and selectivity in ODH are stable in the early measures. For the three catalysts, the best performance is observed at the same temperature 450 °C and for the same reaction time (35 min). All catalysts are activated over time.

Relationship between Surface Acid/Base Sites of Solid Catalysts and their Catalytic Activity in Biomass Derived Reactions

Bennici S., Auroux A.*

Université Lyon 1, CNRS, UMR 5256, IRCELYON, Institut de Recherches sur la Catalyse et l'Environnement de Lyon, Villeurbanne, France

* aline.auroux@ircelyon.univ-lyon1.fr

Keywords: acidity/basicity, adsorption calorimetry, fructose dehydration

1 Introduction

Among other parameters, the catalytic activities of solid materials are dependent on the accessibility of active sites to reactant molecules. Relative acid strengths of solid catalysts depend markedly on whether a solvent is present, on the nature of the solvent, and may vary as the medium in which the acidity is measured is changing [1,2].

2 Experimental/methodology

A series of acid materials such as zeolites (MFI), silica-alumina (Si-Al), niobium oxide (NBO), niobium phosphate (NBP), and resin (Nafion) have been studied in terms of number, strength and activity of their acid sites. In gas phase adsorption calorimetry the acidity was determined using ammonia as basic probe. In water, acidity of samples was estimated through the adsorption of a typical basic probe molecule, phenylethylamine diluted in water; and using a differential titration microcalorimeter for the determination of the strength and UV-vis spectroscopy for the determination of the number of acid sites, both performed in similar conditions. The equilibrium isotherm and heats of adsorption are the critical design variables in estimating the performance of an adsorption process. Their shapes proved significant information on the nature and the strengths of solvate-solvent and sorbate-solvent interactions and also the degree of energetic heterogeneity of the solid surfaces under study.

The same samples were probed as catalysts for the dehydration of fructose to 5-HMF, a reaction which has attracted much attention because of the demand of renewable resources, such as biomass, as substitutes for petroleum chemicals [3].

3 Results and discussion

Correct evaluation of reliable experimental data from titration calorimetry for systems with well-defined initial state and with controlled addition of a base titrant results in differential heats of surface processes. Results allowed to discriminate the active acid sites of catalysts in water by their strength and to assess that their relative acid strength is changing with reaction medium (gas phase or liquid medium).

Figure 1 represents the conversion of fructose (after 6 h reaction in water medium at 130 °C in an autoclave) as a function of the number of strong acid sites at the surface of the various catalysts, as determined in aqueous and gas phases. A nearly linear relationship can be observed in both cases for conversion of fructose except for Nafion sample. When the number of acid sites is determined by NH_3 gas phase adsorption, the Nafion sample (Brønsted sites only) displays a much lower sites number than in liquid phase and does not fit with the other samples

which possess both Brønsted and Lewis acid sites.

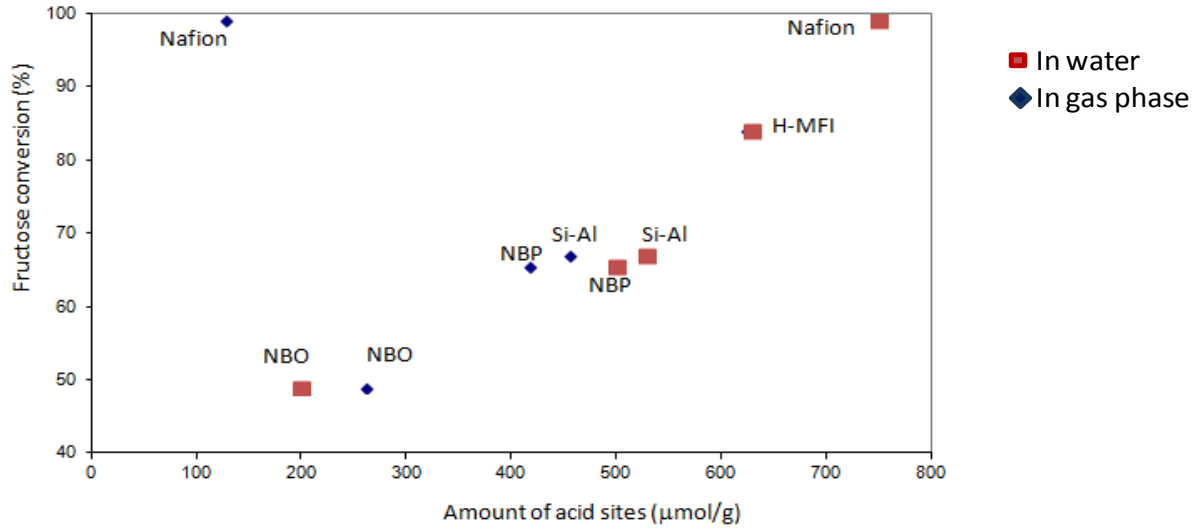

Fig. 1. Fructose conversion over various catalysts vs. acidity in gas and water phases

4 Conclusions

The determination of the acid-base properties of solid catalysts in the same media as used during the catalytic reaction is fundamental to correlate the catalytic activity to the surface properties.

This work has well demonstrated that for reactions performed in water or any other liquid solvent the number and the strength of accessible acidic/basic sites can be different, depending strongly on the solvent-solid bondings.

Keywords: iron-palladium catalysts, phenylacetylene hydrogenation

1 Introduction

Selective hydrogenation of alkynes to alkenes, without further reduction to alkanes, is of particular importance in the production of polymers [1]. Modifications of the Pd-based catalysts by alloying resulted in active and selective catalysts [2-4]. The Pd-Fe_3O_4/SiO_2 catalyst shows the reasonably high conversion and selectivity [4], yet alloyed Pd-Fe NPs exhibit a decrease in TOF as compared with Pd NPs [5]. Therefore, it seems of particular interest to evaluate the effect of Pd and Fe state on the catalytic activity in the hydrogenation of phenylacetylene (PhA) to styrene.

2 Experimental/methodology

The catalysts were prepared by simultaneous or consecutive deposition of the metal precursors on the silica carriers with a specific surface area of 340 m^2g^{-1} (HS) or 30 m^2g^{-1} (LS). $(NH_4)_3Fe(C_2O_4)_3$, Pd acetate, and $[Pd(NH_3)_4]Cl_2$ were used as precursors. Then a different thermal treatment was applied. The samples were characterized by XRD, TEM, TPR. The catalytic activity of prepared samples was tested in the selective hydrogenation of PhA to styrene at the following reaction conditions: 0.1-0.4 M PhA in ethanol, 10-50 mg of a catalyst, 1 atm H_2 , 20-60ºC, molar ratio PhA : Pd = 200-1000.

3 Results and discussion

The XRD analysis revealed the formation of the Pd^0, α-Fe_2O_3, and Fe_3O_4 phases after calcination of the samples at 240–260ºC (Fig. 1). All Pd-Fe calcined or reoxidized samples exhibited the H_2 consumption below the starting reduction temperature of Fe oxides indicating the strong interaction between Fe oxide and Pd species. Formation of the Pd-rich alloys and the Fe^0 phase after reduction at 400ºC was confirmed by XRD (Fig. 1).

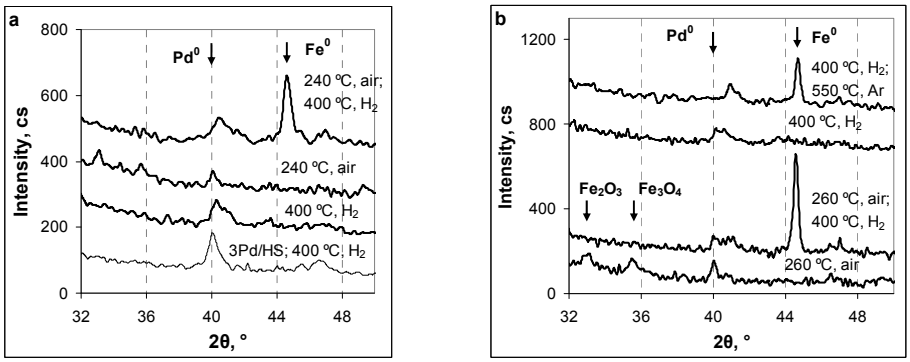

Fig. 1. XRD patterns of the samples 3Pd8Fe on HS (a) and on LS (b) supports after thermal treatment at different conditions

There was no peak of hydrogen release at 50-70ºC on the TPR curves of the samples reduced at 400ºC, which indicated the absence of pure Pd^0 particles and the formation of the Pd–Fe alloy particles suppressing the β-PdH formation at ambient temperatures.

The samples prepared by consecutive deposition of Pd acetate on the Fe precursor surface were active in PhA hydrogenation (Table 1, sample 3Pd7Fe/HS-R), yet fast deactivated. The simultaneous deposition of the Fe precursor and $[Pd(NH_3)_4]Cl_2$ resulted in the more active and stable samples after the precursor reduction (Table 1, sample 3Pd8Fe/HS-R). However, their selectivity was low due to further hydrogenation to ethylbenzene. Intermediate calcination before reduction significantly enhanced the catalytic activity and selectivity, with the catalytic behavior strongly depending on the Pd particle size, alloying and the support texture (Table 1). The styrene yield was comparable or even higher than for the Pd catalyst. The shape of the conversion and selectivity curves (Fig. 2) indicated the different mechanisms of hydrogenation for the samples on the different carriers.

Table 1. The initial rate, selectivity to styrene and its yield at the complete PhA conversion.

Sample[a]	**Fe, %**	**Pd, %**	***d*(Fe^0) nm**	***d*(Pd) nm**	r_0, $mol_{PhA}\ mol_{Pd}^{-1}\ s^{-1}$	r_0, $mol_{H2}\ mol_{Pd}^{-1}\ s^{-1}$	**S_{100}, %**	**Yield, g g_{ct}^{-1} h^{-1}**
3Pd7Fe/HS-R	6.9	3.3	nd	nd	0.034	0.036	-	-
3Pd8Fe/HS-R	7.6	3.0	nd	15 (3)	0.08	0.07	56	2.0
3Pd8Fe/HS-CR	7.6	3.0	19	10	0.23	0.19	86	9.4
3Pd8Fe/LS-CR	7.8	3.2	33	20	0.063	0.065	82	7.7

[a]The prepared samples are denoted as xPdyFe/A-B, where x and y are referred to the Pd and Fe loading (mass %), A was the support abbreviation, and B denotes the sample treatment (C - calcined, R - reduced at 400ºC).

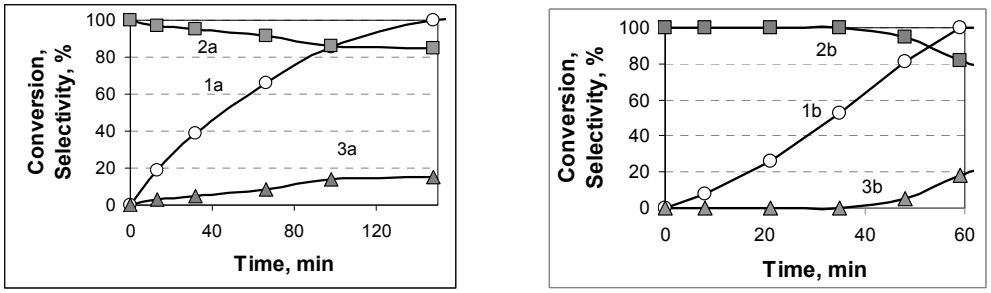

Fig. 2. PhA conversion (1), selectivity to styrene (2) and to ethylbenzene (3) over 3Pd8Fe/HS-CR (a) and 3Pd8Fe/LS-CR (b). Reaction conditions: 23ºC, 0.16 M PhA, PhA:Pd = 940 (a) and 330 (b).

4 Conclusions

The catalytic behavior of the Pd-Fe/SiO_2 system is strongly dependent on the catalyst preparation variables that change the Pd particle size and Pd-Fe alloying, with the Pd^0 NPs of the size 10 nm being preferable.

Keywords: hydrogenation, catalysis, phenols, bimetallic PdRu nanoparticles

1 Introduction

Hydrogenation is one of the most important processes in the petrochemical industry and organic synthesis. In particular, hydrogenation of phenol is used to obtain cyclohexanone and cyclohexanol, the main intermediates for the nylon-6 and adipic acid production [1,2]. Another, novel application in the hydrogenation of phenolic compounds is a biofuel production from lignin [3,4]. Therefore, it is the actual problem to develop high-efficient and selective catalysts for the hydrogenation of phenols. The particular interest is referred to the bimetallic nanoparticles and alloys, whose activity and selectivity can be tuned changing the metals ratio and their nature [5,6]. Here we report the synthesis of the bimetallic PdRu nanoparticles, encapsulated into cross-linked dendritic matrix, and their application in the hydrogenation of phenols.

2 Experimental

The synthesis of the heterogeneous networks, based on the poly(propylene imine) (PPI) dendrimers of the 3rd generation, cross-linked with 1,6-diisocyanatohexane, is described elsewhere in literature [7].

The synthesis of dendrimer-encapsulated PdRu nanoparticles was carried out according to the following procedure. The desired amounts of the dendritic carrier (dendrimer cont. ~ 55%) and water were placed in the round-bottom flask of the volume required, equipped with the magnetic stirrer and reflux condenser. Then, $RuCl_3$ and $Pd(OAc)_2$ were added to the resulting suspension at stirring. The molar Pd : Ru ratio was 1 : 1, and (Pd + Ru) : dendrimer ratio was 10 : 1. The reaction was carried out for 12 h at 70 ^{0}C and vigorous stirring. After that the reaction mixture was evaporated *in vacuo*, resulting in the dark, black-brown powder. At the next stage the precursor obtained was reduced, using the 10-fold molar excess of $NaBH_4$ in the water-ethanol mixture. The reaction was carried out for 12 h at room temperature and vigorous stirring. After the time passed, the reaction mixture was centrifuged several times with water and ethanol, and the residue was dried in the air, resulting in the black powder.

The catalytic experiments were carried out according to the following procedure.

The catalyst and the substrate in the desired ratio were placed into a thermostated steel autoclave equipped with the glass vial-insert and magnetic stirrer. Water was added according to the proportion of 1 mg or 1 μl of substrate per 1 μl of water. The autoclave was sealed, pressurized with hydrogen to a pressure up to 10 or 30 atm. and connected to the thermostat. The reaction was carried out at 90ºC for the required time, after which the reactor was cooled below room temperature and depressurized. The reaction products were analyzed by gas-liquid chromatography.

3 Results and Discussion

A method of co-complexation was used to prepare bimetallic PdRu catalyst [3]. A complex

formation between metal ions and the dendrimers tertiary aminogroups was the driving force of the reaction. Coordination of both Pd and Ru ions with the same types of the donor atoms was suggested to favour to their nearby arrangement and the formation of the bimetallic nanoparticles at the reduction stage [3]. The mean particles diameter according to the TEM data was 2-2.5 nm.

The catalyst obtained was tested in hydrogenation of phenol, its ethers and substituted phenols. It should be noted, that the hydrogenation of phenol in presence of the bimetallic platinum group catalysts has not well developed yet, and there are only few works, dealing with similar systems [8,9], including PdRu nanoparticles [9]. Also there was no any communications concerning the synthesis of the PdRu nanoparticles, encapsulated into the polyamine dendrimers.

Our research revealed, that PdRu catalysts based on the cross-linked PPI dendrimers were active in the liquid-phase hydrogenation of phenol and similar compounds. Varying the reaction time, hydrogen pressure and substrate to catalyst ratio, the high selectivity on cyclohexanone (up to 100%) can be achieved, while the analogous monometallic Ru catalyst yielded only cyclohexanol. Replacement of phenol to more hydrophobic anisole and then to phenethole resulted in the drastical decrease in conversion and the formation of the hydrogenolysis (benzene, cyclohexane) and deoxygenation (phenol) products, which total portion among the reaction products was 10-40% and increased with the increasing the reaction time and decreasing the substrate to catalyst ratio. Introducing the alkylic substituents to the aromatic ring of phenol also led to the decrease in conversion. The main reaction products were corresponding substituted derivates of cyclohexanol. The polar hydrophilic hydroquinone and resorcinol, vice versa, were converted faster than phenol. The latter gave *trans*-1,3-cyclohexanediol as the main reaction product with the selectivity up to 95%, while the former underwent deoxygenation during the reaction, giving up to 50% of the cyclohexanol and phenol. Their portion, as for phenolic ethers, increased, when increasing the reaction time and catalyst amount.

4 Conclusions

Hybrid bimetallic catalyst based on the PdRu nanoparticles encapsulated into the cross-linked dendritic matrix was synthesized. The material obtained appeared to be active in the hydrogenation of phenol and its derivates. For phenol, 100% selectivity on the cyclohexanone can be achieved. Introducing the hydrophobic substituents to the hydroxyl-group or the aromatic ring of phenol led to the conversion decreasing. The formation of the hydrogenolysis and deoxygenation by-products was typical of the hydroquinone and phenolic ethers.

Keywords: hydrogenation, catalysis, phenols, bimetallic, nanoparticles, PdRh, RhRu

1 Introduction

Immobilization of metal complexes and nanoparticles on the surface of heterogeneous carriers is one of the most prospective trends for the high-efficient catalysts development, allowing to combine properties of both homogeneous (high activity and selectivity) and heterogeneous catalysts (stability and recyclability) [1-3]. A particular interest has an application of bimetallic nanoparticles in catalysis, allowing to carry out various processes with higher rate and selectivity [4,5]. Here we propose a new approach for immobilization of bimetallic PdRh and RhRu nanoparticles in channels of mesoporous silica, prepared by sol-gel method and modified by poly(propylene imine) (PPI) dendrimers, and their use in the hydrogenation of phenols.

2 Experimental

The synthesis of hybrid mesoporous carrier was carried out similarly to the following procedure. The PPI dendrimer of the 2nd generation, preliminarily modified by the (3-glycidoxy)propyltrimethoxysilane, was placed in the aqueous solution of the Pluronic 123. After that tetraethoxysilane, preliminarily hydrolyzed by aqueous HCl was added. After the mixture had been vigorously stirred, an aqueous NH_3 solution was added for gelation. The material obtained was heated at 100 ^{0}C, centrifuged with water and ethanol and then dried at air. The synthesis of dendrimer-encapsulated PdRh and RhRu nanoparticles was carried out according to the following procedure. The desired amounts of the heterogeneous hybrid carrier (dendrimer cont. ~ 18.5%) and solvent were placed in the round-bottom flask of the volume required, equipped with the magnetic stirrer and reflux condenser. Then, the metalloprecursors were added to the resulting suspension at stirring. For the PdRh catalyst, the molar Pd : Rh ratio was 0.35 : 0.65, and (Pd + Rh) : dendrimer ratio was 3 : 1. For the RhRu catalyst, the molar Ru : Rh ratio was 0.3 : 0.7, and (Pd + Rh) : dendrimer ratio was 4 : 1. After 12 h the reaction mixture was evaporated *in vacuo*, resulting in the dark, black-brown powder. At the next stage the precursor obtained was reduced, using the 10-fold molar excess of $NaBH_4$. The catalytic experiments were carried out according to the following procedure. The catalyst and the substrate in the desired ratio were placed into a thermostated steel autoclave equipped with the glass vial-insert and magnetic stirrer. Water was added according to the proportion of 1 mg or 1 μl of substrate per 1 μl of water. The autoclave was sealed, pressurized with hydrogen to a pressure up to 10 or 30 atm. The reaction was carried out at 80ºC for the required time. The reaction products were analyzed by gas-liquid chromatography.

3 Results and Discussion

The synthesis of catalysts was carried out in 3 stages: 1) preliminary modification of the dendrimer terminal aminogroups by the silyl-containing linkers; 2) formation of mesoporous silica channels in presence of a template using sol-gel method and grafting the modified

dendrimers to the silica surface formed *in situ*; 3) encapsulation of the bimetallic nanoparticles using a co-complexation method similar to the literature procedures [6,7]. Thus, PdRh and RhRu hybrid catalysts were prepared. Both of the catalysts prepared were examinated in the phenols hydrogenation. It was found out, that RhRu catalyst gave selectivity on cyclohexanone near to 100% even at long reaction times and high catalyst loading, proving a deeper conversion (up to 80%). The similar results were found for the PdRh catalyst. Using anisole or phenethole instead of phenol led to the dramatic downfall in conversion. Also hydrogenolysis (phenol, cyclohexanol, cyclohexanone) and deoxygenation (benzene, cyclohexane etc.) by-products were formed. Their total portion reached up to 50% and decreased when the reaction time and catalyst loading decreased. Introducing the alkylic substituent into the aromatic ring of phenol also resulted in the decrease in conversion in comparison with phenol. Formation of a small quantity (up to 10-15%) of the hydrogenolysis by-products was typical for the both catalysts. At the same time the activity of the RhRu catalyst in the alkyl-substituted phenols hydrogenation did not depend on the substrates size and geometry, whereas for PdRh decrease in activity with the substrate size increased was observed. Both of the catalyst synthesized showed high activity in the hydrogenation of polar hydroquinone and resorcinol, and poor activity for pyrocathechol with *ortho*-position for the hydroxylic groups. Also the formation of the hydrogenolysis by-products (up to 20%, especially for hydroquinone) was observed in presence of the both catalysts. Their portion, as for phenolic ethers, increased, when the reaction time and catalyst amount increased. Generally, synthesized bimetallic catalysts were found to be less active, but more selective in comparison with corresponding monometallic Ru and Rh catalysts.

4 Conclusions

Hybrid bimetallic catalysts based on the PdRh and RhRu nanoparticles encapsulated into the PPI dendrimers, grafted on the mesoporous silica surface, were synthesized. The materials obtained appeared to be active in the hydrogenation of phenol and its derivates. For phenol, 100% selectivity on the cyclohexanone can be achieved for the both catalysts. Introducing the hydrophobic substituents to the hydroxyl-group or the aromatic ring of phenol led to the conversion decreasing. The formation of the hydrogenolysis and deoxygenation by-products was typical of the hydroquinone and phenolic ethers.

Peroxocomplexes Contaning Rare Earth Elements as Effective Catalysts of Oxidation Reaction of Mono and Bicyclic Unsaturated Hydrocarbons with Hydrogene Peroxide

Dadashova N.R.*, Alimardanov H.M., Sadiqov O.A., Qaribov N.I., Quliyev A.D., Huseynova M.E., Aghabayli G.B.

Institute of Petrochemical Processes of NASA, Baku, Azerbaijan

Keywords: peroxocomplexes, liquid-phase, oxidation, hydrogen peroxide, unsaturated hydrocarbons

1 Introduction

A series of peroxotungsten and molybdenum complexes of rare earth elements (REE) (Gd, Nd, Pr, La) in the induced oxidation reaction of unsaturated hydrocarbons with cyclohexene and norbornene fragments was synthesized and studied.

The oxidation reaction of unsaturated hydrocarbons is one of the important directions of obtaining oxygen-containing compounds with the given structure. The catalytic processes based on the use of oxidants and heterogeneous catalysts based on transition metals are of great interest. To create heterogenized peroxo complexes of transition metals as catalysts for the oxidation of unsaturated compounds with the air oxygen and hydrogen peroxide, is the focus of researchers' attention. In this aspect, the development of peroxotungsten and molybdenum complexes of REE, finding conditions for the formation of these complexes, determination of the structure and composition, as well as their use as catalysts for the stoichiometric oxidation of unsaturated alicyclic compounds remains an urgent task.

2 Experimental/methodology

To study the structure of the samples of peroxocomplexes of phospohotungsten and molybdenum- $X\{PO_4[MeO(O_2)_2]_4\}$, (where X=Gd, Nd, Pr,La, Me= Mo,W) FTIR, EPR, XRD and TGA methods of analysis have been used.

In the IR spectra of the obtained peroxocomplexes, the intense bands correspond to the crystallization water (3450-3200 cm^{-1}), ion PO_4^{3-} (1089, 1023 cm^{-1}), the double bond Me = O (955, 935 cm^{-1}), and O-O bond (850 and 858 cm^{-1}). The broad band is characteristic for the seven-coordination diperoxocomplexes at 575 cm^{-1} and the band of medium intensity for symmetric and asymmetric vibrations of Me fragment at 625 and 968 cm^{-1}. The intense bands are characteristic at 414 $cm^{-1}$and at 464 $cm^{-1}$for GdO^+ and NdO^+ fragments,respectively.

Thermograms of complexes are characterized by an endothermic effect associated with the lost of water and by an exothermic effect associated with the decomposition of peroxo compounds and release of oxygen (140 ° C). This proves the assumption that water enters the inside sphere and dimer (or tetramer) forms of peroxotungstate (peroxomolybdate) complexes containing gadolinium and neodymium are formed.

3 Results and discussion

The results of the studies on oxidation of vinylcyclohexene (VCH), tetrahydroindene (THI) and norbornene (NB) show that the reaction products are the corresponding oxiranes and vicinal diols.

In the presence of the samples of diperoxophosphate complexes containing (Nd, Pr, La) the selectivity by the epoxide of VCH and THI at 40ºC is 68-72%, and by that of vicinal diol it is

selectivity of vicinal diol is 10-15 %(at the conversion of hydrocarbons 14-20%) .But in the case of a sample containing gadolinium, yield of VCH and THI epoxide is 75-78%, and vicinal diol 18-22% (at the conversion of VCH and THI 17-23%). This proves that the peroxocomplex of gadolinium as compared with the peroxocomplex of Nd, Pr, and La is more active.

Keywords: $MgNi/SiO_2$, catalyst, water, glass, silver modification, sunflower oil hydrogenation

1 Introduction

Hydrogenation of vegetable oils is a traditional oleochemical process aiming to change the physical properties of the oils as well as to enhance the oxidation and thermal stability of the hydrogenated products. In the view of high activity, inert nature of the metal relative to the oil, availability and economic consideration, metal nickel, supported on different sources of silica, is the most appropriate catalyst for the reaction. Despite intensive research activity in this field, the role of additives or modifiers on the catalytic performance of the vegetable oil hydrogenation catalysts is quite scarce in the literature [1,2]. The aim of the present study is to elucidate the effect of the silver content in $MgNi/SiO_2$ system on the activity and the composition of the fatty acids obtained during the sunflower oil hydrogenation.

2 Experimental/methodology

A series of silver modified Mg-Ni materials with composition Mg/Ni = 0.1 and SiO_2/Ni = 1.15, differing in Ag content (Ag/Ni = 0.0025, 0.025 and 0.1) was prepared by the precipitation-deposition on SiO_2 derived from water glass used as a source of silica support. The designation of the samples corresponds to the Ag/Ni molar ratio, i.e. 0.0025AgNi, 0.025AgNi and 0.1AgNi. The preliminary reduction of the as-synthesized precursors after drying at 105°C was performed in a laboratory set-up using a quartz reactor by means of a "dry reduction" method at 430°C for 5 h with H_2 at a flow rate of 10 dm^3/h and a heating rate of 1.5°C/min. After cooling down to room temperature, the precursors were impregnated with pure paraffin oil in order to prevent the exceptional pyrophority of the Ni^0. The partial hydrogenation of sunflower oil was carried out up to 230 min and was performed in a 1.5 dm^3 glass reactor Series 5100, computer coupled with Mass Flow Controller F-201C and Pressure Meter F-502C under the following conditions: catalyst concentration - 0.03 wt. % of Ni with respect to the amount of oil; stirring rate - 1200 rpm; hydrogenation temperature - 150°C and H_2 pressure - 0.2 MPa. The activity of the catalysts was evaluated by measuring the changes in the Refraction Index at 50ºC of the starting oil, and periodically collected partially hydrogenated oils. The fatty acids content in the starting refined sunflower oil and the fractions of hydrogenated oils were determined after their conversion into fatty acid methyl esters according to IUPAC method II.D.19. The analysis was performed on gas chromatograph SHIMADZU GC-9A with FID detector and capillary GC column Agilent HP-88 (100 m x 0.25 mm I.D., 0.20 μm film thicknesses).

3 Results and discussion

The hydrogenation activity is estimated by the changes in the Refraction Index (RI) values and the quantity of the consumed hydrogen as function of hydrogenation time for the studied

catalysts. A diminution of RI value of the crude oil (1.46368) downs to the level of 1.45688 (0.1AgNi), 1.45721 (0.025AgNi) and 1.46081 (0.0025AgNi) is registered, reviling the low activity of the catalyst with the lowest silver amount. The results obtained are in accordance with the quantity of the consumed hydrogen (dm^3) at the end of the reaction, namely: 0.1AgNi (51.2) > 0.025AgNi (46.3) >> 0.0025AgNi (20.7).

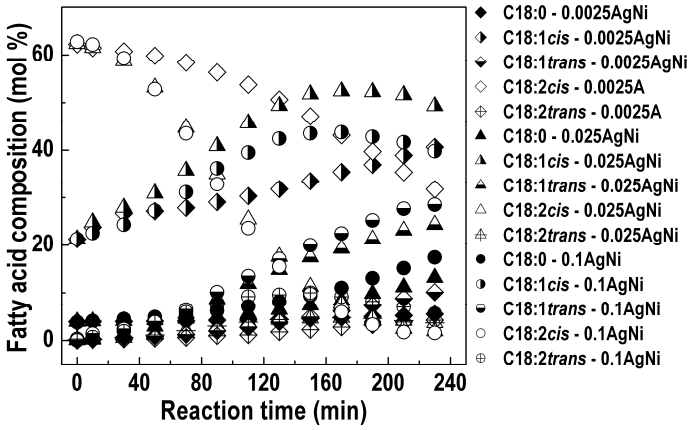

Fig. 1. Fatty acid composition of the studied catalysts

The differences in the activity of the catalysts reflect on the different fatty acid profiles and different composition of the fatty acids obtained during the sunflower oil hydrogenation (Fig. 1). Concomitant with the hydrogenation (partially or fully saturation of double bonds), the catalytic isomerization of naturally occurring *cis* fatty acids to *trans* fatty acids takes place. The overall hydrogenation involves consecutive saturation of linoleic acid (C18:2*cis*) to oleic acid (C18:1*cis*), and subsequent saturation of C18:1*cis* to stearic acid (C18:0) as well as parallel reversible isomerization of C18:2*cis* to C18:2*trans* and C18:1*cis* to C18:1*trans* [1].
It may be seen a decrease of C18:2*cis* (mol %) in the follow order: 0.1AgNi (1.4) < 0.025AgNi (2.0) << 0.0025AgNi (32.0) at the end of the reaction, as well as an increase of C18:0 in a reverse order, both related to the hydrogenation of the double bonds. The results demonstrate high selectivity of 0.025AgNi and 0.1AgNi catalysts toward C18:2*cis* hydrogenation turns it almost entirely into C18:1*cis*. It is well known that C18:2*cis* is one of the ‘‘essential’’ fatty acids, thus its presence is necessary for human nutrition. Therefore, small amounts of it are allowed in the edible hydrogenated oils.

Comparison of the performance of the active 0.025AgNi and 0.1AgNi catalysts permits to be recommended as an appropriate for selective edible sunflower oil hydrogenation the catalyst with intermediate silver content (0.025AgNi). This finding is based on the demonstrated similar hydrogenation activity, higher content of C18:1*cis* formation and lower amounts of harmful for the human health C18:1*trans* and C18:0 fatty acids in the hydrogenated derivatives.

4 Conclusions

It may be concluded that the careful changing the content of silver modifier offers a possibility to control as the hydrogenation activity as well as the composition of fatty acids in the hydrogenated edible oils.

1 Introduction

Heterogeneous catalysis involves specific chemical interactions between the surface of a solid and the reacting gas (or liquid phase) molecules. The catalytic cycle is generally composed of absorption/desorption steps, and surface reaction processes. The 1st step is the activation of the reacting molecules by adsorption. Thus, the study of adsorption phenomena plays an important role. Knowledge about the heat of adsorption of reactants on the surface of a catalyst as well as the number of adsorption sites, energetic distribution of adsorption sites, adsorption constants and the specific surface area can contribute to a better understanding of complex microkinetics. Moreover, quantitative data provide a basis for theoretical modeling. Since perhaps only a minor fraction of all surface atoms form active centers, the determination of their number and strength requires a sensitive analytical method. We focus on adsorption microcalorimetry. To facilitate the correlation of microcalorimetric results with the catalytic performance, a molecule similar to the reactant, or the reactant itself, is used. $T_{ads.}$ is chosen lower than $T_{reaction}$ to separate the adsorption process from the catalytic reactions or closely related to $T_{reaction}$ to study the surface chemical events during reaction.

2 Experimental

Microcalorimetric experiments were carried out in a Calvet calorimeter (SETARAM MS70) combined with a high vacuum system, which enables the dosage of probe molecules within a range of 0.04 □mol. The required pretreatment of the catalysts (reduction, oxidation, dehydration) is conducted in a separate chamber connected to the calorimetric cell. Subsequently the cell is cooled to room temperature ($p_{final} = 10^{-7}$ mbar), placed inside the calorimeter, and connected to the micro-calorimetric gas-adsorption system. Then, the selected probe molecule is dosed stepwise at selected T_{ads}. Pressure, $T_{ads.}$ and the heat signals were recorded during all dosing and desorption steps. Desorption is performed at $T_{ads.}$ under UHV. A positive energy corresponds to an exothermic process. Furthermore, a procedure was developed to characterize the adsorption sites on the surface of a catalyst in any stage along the reaction profile by quasi *in situ* adsorption microcalorimetry.[1,2] The calorimeter cell can be used as a fixed bed reactor containing the catalyst under e.g. propane oxidative dehydrogenation reaction conditions. [2]

3 Results and discussion

In this work, we will demonstrate how structure-activity correlations can be established by combining microcalorimetry with electron microscopy, spectroscopic techniques, DFT calculations and catalytic test reactions. The power of these complementary methods will be illustrated by choosing the following examples:

(i) Propylene metathesis over MoOx/SBA-15 (Fig. 1) [3]
The surface of MoOx/SBA-15 – active in propylene metathesis at 50°C – was probed by propylene adsorption at $T_{reaction}$ in order to trace the initiation step of C_3H_6 metathesis. Catalytic activity is directly correlated with the strength of the propylene interaction with the active surface site. The quantification implies that ca. 1% of Mo atoms formed active sites. The most active catalyst is characterized by strong and irreversible adsorption of propylene, the highest amount of MoO_x adsorption sites for propylene, and a homogeneous distribution of the energy of these adsorption sites.

(ii) Three-phase semi-hydrogenation of 1-hexyne over TiO_2-supported ceria at 80°C (Fig. 2) [4]
In order to correlate the catalytic performance with characteristic properties of ceria, the chemisorption of 1-hexyne at $T_{reaction.}$ was studied on two 20wt%CeO_2/TiO_2 catalysts that show different activity. The more active catalyst is characterized by a higher amount of adsorption places for 1-hexyne. Regeneration of the latter catalyst with H_2 is facilitated. Furthermore, the obtained results indicate that under reaction conditions a significant portion of the surface sites is covered by dehydrogenated species and is not available for hydrogenation. This is in line with DFT calculations of acetylene adsorption on CeO_2(111) showing that the most preferred adsorption mode is dissociative with respect to the C–H bond. [5] Nevertheless, the remaining small number of surface sites is active and highly selective in alkyne hydrogenation.

(iii) Oxidative dehydrogenation (ODH) of propane and ethylbenzene (EB)
The reaction is considered as the model reactions to establish a mechanistic model for carbon-catalyzed ODH. [2] From the mechanistic point of view, quinone groups (C=O, nucleophilic oxygen) are believed to be the active site. It was found that the redox cycle of surface C=O and C-OH groups is the key process, which includes only a small fraction of surface O species and favourably occurs at the zigzag-termination of sp^2 carbon planes. Higher activation barriers in the reduction step correlate with the higher stability of the aliphatic C-H bond in propane over the benzylic C-H bond in EB.

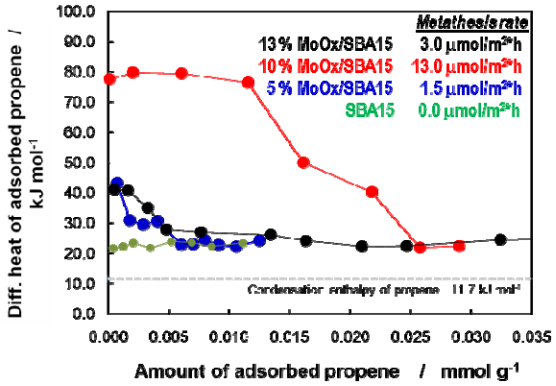

Fig.1: Differential heat of propene adsorbed on MoO_x/SBA-15 and SBA-15 at $T_{reaction}$=50°C.

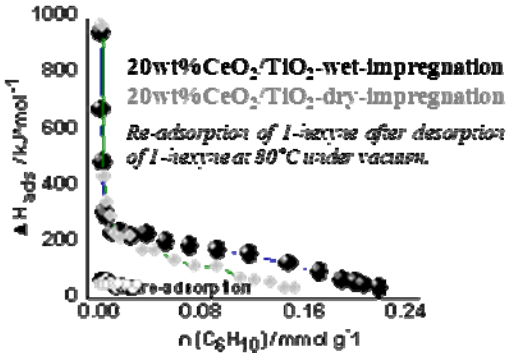

Fig. 2: Differential heat of adsorption of 1-hexyne on CeO_2/TiO_2 at $T_{reaction}$=80°C.

Keywords: Fischer-Tropsch synthesis, cobalt-alumina catalysts, kinetics of reduction, ruthenium

1 Introduction

Cobalt-alumina Fischer-Tropsch catalysts prepared by DPU (deposition by precipitation during urea decomposition) method are highly active and have good C_{5+} selectivity [1]. However the activation temperature is high for these catalysts exceeding 500°C, which makes the activation procedure and equipment expensive.

Introduction of tiny amount of noble metal facilitates cobalt reduction and decreases the required activation temperature [2]. Promoted with 0.2 wt. % of ruthenium Co-Al catalysts have reduction temperatures by 50−85 °C lower than those of unprompted ones [3,4]. Increasing ruthenium content shifts the reduction temperature further (ΔT = 100−110 °C). In cited works authors note rising of reducibility and dispersion of promoted catalysts. Ru was also reported to improve the activity of catalyst, prepared by impregnation of alumina and silica [5,6].

Noble metals may serve as sites for activation of hydrogen and also as nuclei for formation of metallic cobalt phase. Studying the reduction kinetics of Ru-promoted Co-catalysts can help to understand the mechanism of the metallic cobalt particles formation and the role of ruthenium in this process. Meanwhile the kinetic studies data on cobalt reduction are missing in literature. The studying of kinetics in non-isothermal conditions can be carried out by means of thermal analysis. By this poster presentation we report the effect of ruthenium content on the process of reductive activation of Ru-promoted Co-Al catalyst as well as the catalytic activity and selectivity these catalysts in the Fischer-Tropsch synthesis.

2 Experimental/methodology

Cobalt-alumina catalyst was prepared by DPU method using δ-Al_2O_3. Co loading is 9.2 wt. %. Ruthenium was introduced by impregnation with aqueous solutions of $RuNO(NH_3)_2(NO_3)_3$ complex and consequent drying under IR lamp. Ru concentration in the impregnating solutions corresponded to Ru loading of 0.2, 0.5 and 1 wt. % (samples were designated as $Ru_{0.2}$Co-Al, $Ru_{0.5}$Co-Al, $Ru_{1.0}$Co-Al).

Reduction behavior and kinetic parameters of reduction were studied by thermal analysis at varied heating rates using Netzsch STA 449. Reduction was performed in H_2 and Ar gas mixture, composed by pure hydrogen flow fed to the sample chamber and pure argon flow fed to the balance chamber and passed through the balance chamber to the sample chamber. Fischer-Tropsch synthesis was carried out at 190 °C, 2.1 MPa, feed ratio H_2:CO:N_2 = 6:3:1 in a single row fixed bed reactor using 4 mm catalyst grain. Catalytic activity and selectivity were measured at CO conversion being in the range of 8−15 %.

3 Results and discussion

Ru promotion lowered significantly the cobalt reduction temperature. Figure 1 shows that

the temperature maximum which corresponds to formation of metallic Co particles shifts to lower temperature range from 530 °C for Co-Al to 350, 290 and even 280 °C for $Ru_{0.2}$Co-Al, $Ru_{0.5}$Co-Al, $Ru_{1.0}$Co-Al respectively.

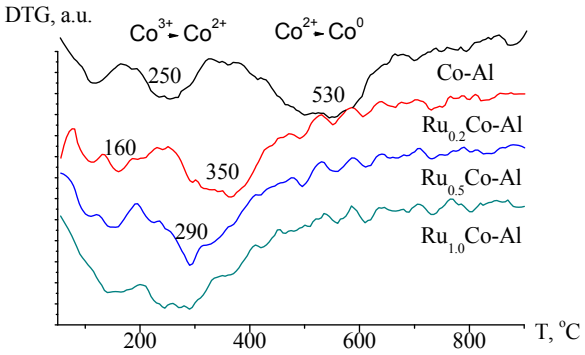

Fig. 1. DTG-profiles of Co-Al and Ru_xCo-Al catalysts in flow of H_2 and Ar gas mixture

Therefore, the activation temperatures for Ru-promoted catalysts are lower by 200 °C than that for Co-Al. The study on kinetics of cobalt reduction is in progress and the results will be reported at the poster.

Table 1. Catalytic properties of Co-Al and Ru_xCo-Al catalysts

Catalyst	Co-Al	$Ru_{0.2}$Co-Al	$Ru_{0.5}$Co-Al	$Ru_{1.0}$Co-Al
$T_{reduction}$, °C	500	350	330	330
W CO, mmol/g_{cat}·h	4.26	3.45	3.41	4.31
W CH_2, mg/g_{cat}·h	59.7	48.3	47.7	60.4
S(C_{5+}), %	78	76	79	79
S(CH_4), %	10.0	9.5	9.3	9.9

Table 1 summarizes some of the parameters of the catalytic performance of Co-Al and Ru_xCo-Al catalysts in the Fischer-Tropsch synthesis at 190 °C, 2.1 MPa. Activation temperature was selected accordingly to the thermal analysis data. The activity and selectivity of promoted catalysts are almost as high as that of unpromoted catalyst.

3 Conclusions

Addition of small amounts of Ru to alumina-supported cobalt catalysts significantly lowers the temperature of cobalt reduction. The promoted catalysts exhibit high catalytic activity and selectivity in the Fischer-Tropsch synthesis, which is comparable with unpromoted catalyst.

Keywords: geopolymer, ice-templating, hierarchical porosity, lamellar porosity, catalyst support

1 Introduction

Geopolymers are synthetic alkaline alumino-silicates [1] that may be regarded as the amorphous counterpart or precursor of crystalline zeolites. At the atomic scale, the geopolymer network is formed by SiO_4 and AlO_4 tetrahedra connected by oxygen corners: the tetrahedra form Si-O-Al-O rings of various sizes and endow the geopolymer matrix with ion exchange properties [2]. These materials show properties ranging from those characteristic of ceramics, cements, zeolites or refractories [1]. Geopolymers are intrinsically mesoporous and a hierarchical pore system may be obtained combining meso and macropores [3]. Water-based freeze casting (or ice-templating) may be used to prepare porous materials with main unidirectional oriented pores and a high open porosity, where the final component results in a lamellar structure [4]. The aim of this study is to produce and characterize novel catalyst supports of different geometries and dimensions, with lamellar macroporosity and geopolymer intrinsic mesoporosity.

2 Experimental

Geopolymer slurries were prepared by mixing metakaolin (M1200S, AGS Minéraux) with KOH/K_2SiO_3 aqueous solutions (Aldrich) at high (H_2O:K_2O=23.0) and low (H_2O:K_2O=13.5) dilutions under mechanical stirring [3]. After a maturation step at r. t., distilled water (50 vol. %) was added to the slurries, then mechanically mixed. The mixtures were cast in pre-cooled rubber molds to produce monoliths, cylinders and plates up to 15 cm side. Then cast slurries were frozen at -40°C and sublimated at P= $8 \cdot 10^{-2}$ torr for 24h (Edwards MFD01). After demolding, the samples were rinsed in deionized water and then dried at 100°C.

The morphological and microstructural features were examined by environmental Scanning Electron Microscopy (E-SEM). The bulk density of the samples was determined by weight-to-volume ratio. Ultra-macro-porosity was investigated by image analysis. Pore size distribution in the range 0.0058–100 μm was analyzed by porosimetry by Hg intrusion. Measurements of specific surface area, pore volume and pore size distributions in the 2-500 nm range were carried out by N_2 adsorption/desorption at −196 °C. The Si/Al and K/Al molar ratios in the final consolidated samples were determined by X-Ray Fluorescence (XRF) analysis.

3 Results and discussion

Figure 1 shows how basic (due to the presence of K) catalyst supports, with different size and geometry and a lamellar macroporosity may be prepared by ice-templating. The porosity and stoichiometry may be altered by varying the dilution of the starting geopolymer slurry (Table 1). A broad mesopore distribution was detected between 4 to 100 nm, with maximum from 5 to 7 nm. While, the pore size distributions measured by Hg intrusion porosimetry are bi-

and tri-modal, respectively for low and high dilution. The results account for the intrinsic porosity of the geopolymer matrix (pores ranging from 0.0058 to 1 μm) [3], suitable for the inclusion of a catalytic active phase to prepare bifunctional catalysts. The smallest macro-pores due to ice-templating may decrease the mass-transfer phenomena. In details, water is the reaction medium in geopolymerization, but it does not enter into the geopolymer framework; it gives rise to a steric hindrance acting as a pore forming agent upon its removal during setting. Consequently the starting dilution of the geopolymer slurry greatly affects the intrinsic porosity and the textural characteristics in term of lamellar pore width.

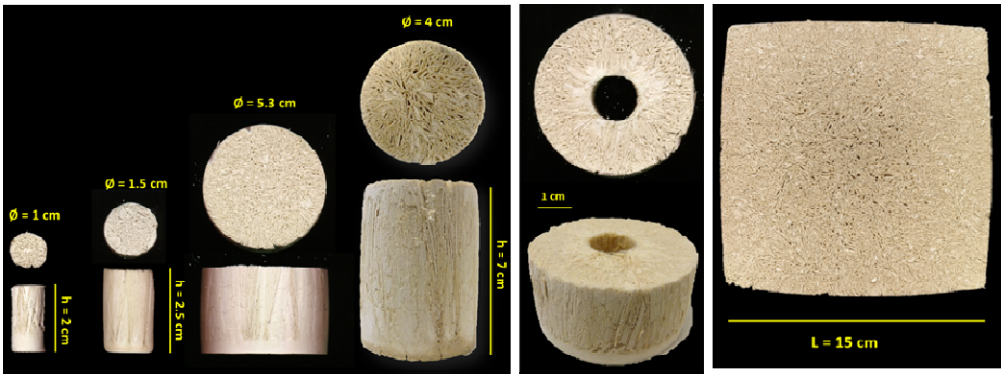

Fig. 1. Some catalyst supports of different size and geometry a with lamellar macroporosity

Table 1. Characteristics of the catalyst supports prepared with low diluted (LD) and high diluted (HD) geopolymer slurries added with 50 vol% of water.

Sample	Bulk density $g \cdot cm^{-3}$	Total porosity (%)	Lamellar Pore width, μm	Total pore volume $mm^3\ g^{-1}$	S_{BET} $m^2\ g^{-1}$	V_p $cm^3\ g^{-1}$	Si/Al	K/Al
LD	0.7	70	15-100	853	39.4	0.115	1.87	0.36
HD	0.5	80	20-250	1404	26.0	0.091	1.69	0.37

4 Conclusions

Unidirectional lamellar catalytic supports with different geometries and large dimensions may be easily produced by the ice-templating of geopolymer slurries. Hierarchically porous materials are realized with textural characteristics depending on the starting dilution of the geopolymer slurries. Due to the alkaline properties and textural features, these novel supports may be useful to prepare tailor-made bifunctional catalysts. Catalytic tests are ongoing to assess the suitability of these systems.

Keywords: *operando* synchrotron, Pt(111), roughening, on-line electrochemical mass-spectrometry, electrocatalysis

1 Introduction

Solar hydrogen produced by (photo)electrochemical water splitting (PWS) is a promising alternative to conventional fossil energy resources. Mostly, photocatalysts are complex multicomponent semiconductor based systems. However, even the most active photocatalytic materials are not able to drive PWS without electrocatalyst due to interfacial energy losses. In order to design optimal electrocatalysts, structure-activity relationships are needed. Platinum as the best-performing and best-known H_2 evolution catalyst has thus been chosen as a model catalyst to setup a novel technique combination enabling to simultaneously track structural changes together with reaction products detection and electrochemical characterization.

2 Experimental/methodology

In our experiments an OLEMS (on-line electrochemical mass-spectrometry) tip [1] was implemented to an *in-situ* electrochemical cell designed at ID03 (ESRF, Grenoble) [2] (Fig. 1a). The tip was approached at 20 μm distance to working electrode surface with piezo stage driver (Thorlabs), fine positioning has been done by maximizing hydrogen response. 0.1 M $HClO_4$ degased solution was used as electrolyte. Alongside the OLEMS product characterization, surface X-ray techniques were utilized to follow changes in surface morphology and crystallography. GISAXS (Grazing-Incidence Small-Angle X-ray Scattering) and XRR (X-Ray Reflectivity) could provide information on surface roughening, while SXRD (Surface X-Ray Diffraction) was used to determine the surface crystal structure. As a showcase to validate the combined OLEMS–[SXRD/GISAXS/XRR] setup for *operando* studies of electrode transformations, we chose H_2 and O_2 evolution reactions (HER and OER) on Pt(111).

3 Results and discussion

During the combined XRR-OLEMS experiment, the Pt(111) electrode was repeatedly switched between OER (1.6 V, 10 s) and HER (−0.4 V, 10 s) potentials with intermittent resting potential (0.3 V, 10 s). XRR was continuously recorded at the point of maximal intensity change at fixed angular position together with simultaneous mass spectrometric analysis of the produced gases by OLEMS. The combined dataset shown in Fig. 1b comprising structural and reactivity data demonstrates the strength of the multi-technique approach to study reactivity trends of electrocatalytic model surfaces under *operando* conditions. Complementary GISAXS and SXRD data obtained under identical conditions can provide additional insight into structural development of the surface as well as oxide formation finally arriving at solid *operando* structure-activity relationships for electrocatalytic (model) systems.

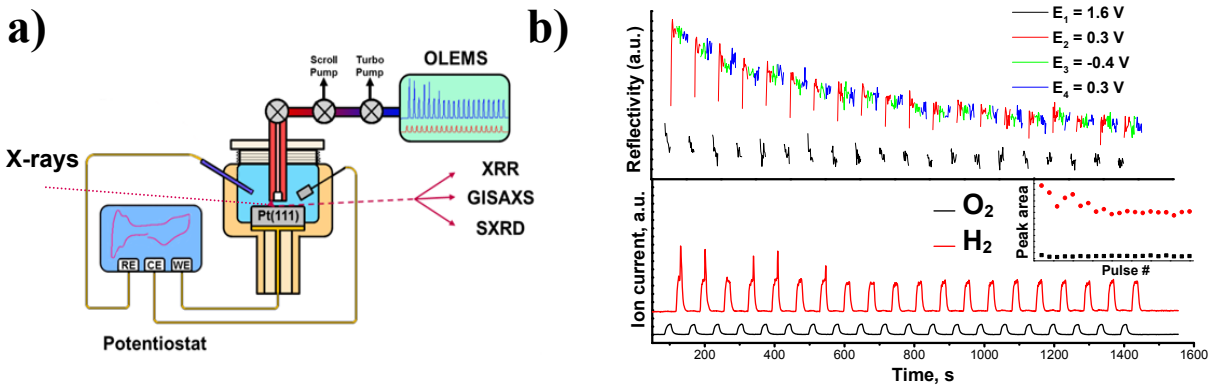

Fig. 1. a) Scheme of combined OLEMS-[SXRD/GISAXS/XRR] setup; b) XRR-OLEMS curves upon switching between OER and HER potentials.

4 Conclusions

The ultimate combination of electrochemical and surface x-ray characterization techniques have been applied to study structure-activity relationships on example of model electrocatalyst Pt(111).

The Problem of Correct Interpretation of Catalyst Acidity by the TPD NH_3 Curves

Solomonik I.G.[1,2], Mordkovich V.Z.[1,2*]

1 - Department of New Chemical Technologies and Nanomaterials, Technological Institute for Superhard and Novel Carbon Materials, Moscow, Russia

Keywords: Fischer–Tropsch synthesis, catalyst, zeolite, TPD NH_3

1 Introduction

The way the catalyst functions is determined by the specific genesis of the system, including formation and activation modes. Thus, the mere use of literature data on the individual components when considering the behavior of the composite in different experimental conditions can not be entirely correct.

A Fischer-Tropsch process is well known [1] to have the surface acidity effect on the hydrocarbon synthesis, hydrocarbon isomerization, and olefin formation. A study [2,3] on the acid properties of the catalyst carriers by spectroscopic methods using probe molecules allows the identification of Lewis and Bronsted centers of different nature and strength both on the outer surface of the particles and inside the pores. At the same time, it is complicated to quantify the correlation due to the difficulty in determining the extinction coefficients. Simpler thermodesorption methods allow us to determine the total acidity of the samples (e.g., ammonia desorption). However, the correlation of the observed desorption peaks with the centers of a certain type, as well as their identification based only on the thermal desorption curves, is hampered. In this study, we use a TPD NH_3 method (detector - TCD) to investigate the acidic properties of the Fischer-Tropsch reaction molded catalysts with Raney cobalt as an active component based on the metal aluminum-containing composites, varying only in the type of their constituent zeolite.

2 Experimental/methodology

The catalysts were prepared by [4] by extrusion of a paste containing powders of Al°, binder (boehmite), dispersed Co° [5], and the corresponding zeolite (H-beta, mordenite, H-ZSM5, HY, Vegobond) in a ratio of 50:20:20:10 in the calculation of the dry mixture.

Thermal desorption of ammonia was registered (by an Autosorb-1C Quantachrome Instr. with a katharometer) after pretreatment of a granular catalyst formed "as is" in a vacuum (300° C, 4 hours), or without pretreatment for a full compliance of the activated catalyst with the system undergoing the acidity test.

The sample after (or without) pretreatment was heated (10°/min) in a stream of pure H_2 to 400°C, and was recovered at this temperature for 1 hour and cooled to 40°C. Then, at this temperature, the surface was cleaned by evacuation of recovery products for 0.5h, and ammonia was sorbed (0.5 hours, 40°C, 1%NH_3/N_2). Further, ammonia was desorbed (20°/min) in a stream of helium.

Thus, the acidic properties of the experimentally obtained system correspond to the acidic properties of a Fischer-Tropsch catalyst after reductive activation. The control experiments (without evacuation after recovery) confirmed the adequacy of the hydrate-hydroxyl cover of the emerging surface existing in the real conditions of the catalyst surface. The modeling compounds (individual zeolites, γ-Al_2O_3, boehmite gel after acid treatment) were activated

similarly to the functioning catalysts.

3 Results and discussion

For zeolites proper, ammonia desorption acidity is shown in Fig.1. Apparently, Vegobond has the lowest total acidity, while mordenite has the greatest number of strong centers.

The total intensity of a TPD curve of the zeolite-based catalyst (Fig. 2, an exemplary system with Hβ) differs significantly from the curve of individual zeolite introduced into its structure.

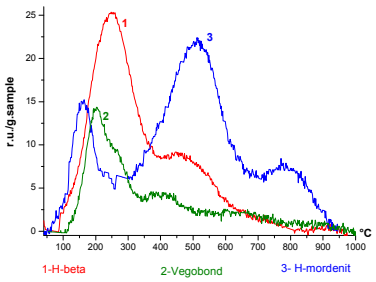

Fig.1 TPD NH_3 for individual zeolites

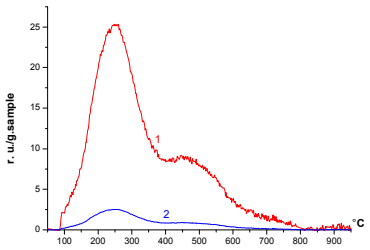

Fig.2 TPD NH_3 for an Hβ-based catalyst (1) and Hβ (2) in 10% of the catalyst weight

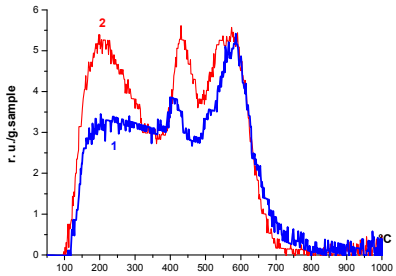

Fig.3 TPD NH_3 for a zeolite-free catalyst (1) and a catalyst with an Hβ zeolite (2)

A careful study of the initial catalyst and model systems, upon activation by a thermal vacuum treatment, with modification by nitric acid and potassium hydroxide, and a number of binder (boehmite) treatments, showed that the high-temperature peak with a maximum at 600°C is caused not only by desorption of ammonia, and the release of water in the conversion of the binder in the already molded catalyst may contribute up to 50% in the signal intensity. A 410-430°C maximum is mainly due to ammonia desorption from the unreduced cobalt oxide phase, wherein the catalyst has no more than half of $Co^{\delta+}$ ions initially introduced with Raney cobalt available for adsorption. Modification of systems allows a purposeful removing of the weak acid sites (thermal vacuum treatment, acid treatment) and strong acid sites (alkali treatment).

3 Conclusions

It is shown that the TPD curves are very similar for catalysts containing different zeolites; at the same time, the effects are significantly different from the respective ones in individual zeolites. The observed TPD curve peaks are determined not only by the desorption of ammonia, but also by the hydroxyl removal in the processes of phase transformations of aluminum oxide, formed from the binder or due to zeolite lattice destruction. A correct comparison of acidity and catalytic activity of composites is possible only for the systems subjected to the same effects.

XPS Study of Au/C Model Samples Oxidation by NO_2

Kalinkin A.V.*, Smirnov M.Yu., Bukhtiyarov V.I.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* avkalinkin@mail.ru

Keywords: supported, gold, graphite, oxidation, NO_2

1 Introduction

Gold catalysts exhibit high activity in a number of oxidative processes. Nevertheless, it is believed that gold cannot adsorb an oxidant from the gas phase without its specific activation (atomization, microwave discharge, etc.). As a result, the mechanism of action of gold catalysts is currently the subject of debate. Previously, we have shown that nitrogen dioxide produced by the decomposition of lead nitrate directly in a vacuum chamber of an XPS spectrometer possesses the ability to selectively oxidize fine particles of platinum with the formation of a mixture of oxides of Pt(II) and Pt(IV). In the present study, this technique was used to study the possibility of oxidation of gold deposited on highly oriented pyrolytic graphite (HOPG).

2 Experimental

This work was performed using an X-ray photoelectron spectrometer (SPECS, Germany) equipped with a hemispherical analyzer and a 9-channel detector. Photoelectron spectra were recorded using monochromated X-ray radiations Al Kα ($h\nu = 1486.7$ eV) and Ag Lα ($h\nu = 2983.4$ eV). HOPG was preannealed for 1 h in ultrahigh vacuum. Photoelectron spectra of these samples contained only photoelectron and Auger lines of carbon. Gold was deposited onto the HOPG surface kept at room temperature with the use of an EFM3 evaporator by heating a premelted gold wire with an electron beam. Two type samples were prepared for the study. In the first case, gold was directly evaporated onto a clean, atomically smooth HOPG surface (Au/HOPG); in the second case, gold was deposited onto a preactivated surface (Au/HOPGA). The activation consisted in a short sputtering of the HOPG surface with low energy Ar ions (1 s, 500 eV) in order to produce defects. The gold coverage was evaluated by comparing the intensities of Au 4f and Au $3d_{3/2}$ peaks from the model samples with those from an Au foil. To treat the samples, NO_2 at a total pressure of $3 \cdot 10^{-5}$ Torr was produced directly in the chamber of the SPECS spectrometer by thermal decomposition of $Pb(NO_3)_2$. The sample temperature during this treatment was near 300 K.

3 Results and discussion

During the deposition of gold on the smooth surface of HOPG, the FWHM (full width at half maximum) for the doublet Au 4f and the binding energy (BE) Au $4f_{7/2}$ were constant and characteristic of a gold foil in the whole range of gold coverages. During the deposition of gold on the activated surface with coverage $\Theta(Au) \geq 0.1$ML, the spectral characteristics of the doublet Au 4f also corresponded to bulk gold. At lower coverages, the doublet Au 4f broadened and its BE increased. For example, at $\Theta(Au) = 1.2 \cdot 10^{-2}$ ML, the BE was 84.8 eV. Figure 1 shows the spectral region Au 4f for the samples Au/HOPG and Au/HOPGA with similar coverages Θ(Au). It is assumed that the deposition of gold on the smooth surface of HOPG leads to the formation of 3D gold particles a few nm in size. The BE(Au $4f_{7/2}$) of the 3D particles does not depend on the particle size and equals 84.0 eV. For the HOPGA samples, the deposition of gold leads to the formation of not only 3D particles but also isolated atoms of gold. The Au atoms in

this case can stabilize on surface defects with the formation of a bond Au-C_n with one or several atoms of carbon. In this case, the electron density of the Au atom transfers to the carbon atoms, thereby increasing the BE(Au $4f_{7/2}$) relative to bulk gold. Superposition of different Au-C_n states leads to the broadening of the doublet Au 4f.

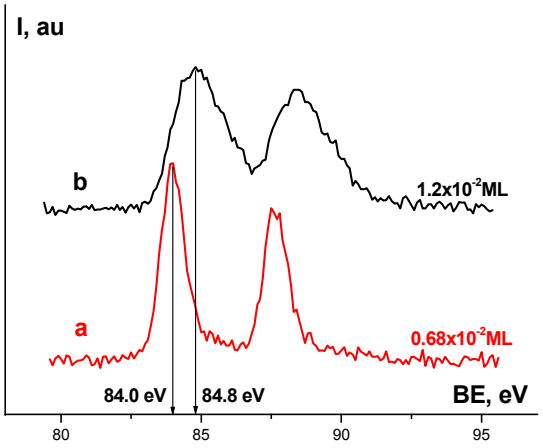

Figure 1. Au 4f core-level spectra of samples Au/HOPG (a) and Au/HOPGA (b).

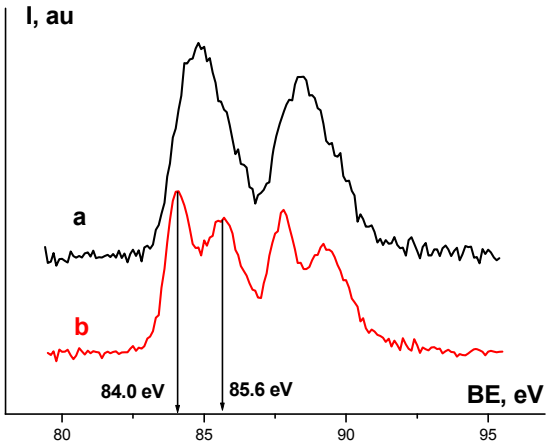

Figure 2. Au 4f core-level spectra of the sample Au/HOPGA with Θ(Au) = $1.2 \cdot 10^{-2}$ ML before (a) and after (b) treatment in NO_2 for 150 min.

The prepared samples were treated with nitrogen dioxide. It was shown that this treatment does not lead to any changes in the region of Au 4f for the samples Au/HOPG with any Θ(Au) and for the samples Au/HOPGA with Θ(Au) ≥ 0.1 ML. This result suggests that 3D gold particles are resistant to NO_2. The treatment in NO_2 of the sample Au/HOPGA with Θ(Au) < 0.1 ML resulted in the oxidation of gold. Fig. 2 shows the Au 4f spectra of the sample Au/HOPGA with Θ (Au) = $1.2 \cdot 10^{-2}$ ML before and after the treatment in NO_2. As is seen, the doublet Au 4f after this treatment changes into a superposition of two narrow doublets with the BE(Au $4f_{7/2}$) equal to 84.0 and 85.6 eV. The state with BE = 84.0 eV corresponds to 3D particles of metallic gold. The state with BE = 85.6 eV presumably corresponds to Au(III) in the surface compound (C–Au=O), which is formed during the oxidation of bound gold atoms Au-C_n with nitrogen dioxide. Thus, gold atoms that are chemically bound to the support can be oxidized under relatively "mild" conditions and hence can act as the active sites in the oxidation catalysis.

4 Conclusions

The deposition of gold on the atomically smooth surface of HOPG results in the formation of 3D gold particles with the BE(Au $4f_{7/2}$) = 84.0 eV. The form of gold deposited on the surface activated with argon ions (HOPGA) depends on coverage Θ(Au). At low coverages, the deposition leads to the formation of isolated gold atoms. The atoms are stabilized on the graphite surface by chemical bonding with carbon with the formation of surface compounds Au-C_n. The 3D gold particles are resistant to oxidation with nitrogen dioxide at a pressure $3 \cdot 10^{-5}$ torr. The isolated atoms of gold under these conditions are oxidized to form the state Au(III) stabilized on the surface of graphite. The stabilized gold atoms may act as active sites of gold catalysts.

Keywords: Cu-spinels, physico-chemical studies, WGSR

1 Introduction

Studies of spinel-type catalysts for WGSR attract great attention last years because of their high activity and high resistance to adverse factors of the reaction medium - high temperature and high steam content [1]. Although the study of these catalysts continues for a long time, the impact of the chemical composition and the ratio of trivalent cations on the distribution of copper cations in the oxide and its catalytic properties is still unclear. In the present paper we report the results of the study of the effect of chemical composition on the structural peculiarities and catalytic properties of mixed CuFeCr, CuFeAl and CuCrAl oxides of spinel structure.

2 Experimental

The samples were obtained by thermal decomposition of mixed hydroxocarbonates. Coprecipitation method at constant pH=6.6-6.8 and temperature 70-75°C was applied for hydroxocarbonates synthesis, using 10% nitrates and 6% sodium carbonate aqueous solutions. Precipitants were washed with distilled water and air dried under an IR lamp at 90°C for 12 hours. Netzsch STA-409 station was used for studying the process of decomposition in Ar flow at a temperature rise rate of 10 K/min. XRD studies were performed on D-8 diffractometer (Bruker) using Cu-K_α–irradiation (graphite monochromator in the reflected beam). Electron microscopic study of high resolution (HREM) of the samples was performed on a transmission electron microscope JEM-2010 (JEOL) (resolution 0.14 nm, the accelerating voltage of 200 kV). To determine the appropriate concentrations and ratios of elements the local energy-dispersive X-ray microanalysis (EDX-analysis) was used. Samples for studies were supported to the Al- grid. IR adsorption spectra are recorded on a Fourier transform spectrometer Bomem MB-102 in the region 250-4000 cm^{-1} and Bruker spectrometer in the region of 100-300 cm^{-1}. Samples were prepared by pressing in CsJ and polyethylene, respectively. Electronic spectroscopy of diffuse reflectance (ESDR) was used for the characterization of the electronic state of copper in studied spinels. Shimadzu spectrophotometer UV-2501 PC with diffuse reflectance attachment with ISR-240 A was used. Samples in powder form were placed in a quartz cuvette with a pathlength of 2mm and diffuse reflectance spectra were recorded relative to a standard sample reflection - $BaSO_4$ in the wavelength range 190-900 nm (11 000-53 000 cm-1). The catalytic activity of the samples in the water gas shift reaction was measured in a catalytic flow system over a temperature range of 150-210°C at a near atmospheric pressure. The tests were performed in a reaction mixture CO : H_2O : H_2 = 8 : 42 : 50 on a catalyst fraction of 0.14– 0.25 mm mixed with quartz glass of the same particle size in a ratio of 1:1.

Before the onset of the tests, the catalyst was activated in 5% H_2 in He for 2 h at 270°C.

3 Results and discussion

It is shown that depending on the Fe^{3+}/Cr^{3+} (Al^{3+}/Cr^{3+}) ratio the formed spinels exist in two structural modifications - a cubic and tetragonally distorted cubic. To follow the connection of composition and structure the tetragonal distorted spinels were examined in non-standard space group $F4_1/ddm$. Crystallographic relation between the cubic and tetragonal distorted cubic spinel phases was analyzed. It is shown that the distribution of cations on the crystallographic positions, the nature and extent of tetragonal distortion CuFeCr, CuAlCr spinel depends on the ratio of Fe^{3+}/Cr^{3+} (Al^{3+}/Cr^{3+}). Taking into account the energy preference of cations and mixed spinel structure the expected cation distribution was calculated. Dependence between the Fe^{3+}/Cr^{3+} (Al^{3+}/Cr^{3+}) ratio and the cation distribution was confirmed by spectral methods - IR, ESDR, EXAFS. Cu^{2+} ions are placed in tetrahedral positions in $CuCr_2O_4$ and the amount of tetrahedrally coordinated Cu^{2+} reduces with Fe^{3+}/Cr^{3+} growth in CuFeCr spinels. CuFeAl spinels structure remains cubic and partially reversed for all compositions.

Figure 1 shows a dependence of apparent activation energy (E_a) of WGSR from the mole fraction of Fe for CuFeCr and CuFeAl. For partially reversed CuFeAl spinels we didn't observe a dependence between Cu ions distribution and E_a (Fig.1 curve 1). In accordance with estimated cations distributions for CuFeCr spinels E_a changes from 8 kcal/mol for $CuCr_2O_4$ to 24 kcal/mol for $CuFe_2O_4$ (Fig.1 curve 2). Such a dependence correlates with Cu ions amount in octahedral positions (Fig.1 curve 3).

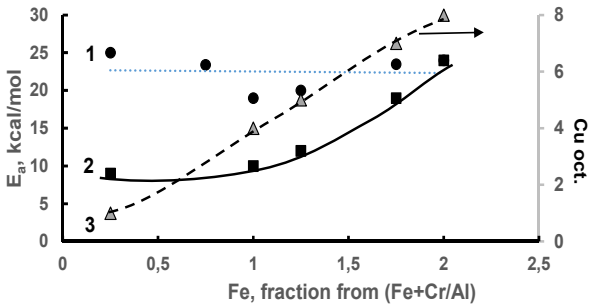

Fig. 1. Dependence of apparent activation energy (E_a) of WGSR from mole fraction of Fe for: (1) CuFeCr; (2) – CuFeAl; (3) Cu^{2+} in octahedral positions of CuFeCr spinels

4 Conclusions

The effect of chemical composition and Fe/Cr (Fe/Al) ratio on the extent of spinel structure tetrahedral distortion and on distribution of cations between tetrahedral and octahedral positions was systematically studied. The correlation between distribution of copper ions and catalytic behavior in low temperature WGSR was experimentally confirmed.

Keywords: silver, cerium, oxide, strong, metal-support, interaction

1 Introduction

Catalytic activity of supported catalysts depends on both particle size of the active component and interaction between active component and support. Several strategies have been developed to control the interfacial interactions. Nevertheless, it is very difficult to get insight into the interfacial roles in catalytic system and control the interfacial interaction to designing new materials. Thus, obtaining of strong metal-support interaction (SMSI) and its discovery has awakened interest [1].

The aim of the present work was to study the interfacial interaction of silver nanoparticles with cerium oxide and the effect of this interaction on the activity in low-temperature oxidation of organic compounds.

2 Experimental/methodology

Two series of Ag/CeO_2 catalysts prepared by impregnation and co-deposition methods were compared. Cerium oxide was prepared by deposition method using $Ce(NO_3)_3$ as ceria precursor and ammonia solution as precipitant. Ag/CeO_2 catalysts (loading of silver was 10% wt.) were prepared by two methods: impregnation and co-deposition. Aqueous solution of silver nitrate was used for impregnation of CeO_2 support (Ag/CeO_2-imp catalyst). Co-deposition method was used to prepare catalyst with increased interfacial interaction between Ag and CeO_2 support (Ag/CeO_2-coDP catalyst). Aqueous ammonia solution was slowly dropped into mixture of cerium (III) and silver nitrates aqueous solution at room temperature to precipitate and provoke red-ox reaction:

$$Ce(OH)_3 + Ag(NH_3)_2^+ + 2\ H_2O = Ce(OH)_4 + Ag^o + NH_4^+ + NH_4OH$$ [2, 3]

Discoloration to darker tones was an indicator of this reaction.

Specific surface area (S_{BET}) and pore size distribution of samples were determined according to low-temperature N_2 sorption using TriStar II 3020 analyser (Micromeritics, United States). XRD patterns were recorded with Shimadzu XRD-6000 diffractometer using CuKα in the range from 10 to 80º (2θ). Structure of samples and features of Ag-CeO_2 interfaces were studied by TEM HR using the JEM-2200FS microscope (JEOL). The oxidative ability of catalyst was studied by TPR H_2 and TP reaction of CO oxidation using ChemiSorb 2750 (Micromeritics, United States).

3 Results and discussion

Cerium oxide prepared by deposition methods had specific surface area of 66 m^2/g and pore size of 2-10 nm. According to XRD data, cerium oxide average partical size was ~ 12 nm. TEM result showed CeO_2 particle size distribution in the range of 5-16 nm.

The interaction of ceria with silver nanoparticles was observed by TPR H_2, which is the main

way to control the SMSI effect [4]. TPR profile of CeO_2 (Fig. 1a) is characterized by hydrogen consumption at 350-650 °C and over 700 °C, which can be associated with reduction of surface and bulk of CeO_2, respectively. The main H_2 consumption was observed at 50-300 ^oC for Ag/CeO_2 catalysts. These peaks were associated with simultaneous reduction of dispersed silver and ceria oxides, which characterized the $Ag\text{-}CeO_2$ interaction. The high peak intensity at 218 ^oC for Ag/CeO_2-coDP catalyst may be a result of strong interaction between Ag particles and CeO_2 support.

The features of the interaction of silver particles with surface of CeO_2 were explained by TEM HR results. The epitaxy of silver particles on cerium oxide was observed for Ag/CeO_2-coDP catalyst. The transition of lattice of well-faceted silver nanoparticles (111) (d_{111}=2.3Å) to lattice of CeO_2 with d_{111}=3.1Å is shown in TEM HR image for this catalyst (Fig.1 b). While silver clusters with size of 0.5-3 nm were observed for catalyst prepared by impregnation method (Fig.1c). The epitaxy of silver on the ceria surface may indicate on strong metal-support interaction. The formation of small cluster might be result of weak interaction of silver with ceria support.

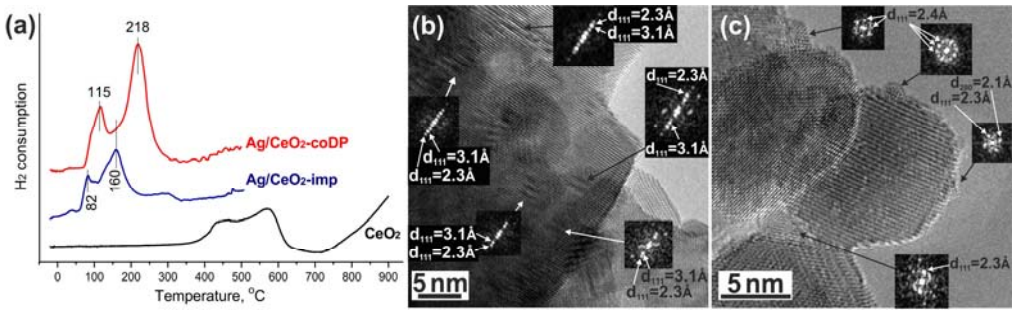

Fig. 1.TPR H_2 profile of Ag/CeO_2 catalysts (a), TEM images of Ag/CeO_2-coDP (b) and Ag/CeO_2-imp (c)

CO oxidation over Ag/CeO_2 catalysts was observed over 20 ^oC and temperature of 50 % CO conversion was 297, 204 and 107 ^oC for CeO_2, Ag/CeO_2-coDP and Ag/CeO_2-imp, respectively. The highest activity of Ag/CeO_2-imp catalyst may be associated with cluster state of supported silver or weak interaction of silver with ceria support. The strong metal-support interaction in Ag/CeO_2-coDP catalyst was not favourable for low-temperature CO oxidation.

4 Conclusions

Thus, it was shown that distribution of active component on support surface and their interaction depend on preparation method . It was shown that Ag/CeO_2 catalysts prepared by co-deposition had strong support-metal interaction expressed in epitaxy of silver on the ceria surface and more intensive simultaneous reduction of silver and cerium oxides in TPR. Weak interaction of silver clusters with ceria support was observer for catalyst prepared by impregnation method. The activity of supported small silver cluster in CO oxidation was higher in comparison with silver particles strongly bonded with ceria support.

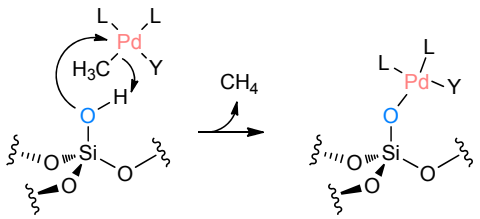
Keywords: grafting, single-site catalysis, coupling reactions, surface science

1 Introduction

In order to prepare supported metal catalysts, precursors are in most cases immobilised via ion exchange or impregnation techniques. These methods are often based on electrostatic interactions between the metal ion and the support. Grafting has been established as a method to obtain catalysts with atomically dispersed active sites.[1] During grafting, chemical bonds between the precursor and the functional groups of the support are formed (see Scheme 1).



Scheme 1: Grafting: reaction between the functional group of the support surface (silanol for silicon dioxide) and the reactive methyl ligand of the metal precursor complex.

Up to now, only a few contributions about grafting of palladium have been reported.[2,3] The synthesis procedure was optimised based on a methodology already successfully applied for platinum catalysts.[4] As prepared materials were applied as model catalysts in coupling of deactivated aryl halides such as chlorides or donor-substituted bromides in HECK and SUZUKI-MIYAURA reactions. Isolated surface metal complexes depict the highest possible metal dispersion, namely a single atom under ideal conditions and mark a versatile starting point for various material-scientific investigations in working catalysts.

2 Experimental/methodology

The materials were synthesised by methods which are mostly used in surface organometallic chemistry. Applied methods comprise classical organometallic and complex chemistry as well as high vacuum technique for support preparation.

Silicon dioxide in 100 – 300 µm grain size was calcined at 500 °C prior to use. High vacuum treatment at this temperature leads to isolated and vicinal silanol groups on the surface. The grafting reaction was performed in aprotic solvents (benzene, toluene).

The precursor dimethyl-(bis-(diphenylphosphino)-ethane)-palladium(II) was prepared according to modified literature procedures.[7] Any treatment subsequent to dehydroxylation of the support was carried out under aprotic and dry conditions in order to preserve the homogeneous surface properties.[5] The palladium surface species were investigated by IR spectroscopy, CO chemisorption and temperature programmed reaction techniques.

3 Results and discussion

Organometallic precursors for grafting generally comprise basic ligands for the actual

grafting reaction (leaving groups) and stabilising spectator ligands. Noble metals seek towards an oxidation state of zero which is well known for preparing and handling their complexes; a phenomenon generally referred to as 'self-reduction'. The key was to find a balance between reactivity of the leaving ligand and the overall stability of the metal complex. Alkanides are strong BRØNSTED-bases ($pK_a(CH_4)$ = 49) and react readily with protons of surface hydroxyl groups on oxidic support materials. Silica was thermally treated *in vacuo* to generate only isolated and vicinal silanol groups on the surface.

The grafted materials with highly (atomically) dispersed palladium species were tested in C-C coupling reactions of SUZUKI-MIYAURA and HECK type. They showed excellent catalytic activity in conversion of demanding substrates and hence outperform supported palladium nanoparticles prepared by common methods. The materials allow the investigation of leaching phenomena during the catalytic reaction und thus acquiring deeper understanding of mechanistic details. It has been and still is subject of discussion what is the actual active species in catalytic carbon-carbon (CC) coupling reactions by immobilised catalysts. The catalysts obtained by grafting show superior activity in CC coupling reactions when compared to materials synthesised by conventional methods. The release of the required amount of palladium into the solution to perform the reaction takes place under conditions when rather inert substrates (aryl chlorides) can be successfully activated (see Fig. 1). Eventually, re-deposition of palladium affords a material which, regarding its surface species is chemically altered compared to the fresh catalyst.

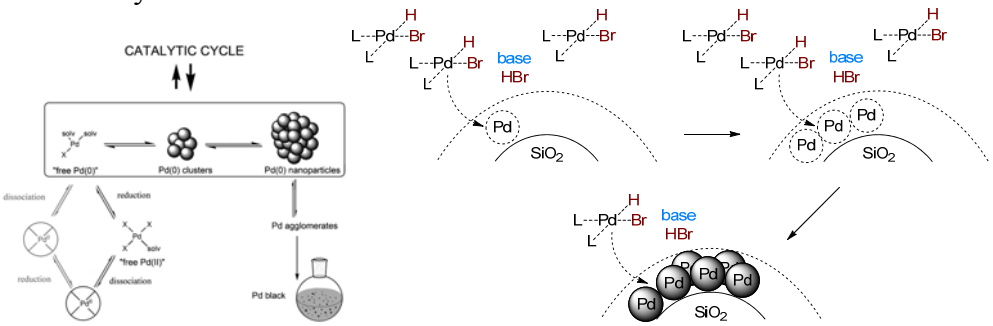


Fig. 1: Reaction mechanism in 'heterogeneous' HECK reactions (left)[6] and proposed re-deposition of the active species after running out of substrate.

4 Conclusions

Even though grafted metal complexes provide the highest possible dispersion (of 100 %), a molecular surface mechanism in CC coupling reactions seems unlikely due to sterical hindrance. However, the catalysts are capable of readily providing highly active palladium species in the required amount, which makes them a versatile tool in converting rather inert substrates in CC coupling reactions. Additionally, the highly dispersed palladium centres provide a starting point in for vast studies in catalyst degradation, their long-term stability and applicability.

Keywords: grafting, single-site catalyst, model catalyst, redox properties, EPR

1 Introduction

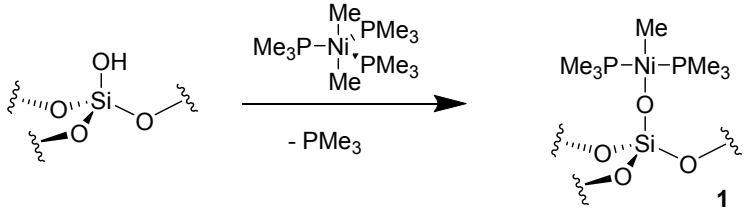
Heterogeneous catalysts with a high number of uniform and isolated active sites offer advantages over supported metal particles, in particular as model catalysts. Due to their higher dispersion, these materials are expected to possess enhanced catalytic activities and offer the possibility of getting better insights into reaction mechanisms.[1] During grafting, chemical bonds between the metal center of the precursor and the functional groups of the support are formed, leading to single-site catalysts. In contrast to early transition metals and to the 4d and 5d homologues there are only few contributions for grafting of nickel.[2-4] Especially the oxidation state and the redox properties of grafted nickel species are an interesting field of investigation, as the oxidation state of the catalytic site is expected to be crucial for its activity and often a matter of discussion.[5]

2 Experimental/methodology

Oxidic supports were pre-treated thermally under high vacuum conditions, in order to generate isolated and vicinal silanol groups on the surface of the support, whereupon the number of hydroxyl groups can be adjusted by the pretreatment temperature.[6] These hydroxyl groups serve as binding site for the isolated metal centers on the surface. Organometallic complexes were reacted with the hydroxyl groups on the support. The obtained catalysts were characterized by the means of elemental analysis, IR, NMR and EPR spectroscopy.

3 Results and discussion

Different organometallic complexes with basic ligands, such as alkanides, and stabilizing spectator ligands were used as precursors for the grafting procedure. Amongst the tested precursors dimethyltris(trimethylphosphine)nickel(II)[7] meets the requirements regarding precursor reactivity under optimized conditions in the best way. It showed the best performance to strike the balance between high reactivity towards the acidic surface hydroxyl groups and sufficient stability to handle the complex without premature decomposition. The precursor was reacted with a carefully pretreated and highly specified silica surface (Scheme 1).



Scheme 1: Grafting reaction of dimethyltris(trimethylphosphine)nickel(II)[7] with silica

The as-obtained single-site catalysts were characterized by IR-spectroscopy, solid state NMR and elemental analysis. The results prove that isolated nickel species were formed. The results of the elemental analysis indicate that one phosphine ligand of the precursor is released during the reaction. The molar ratio Ni/P is 1:2 and the carbon and hydrogen analyses indicate an elemental composition matching the structure of **1**. Solid state NMR-investigation support the proposed structure as two signals occur in the ^{1}H-spectrum at δ = 1.30 ppm and -1.28 ppm with a ratio of 18:3. The ^{13}C-spectrum shows two signals at δ = 11.66 and δ = -27.83 ppm. The ^{31}P-spectrum shows one signal at δ = -18.78 ppm.

The oxidation state of the precursor before and after the reaction was monitored by means of NMR and EPR spectroscopy. A change of the oxidation state of the nickel centers from II to I was observed. Surprisingly, isolated paramagnetic NiI species were found as well as sharp NMR signals which are caused by diamagnetic NiII species. The EPR spectra show the hyperfine structure of an axial d9 NiI system with g values $g_{\parallel}$ = 2.265 und $g_{\perp}$ = 2.079. The hyperfine coupling constants were A1= 98.0 G and A2=49.5 G indicating that the two phosphine ligands are not equivalent due to the distortion caused by the bulky surface in the metal ion's coordination sphere.

These results indicate that two different isolated species, a diamagnetic and a paramagnetic one, were formed on the surface. The reactions of the catalysts towards different reducing and oxidizing agents were investigated by temperature programmed reduction and EPR. The calcined catalysts could only be reduced at temperatures above 550 °C. The reduction was accompanied by agglomeration of the nickel species to particles. The agglomeration was monitored via transmission electron microscopy.

In order to get a better insight into the occurring processes on the surface, additional model experiments were performed in solution with tris-(*tert*-butoxy)silanol as model for a silica surface.

4 Conclusions

Supported catalysts with isolated nickel centers were synthesized by grafting procedures. These catalysts exhibit a very interesting redox behaviour. Diamagnetic Ni^{II} as well as paramagnetic Ni^{I} species could be detected after the grafting procedure. This feature predestines these catalysts as model system for investigating the relation of the oxidation state and the catalytic activity for alkene oligomerization reactions on isolated metal centers.

Surface Composition of the Industrial Dehydration Alumina Catalyst

Vasilyev V.A.*, Oparkin A.V., Karalin E.A., Kharlampidi Kh.E.

Kazan national research technological university, Kazan, Russia

* viktormemfis@mail.ru

Keywords: alumina, styrene, dehydration, alkali metals, alkali earth metals

1 Introduction

Sodium is the only one of alkali and alkali earth metals, the content of which is regulated by the state standards of Russian and Foreign manufacturers of alumina (excluding high-purity alumina of Sasol company [1]). However, a qualitative analysis of the outer surface of the industrial dehydration catalysts of 1-phenylethanol to styrene, that we carried out by XRD (X-ray fluorescence analysis), showed the presence of the potassium and calcium – catalytic poisons for solid acids (like sodium) [2].

2 Experimental/methodology

Determination of the content of cations on the surface of alumina were carried out by flame photometry in the low-temperature multi-channel flame photometer BWB - XP (BWB Technologies, UK); multi-point calibration.

3 Results and discussion

The results of quantitative analysis of samples of industrial alumina AOK-63-22K (JSC SCTB "Katalizator", Novosibirsk, Russia) from various serials (production 2008 - 2013), industrial alumina AOA (Dnipropetrovsk, Ukraine) from various serials (production 2009 - 2010), and several samples of aluminum oxide produced in non-CIS countries (samples 3-6) are shown in Table 1.

Table 1. Average surface concentration of elements

Catalysts sample	Concentration, μmol/g		
	Na	K	Ca
AOK catalyst	33,4	3,70	1,8
AOA catalyst	7,1	0,12	3,9
Sample № 3	1,6	0,06	0
Sample № 4	1,2	1,90	0
Sample № 5	49,0	2,74	12,4
Sample № 6	24,2	1,67	7,4

As shown in Table 1, the content of potassium and calcium at the surface of some samples is sufficiently high and reaches (in total) 60% of the sodium concentration (alumina AOA).

It should also be noted, that we detected an intense oscillations of the contents of these elements in the composition of the alumina, produced during one calendar year at one factory (Table 2).

Table 2. Surface concentration of elements, alumina AOA

Production date, serial number	Concentration, μmol/g		
	Na	K	Ca
2009, № 1	4,9	0,13	2,5
2009, № 2	4,9	0,13	4,4

2009, № 3	17,7	0,14	11,4
2009, № 4	4,1	0,12	3,3
2009, № 5	15,9	0,18	10,7

4 Conclusions

Based on the experimentally observed reduction effect of K^+ and Ca^{2+} cations on dehydrating activity of catalyst, we conclude that it is reasonable for consumer perform incoming inspection of the content of these elements in the alumina industry serials.

Keywords: pillared, clays, montmorillonite, catalysts, copper, zinc

1 Introduction

The development of a new bifunctional catalyst, containing two types of active sites (metallic and acid), can be the key to improve performance of the catalysts in catalytic reactions in one-step. Metallic copper is the active site, often being used in methanol synthesis. ZnO is used to increase Cu dispersion in the sample, thus providing a high number of active sites exposed to gaseous reactants [1]. Pillared clays (PILC´s) have been studied as acid catalysts due their performance and low cost. The introduction of aluminum polycations in the clays leads to a significant modification in their acidity. The acidity modification is due to two factors: (a) increase in the specific area and (b) appearance of new acid sites in the pillars molecular introduced and the binding sites between the pillars and the lamellae [2].

The goal of this study is production of a new bifunctional catalyst, which can be applied in the future for direct conversion of syngas to dimethyl-ether (STD-process).

2 Experimental/methodology

The clay used was Volclay (region Wyoming (EUA)) montmorillonite. The synthesis of the aluminum-pillared clay was carried out from a pillaring agent, which was prepared from the hydrolysis of an $AlCl_3.6H_2O$ 1M solution with NaOH 0.4 M (OH^-/Al^{3+} = 2.0). A montmorillonite aqueous suspension of 2 % (w/v) was prepared and stirred for 3h. The pillaring agent was added drop wise while stirring, then this mixture was stirred for a further 3 h and left to settle for 24h. The solid was calcined at 500 ^oC/2h at a heating rate of 3 °C.min^{-1}, obtaining V- Al PILC.

Cu-Zn catalysts supported on V-Al PILC were prepared by the impregnation method using 5wt% and 10wt% of Cu and 5wt% Zn. The catalysts were named 5%Cu V-Al PILC, 5%Cu 5%Zn V- Al PILC and 10%Cu 5%Zn V- Al PILC.

The materials were analyzed by X-ray diffraction (XRD), energy dispersive spectroscopy (EDS), N_2 adsorption/desorption isotherms, temperature-programmed reduction (TPR) and X-ray absorption near edge structure (XANES). The acidity studies were performed using FTIR after pyridine adsorption.

3 Results and discussion

XRD pattern for natural clay showed an intense reflection for the basal spacing d_{001}=9.4Å and XRD patterns for V-Al PILC indicated that the pillaring procedure was successful due to the increase of the basal spacing, d_{001}= 16.7 Å. XRD patterns for the bifunctional catalysts showed two peaks at 2θ values of 35.57º and 38.73º and are related to the monoclinic structure of CuO (JCPDS card Nº. 05-0661), and other peaks at values of 2θ= 31.73º, 34.37º, 36.21º, 47.48º, 56.53º and 67.86º, related to hexagonal structure of ZnO (JCPDS card Nº. 89-1397).

Analysis by EDS for natural clay compared to V-Al PILC showed a significant decrease in the amount of Na and Ca. This is indicative of exchange of these ions by aluminum polycation.

The bifunctional catalysts showed Cu and Zn real values close to nominal. It was observed in the TPR profiles of bifunctional catalysts, that ZnO did not improve the reduction of CuO, when compared to the catalyst without ZnO. It was observed that the pillaring process increased the specific surface area. After impregnation of Cu-Zn, it a decrease was observed in the specific surface area and pore volume. This may be due to Zn covering the pores of the V-Al PILC, however the higher Cu content impregnated increased the specific surface area and pore volume. N_2 adsorption isotherms of the bifunctional catalysts have a combination of shapes I and IIb, with hysteresis cycles of the Type H3 and H4 [3].

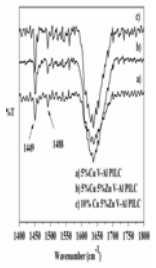

Fig. 1. FT-IR spectra of adsorbed pyridine on bifunctional catalysts.

Table 1. XANES- Quantification of oxide species Cu K-edge under H_2 flow at 300 °C.

Catalysts	Molar ratios	
	CuO	Cu_2O
5%Cu	6.0 ± 1.3	19.0 ± 2.1
5%Cu 5%Zn	17.0 ± 0.7	21.0 ± 1.0
10%Cu 5%Zn	3.0 ± 1.5	23.5 ± 2.5

FTIR spectra with pyridine adsorbed are shown in Fig 1. The bifunctional catalysts showed two bands characteristic of pyridine adsorbed in the acids sites. The band at 1449 cm^{-1} is characteristic of physisorbed pyridine, related to Lewis acids sites. The band at 1488 is associated with both Brønsted and Lewis acid sites [4]. XANES results (Table 1) demonstrated that Cu local order under the temperature studied is composed of a mixture of phases: CuO, Cu_2O and Cu^0, with Cu^0 phase in higher quantities. ZnO did not favored the reduction of Cu, as already discussed in the TPR analysis, when the 5%Cu and 5%Cu5%Zn samples are compared.

4 Conclusions

The 10%Cu5%Zn-V-Al PILC catalyst can be the most promising to the STD-process, this is due the presence of Lewis and Brønsted acids sites and higher specific surface area and Cu^0 molar ratios.

Keywords: sulphided, Re catalyst, Co, Ni additives, N_2 sorption, WGS reaction, sulphur presence

1 Introduction

The water-gas shift (WGS) reaction ($CO + H_2O \leftrightarrow CO_2 + H_2$) is keeping up its key position as an integral stage of ammonia and methanol synthesis as well as hydrogen production. Alumina-supported Re-based catalysts have been used in various reactions as hydrogenation, metathesis, reforming as well as hydrodesulfurization and hydrodenitrogenation process [1, 2]. To our knowledge, such catalysts have not yet been investigated in the WGS reaction conditions in the presence of S-containing gases. This promoted us to study the activity of Re_2O_7/γ-Al_2O_3 system in the WGS reaction over preliminary sulphided samples using Ni, Co and K as additives. The alkali character of K provokes a question about its effect on the pore texture of an amphoteric support like γ-Al_2O_3 after addition as a second or third component. The present study provides information how the deposition of K, Ni and Co additives on Re/γ-Al_2O_3 affects the catalyst texture after the calcination procedure and after activity test in WGS reaction.

2 Experimental/methodology

The single-component Re (15.3 wt.% Re_2O_7), Ni (3 wt.% NiO), Co (3 wt.% CoO) and K (5 wt.% K_2O) samples were prepared by incipient wet impregnation of the γ-Al_2O_3 support with aqueous solutions of the corresponding metal salts followed by drying at 105°C and calcination at 450°C. Ni and Co was added as second component and K was introduced either as a second or a third component to single-component Re sample, following the same preparation procedure of drying and calcination. The synthesized bi- and tri-component samples were denoted as KRe, NiRe, CoRe, KNiRe and KCoRe. The weight content of the Re_2O_7 corresponded to a surface density of 2 atoms Re/nm^2 support. The calcined samples were pre-sulfided *in situ* (6 vol.% H_2S in H_2 at 400°C for 2 h) in continuous-flow reactor. The WGS reaction was carried out at: 2 vol.% H_2S, 7.8 vol.% CO, 90 vol.% Ar gaseous mixture; atmospheric pressure; 180-400°C temperature range; GHSV 4000 h^{-1}; 0.3 steam/gas ratio.

Multipoint BET surface areas (S_{BET}) of the support and the samples were estimated using N_2 sorption at –196ºC (Quantochrome Autosorb Automated Gas Sorption System), according to the BET equation. Evacuation at 200ºC for 18 h was performed prior to sorption analysis. Adsorption-desorption isotherms were used to calculate multipoint BET surface areas, pore size distribution (PSD), using Barrer, Joyner and Halenda (BJH) method, and total pore volumes (V_{tot}) at a relative pressure P/P_o=0.995±0.001 [3].

3 Results and discussion

The sorption isotherms of the calcined and tested γ-Al_2O_3 support and promoted Re-containing samples are of type IV, typical for mesoporous structure with the hysteresis loops of

H2 type, related to the interconnected network of pores with different size and shape according to IUPAC classifcation.

The BET surface area of the calcined support decreases after component deposition in the order: CoRe ≈ NiRe ≈ KCoRe ≈ Re > KRe > KNiRe. The trend is different for the corresponding tested samples: Re > KRe ≈ NiRe ≈ CoRe > KNiRe > KCoRe.

The total pore volume does not change practically, being in range of 0.4-0.6 m^3/g for the calcined samples and 0.3-0.6 m^3/g for the tested ones. The Re deposition on γ-Al_2O_3 leads to the formation of new micro pores - S_{micro} increases by 85 %. The addition of Ni (NiRe sample) and K (KRe, KNiRe and KCoRe) results in the diminution of the amount of the micro pores. The reaction conditions cause the increase of S_{micro} in all samples. The values are in 15-21 m^2/g range, the most significantly being in KRe, NiRe and KNiRe (with 67%, 100% and 320%, respectively).

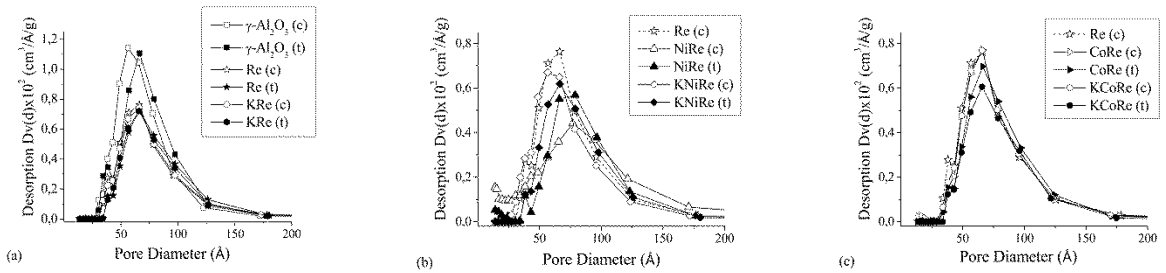

Fig. 1. Pore size distributions

The overall view on pore size distribution in the γ-Al_2O_3 support and in the calcined samples demonstrates mainly a bimodal distribution of the free mesopores in the range 30-180 Å. The data clearly show that after calcination and after test the mesoporous texture of the γ-Al_2O_3 support is preserved (Fig. 1a). The impregnation of the Re active component leads only to filling of pores by the surface species formed. The deposition of Ni on calcined Re sample induces greater changes (Fig. 1b) in the PSD than the K and Co do (Fig. 1a,c). The addition of K causes the redistribution of the pores in the tri-component KNiRe sample, whereas the PSD remains the same in the tri-component KCoRe sample. Only filling and/or partial blocking as well as unblocking of the carrier pores is registered after activity test in WGS reaction because of generated migration of the surface species.

4 Conclusions

Contrary to our expectations, introduction of K to calcined Re, NiRe and CoRe samples does not exert a strong impact on the primary mesopore texture of γ-Al_2O_3, and neither does addition of Co. Greatest changes in the catalyst texture are induced by Ni deposition.

Keywords: hybrid, nanomaterials, resorcinarene, silver nanoparticles

1 Introduction

Metallic nanoparticles (Au, Ag, Pd, Pt) show unique optical, electric and catalytic properties [1,2] and, therefore, are of a great interest for researchers. Silver nanoparticles have been applied in electronics, optoelectronic [3] and in medicine [4]. We have used amphiphilic derivatives of resorcinarenes with decyle ($C_{10}H_{19}$-CA), decynyl ($C_{10}H_{21}$-CA), methyl (CH_3-CA) and ferrocene (Fc-CA) groups at the lower rim as stabilizers in the synthesis of the monodisperse silver nanoparticles (AgNPs). The resorcinarenes prevent the aggregation of AgNPs and influence the size and shape of the silver nanoparticles produced.

2 Experimental/methodology

Stable colloidal silver nanoparticles have been obtained in aqueous media using common methods in the presence of $C_{10}H_{19}$-CA, $C_{10}H_{21}$-CA, CH_3-CA as stabilizers and sodium borohydride as a reducing agent. In the case of Fc-CA, the reducing agent was not used, the ferrocene groups act as reducing agents.

AgNP were characterized by the data of UV-vis and IR spectroscopies, static and dynamic light scattering (SLS and DLS), atomic force microscopy (AFM), scanning electron microscopy (SEM) and transmission electron microscopy (TEM) and thermogravimetry (TG).

3 Results and discussion

The influence of the length of the hydrophobic tail of the size and shape of AgNPs is investigated. The silver particles of different sizes are formed using of methyl-resorcinarene CH_3-CA. while the assembled resorcinarenes $(C_{10}H_{19}\text{-CA})_n$ and $(C_{10}H_{21}\text{-CA})_n$ produce monodispersed AgNPs of about 30 nm. The average size of hybrid systems Ag@$C_{10}H_{21}$-CA and Ag@$C_{10}H_{19}$-CA is about 85 nm, and the hydrodynamic diameter is about 90 nm. Hybrid nanosystems stable in water for a long time, and turbidity of the solutions is observed only after several months of storage.

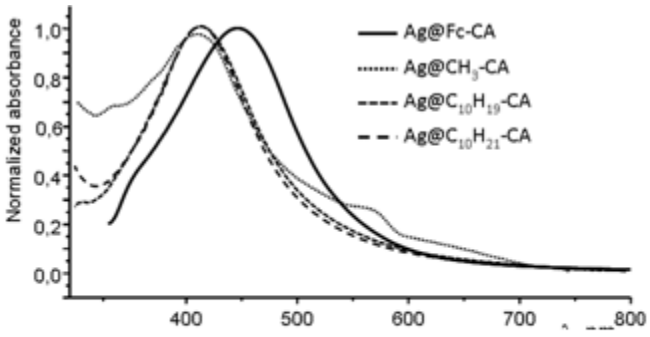

Fig.1. UV-Vis spectra of hybrid nanoparicles Ag@Fc-CA, Ag@$C_{10}H_{19}$-CA, Ag@$C_{10}H_{21}$-CA and Ag@CH3-CA.

In the synthesis of silver nanoparticles was also used ferrocene-resorcinarene. It acts not only as a template and stabilizer, but also as a reductant. Formation of Ag(0) is due to the

reduction of silver ions ferrocene groups resorcinarene by followed the organization in hybrid nanoparticles Ag@Fc-CA.

In the case of Ag@Fc-CA the average size of AgNPs is slightly larger and it is about 35-40 nm. The diameter of the hybrid nanoparticle Ag@Fc-CA is slightly smaller than Ag@$C_{10}H_{19}$-CA and Ag@$C_{10}H_{21}$-CA. At the data of AFM and SEM mean diameter of Ag@Fc-CA is about 60 nm, and the hydrodynamic diameter is about 80 nm. Evidently, the ferrocene-resorcinarene forms thinner organic cover in Ag@Fc-CA, as compared with the Ag@$C_{10}H_{19}$-CA and Ag@$C_{10}H_{21}$-CA.

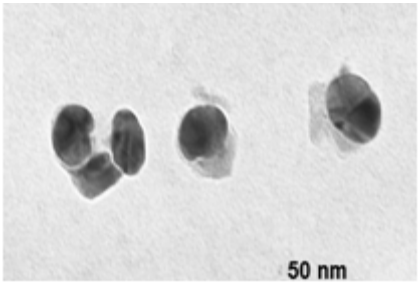

Fig.2. TEM image of Ag@Fc-CA.

Catalytic properties of the hybride nanosystems Ag@CA were studied in the common used reaction of reduction of p-nitrophenol with sodium borohydride in water. The results shows that sodium borohydride does not reduce nitrophenol in pure water. The addition of 40 nanomole of Ag@CA rapidly accelerates the reaction, and it is finished in a few minutes. The highest catalytic activity is observed for Ag@$C_{10}H_{19}$-CA. The lowest activity is detected for Ag@Fc-CA due to the lower surface area of metal nanoparticles or formation of dense packing of Fc-Ca molecules on the silver surface.

The synthesis and characteristics of Ag@CA will be discussed in the presentation.

Table 1. Observed rate constants and normalized rate constant of reduction reaction p-nitrophenol using hybrid nanoparticles Ag@CA.*

Catalyst	**Rate constants, k, s^{-1}**	**Normalized rate constant, k_{cat}, Ag-$mol^{-1}s^{-1}$**
Ag@Fc-CA,	0,0029	72500
Ag@$C_{10}H_{21}$-CA	0,0045	112500
Ag@$C_{19}H_{19}$-CA	0,0128	320000

*n(Ag@CA) = 40 × 10^{-9} M, C(*p*-nitrophenol) = 0,113 mM, C($NaBH_4$) = 5 mM, H_2O, 25 °C.

4 Conclusions

Thus, amphiphilic resorcinarenes with carboxylic groups on the upper rim were used as templates for the creation of silver-containing hybrid organic-inorganic nanoparticles Ag@CA. The hybrid nanoparticles exhibit high catalytic activity, which was demonstrated by the reduction reaction of nitrophenol in water.

A Theoretical Study on the Effect of Active Centers of SiO_2 Surface on O_2 Interaction with Small Supported Silver Clusters

Ivanova-Shor E.A.*, Laletina S.S., Shor A.M., Nasluzov V.A.

Institute of Chemistry and Chemical Technology SB RAS, Krasnoyarsk, Russia

Keywords: density, functional, theory, silver, oxygen, adsorption, supported cluster, silica

1 Introduction

Silica plays important role in heterogeneous catalysis as a support for variety of metal clusters with a size from few to some thousands atoms. Many properties of silica as a support depend on the nature of its surface. The clean dehydroxylated surfaces of crystalline silica or silica film as well as hydroxylated surfaces of amorphous silica are rather inert toward binding of metal clusters. However, various imperfections and point defects being in abundance on real silica surface can act as sites for trapping metal clusters. The physical and chemical properties of supported metal clusters strongly depend on the existence and the nature of such defects. Among various defects of SiO2 surface, paramagnetic surface centers such as silicon dangling bond, ≡Si▪ (E□), and nonbridging oxygen, ≡Si–O▪ (NBO), [1] are considered as the most essential for effective trapping of metal clusters [2].

In the current work we report the results of theoretical study on how properties of NBO and E□ adsorption sites affect the interaction of O2 with small silver clusters (Agn, n=3,4) attached to these SiO2 defects. Ability of silver to activate oxygen is the key factor determining its catalytic activity in many oxidation reactions. It is well known that silver clusters of nanometer size supported on oxide surface are effective catalysts in such important industrial processes as epoxidation of ethylene and oxidation of methanol. At the same time, small supported Ag clusters containing few atoms (<10) attract growing attention as, in particular, perspective catalysts of propylene epoxidation and selective catalytic reduction of NO by hydrocarbons.

2 Experimental/methodology

The calculations were performed using all-electron scalar relativistic density functional method and accurate quantum mechanics/molecular mechanics (QM/MM) scheme of embedding QM clusters in an elastic polarizable environment described at the MM level [3]. The SiO2 surface was modeled as idealized structure of the walls that form the hexagonal channels of mesoporous silicalite MCM-41.

3 Results and discussion

Attaching neutral Ag3 and Ag4 clusters to E□ centers results in formation of the covalent Si–Ag bond. A transfer of electron density from support to metal clusters is observed, yielding a small negative effective charge, about -0.1e. In contrast, adsorption at NBO centers results in the partial oxidation of silver clusters and formation of the polar covalent O-Ag bond. The spin state of unsupported Ag3 and Ag4 clusters are exchanged upon adsorption at NBO and E□ centers [4]. In line with these changes, silver trimers and tetramers anchored at NBO centers feature ability to adsorb O2 similar to those of their gas-phase cationic counterparts [5]. At Ag3/NBO site O2 is stabilized in the terminal form only with small binding energy, BE < 12 kJ/mol. Similarly to gas-phase cation Ag4+, bridge (two-end) orientation of O2 is the most stable O2 adsorption form at Ag4/NBO site. It is accompanied by 2D→3D transformation of the silver tetramer and characterized by substantial binding energy (BE=97 kJ/mol). The interaction of O2 with Ag3/E□ center results in formation of two adsorption forms with terminal and bridge orientations of oxygen molecule. The

calculated interaction energies of these two forms fall in the narrow interval of 39-42 kJ/mol. Similarly to Ag4/NBO, the bridge orientation is the most stable O2 adsorption form at Ag4/E□ site; 2D→3D transformation of the metal moiety is also observed. O2 adsorption energy at Ag4/E□ site is notably smaller, BE=59 kJ/mol.

The positively charged bare Agn clusters attached to NBO defects interact with negatively charged regular oxygen centers of SiO2 surface due to electrostatic forces. Molecular adsorption of O2 results in transfer of electron charge density from metal moieties to oxygen and, as a consequence, further increases the oxidation state of the silver clusters supported at NBO centers and partially oxidizes them on E□ defects. The value of the charge transfer correlates with the O2 interaction energy: it is minimal for the O2 adsorption at the Ag3/NBO complex and maximal for the O2/Ag4/NBO system. In turn, the increased positive charge on silver cluster strengthens its electrostatic interaction with support and additionally stabilizes O2 adsorption forms. This effect is most pronounced for Ag4/NBO site, where the adsorption of molecular O2 is almost twice as strong as that on free cation Ag4+. For such small unsupported clusters as Ag3 and Ag4 dissociative O2 adsorption is not favorable process [6]. At variance, for the Ag4/NBO and Ag4/E□ centers a strong electrostatic interaction with silica surface makes dissociative mode the most preferable form of O2 adsorption with the binding energies 123 and 75 kJ/mol, respectively. At Ag3/E□, the stability of O2 dissociative and molecular adsorption forms is similar. O2 dissociation is unfavorable at Ag3/NBO site.

To elucidate the O2 dissociation mechanism on supported silver clusters various transition states (TS) with respect to breaking of O–O bond were located. The ability of silver clusters to dissociate O2 depends on their ability to activate adsorbed molecule. This activation, in general, occurs as electron charge transfer from metal cluster to O2. It works better for the metal cluster with unpaired electron and higher electron density. Indeed, the activation barriers of O2 dissociation are reduced on going from supported closed-shell Ag3 to open-shell Ag4 clusters and from positively charged Agn/NBO to neutral Agn/E□ systems. As a consequence, the lowest activation barrier, 142 kJ/mol, was calculated for O2 dissociation at Ag4/E□ site, whereas the dissociation at Ag3/NBO centers is characterized by the highest activation barrier, 316 kJ/mol. O2 dissociation barrier at Ag4/NBO and Ag3/E□ clusters has the intermediate value of the activation barriers, 175 kJ/mol. Besides the main reasons mentioned above, the heights of the barriers are also determined by the metal cluster reconstruction along reaction path. The calculated activation barriers are by 78-304 kJ/mol higher than O2 adsorption energies.

4 Conclusions

Therefore, it is supposed that any attempts to overcome these barriers will lead to O2 desorption rather than its dissociation. This manifests that small SiO2 supported silver clusters studied in this work are very stable with respect to oxidation.

Hydroprocessing of Heavy Crude Oil

Schacht P.*, Díaz-García L., Portales B., Ramirez S.

Instituto Mexicano del Petróleo Eje Central Lázaro Cárdenas Norte, México, México

* pschacha@imp.mx

Keywords: heavy crude oil, supported catalyst, upgrading viscosity

1 Introduction

The objective of the hydrotreating processes is to convert high molecular weight hydrocarbons in lighter fractions and upgrade the crude oil (1). In the presence of hydroprocessing catalyst loaded with metal transitions supported on alumina and hydrogen donor it is induced simultaneous hydrocracking, hydrodesulphurization and asphaltenes conversion to minimize the sulfur, nitrogen and metal content of the heavy oil at high hydrogen pressure (2). In the present work, a comparative study of four hydrotreating catalysts, namely, MoNi, NiW, CoMoP and, CoMoNiWP supported on alumina, were synthesized and evaluated in a batch reactor of 500 ml, at 673 K during 1 hour.

2 Experimental Section

All of the catalysts were prepared by successive impregnation on γ Al_2O_3 and dried at room temperature overnight, and finally calcined at 773 K for 2 h, the catalysts were characterized by Elemental Analysis, Textural properties and Temperature-programmed reduction (TPR).

A: Ni-W: [$Ni(NO_3)_2.6H_2O$ Aldrich 98%] and [$(NH_4)_{12}W_{12}O_{40}$].
B: Mo-Ni: [$(NH_4)_6Mo_7O_{24}$ Aldrich 99%], and [$Ni(NO_3)_2.6H_2O$ Aldrich 98%].
C: Co-Mo-P: [$(NH_4)6Mo_7O_{24}$, Aldrich 99%], [$Co(NO_3)_2$), Aldrich 98%], [H_3PO_4, Baker 86 %].
D: Co-Mo-Ni-W-P: [$Co(NO_3)_2$), Aldrich 98%], [$(NH_4)6Mo_7O_{24}$, Aldrich 99%],[$Ni(NO_3)_2.6H_2O$ Aldrich 98%], [H_3PO_4, Baker 86 %], and [$(NH_4)_{12}W_{12}O_{40}$].

The Activity Tests of heavy crude oil were carried out in a Parr batch reactor, physical and chemical properties of the feed and products were characterized according to the ASTM methods.

3 Conclusions

In this paper, it was shown a comparative study of four different hydrotreating supported alumina catalysts, formulation: NiMo, NiW, CoMoP and NiCoMoWP. We determine that the catalyst D showed the best catalytic behavior measured as API gravity increase and the lower asphaltenes content, 1.5 wt%. However, the CoMoP catalyst showed the higher aromatic content taking account the lower metal loading (13 wt%).

Keywords: EPR, Cu-CHA, NH_3-SCR, zeolites, SCR-mechanism, copper

1 Introduction

Selective Catalytic Reduction (SCR) is one of the most effective ways to reduce the environmentally harmful NO_x gasses emitted from combustion process. The NH_3-SCR process uses ammonia as the reducing agent, and copper exchanged zeolites have proven to be a good catalyst for this process [1]. Especially the small pore zeolite chabazite (CHA) have received increasing attention due to its high stability [2]. The knowledge of the mechanism of this process can improve the understanding of the role of the reactants and intermediates and lay the foundation of future catalyst systems.

Very recently a mechanism for the NH_3-SCR process catalyzed by Cu-CHA was proposed, with a key step involving the formation of a copper nitrate species [3]. This species and the whole mechanism are investigated using *in-situ* Electron Paramagnetic Resonance (EPR) spectroscopy.

2 Experimental

Samples investigated consisted of a series of Cu-CHA with constant Cu/Al ratio of 0.5 and varying Si/Al ratio in the range 15-30 and a series with constant Si/Al ratio of 15 and varying Cu/Al ratio in the range 0.1 to 0.6.

EPR spectra were collected on an X-band Bruker EMX EPR Spectrometer. Samples were fractioned to 150-300 μm before placed in a quartz tube and positioned using quartz wool. Time resolved EPR spectra were recorded during heating to maximum 300 ^{o}C under flow conditions (GHSV = 400,000 h^{-1}). The exit gas content of NO, NO_2 and NH_3 was measured using a Thermo Electron Corporation Ammonia Analyzer.

3 Results and discussion

The black trace in Figure 1 left shows the dehydrated Cu-CHA with the two distinct EPR active species corresponding to copper sites located in 6 membered ring sites as described by Godiksen et al. [4]. Starting from the dehydrated sample the flow is changed from He/O_2 to $NO/O_2/He$. A species with an EPR spectrum described with the parameters: $g_{||}$ = 2.28 and A = 462 MHz emerges which is assigned to a Cu(II)-nitrate species [5].

By removal of nitrogen monoxide from the feed gas the EPR signal assigned to Cu(II)-nitrate disappears (Figure 1 right), which could be related to the equilibrium between NO, O_2 and $(2\,NO + O_2 \rightleftharpoons 2\,NO_2)$ NO_2 . The resulting spectrum is similar to the spectrum recorded on dehydrated Cu-CHA, which indicates that no new EPR active sites are present.

A flow of ammonia together with nitrogen monoxide results in almost complete disappearance of the EPR signal (Figure 1 right).The disappearance of EPR signal can originate from reduction of Cu(II) to Cu(I), from ferromagnetism (coupling of Cu(II)) or the Pseudo Jahn-

Teller effect [4]. XANES spectra confirm that Cu(II) is reduced to Cu(I) [2], and thus the EPR signal loss is ascribed to reduction.

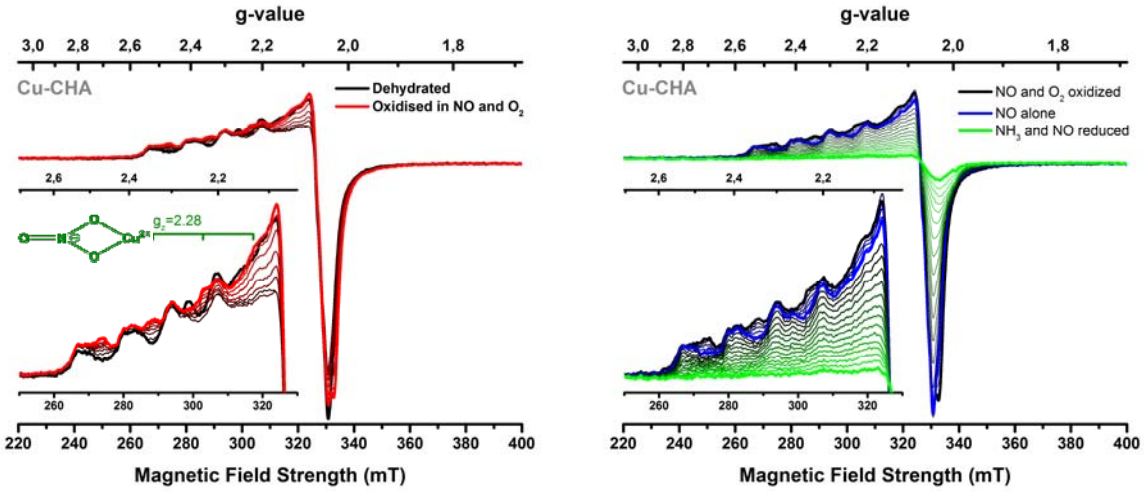

Fig. 1. Left: In-situ EPR spectra of Cu-CHA dehydrated in oxygen at 200 °C (black) and intermediate spectra when flow changed to NO and O_2 (red). In the last spectra of the series (red) a new copper species is seen with $g_{||} = 2.28$ which corresponds to a Cu(II)-nitrate, illustrated in green. Right: In-situ EPR spectra of Cu-CHA starting from the species oxidised in NO and O_2 (black), then removing oxygen from the flow results in the collapse of the EPR active Cu(II)-nitrate, and results in the blue spectra which is similar to the dehydrated spectrum. Finally the flow is changed to ammonia and nitrogen monoxide, whereby the EPR signal disappears almost completely (green).

4 Conclusions

EPR spectroscopy is a very specific and sensitive method for the analysis of the coordination environment and oxidation state of copper. In this work *in-situ* EPR is used to identify steps of the NH_3-SCR mechanism. A Cu(II)-nitrate species is observed in a flow of nitrogen monoxide and oxygen, which disappears upon removal of oxygen in the flow. The EPR signal disappears in a flow of ammonia and nitrogen monoxide, which indicates an almost complete reduction of the copper, and thus loss of the EPR activity.

In situ EMR / GC Study of the Conversion of Ethanol into Hydrocarbons on Fe-Zr/Al2O3 Catalysts

Aliyeva N.M.*, Mammadov E.E., Huseynova F.I., İsmailov E.H.

Institute of petrochemical processes, Azerbaijan National Academy of Sciences, Baku, Azerbaijan

Keywords: ethanol, hydrocarbons, Zr-Fe-Al, oxide, catalysts, *in situ* EMR/GC

1 Introduction

The conversion of ethanol to hydrocarbons over solid catalysts is one of the most studied reactions in heterogeneous catalysis [1-5]. At the Institute of Petrochemical Processes of Azerbaijan National Academy of Sciences the system based on Jeol JES-PE-3X ESR spectrometer, LXM 80 (Russia) chromatograph and flowing micro-catalytic reactor is constructed and used to obtain the simultaneous kinetic and spectral data directly about magnetic sites of catalysts and reaction products [6].

The aim of this work is monitoring of the state of active components by in-situ EMR in combination with simultaneous GC analysis of gas phase products of ethanol to hydrocarbons conversion over Fe-Zr/γ-Al_2O_3 catalyst with different content (1-5 wt%) of iron and zirconium, identification of the magnetic species and study of their role in the activity and selectivity control of this reaction.

2 Experimental/methodology

The catalysts were prepared by wet impregnation technique of γ-alumina support with the $ZrOCl_2$ $8H_2O$ and $FeCl_3$ $2H_2O$ solutions. The prepared samples of catalysts were dried at 393K and then calcined in the presence of flow of purified air at 673K for six hours. These catalysts are tested in the conversion of ethanol to hydrocarbons at 473-573K and atmospheric pressure. Element composition on the surface and phase composition of the samples are determined by X-ray fluorescence microscopy and X-ray diffraction methods using XGT 7000, Horiba, Japan, microscope and XRD TD3500, China diffractometer, respectively. The composition of elements on the surface and the phase composition of catalyst before and after conversion of ethanol are studied.

3 Results and discussion

The catalytic conversion of ethanol was studied at reaction temperature range from 473 to 573°K. The hydrocarbons was not detected at 473 K by GC. For monometallic Fe and Zr/ γ-Al2O3 catalysts, the main reaction products consisted of ethane, propane and hexane at all reaction temperatures, benzene and toluene start to appear at reaction temperature 523K, and xylene - as traces at 573K also detected. Maximum values of the yield of ethane (70.6%) and propane (2.8%) detected at reaction temperature 553K for Fe/γ-alumina and at reaction temperature 523K (38.5 and 2.0%, respectively) for Zr/ γ-alumina catalysts. The yield of hexane hydrocarbons at all reaction temperatures is higher for Zr catalyst than for Fe one. Benzene and toluene appear as traces at reaction temperature 523K and increase with increasing the reaction temperature up to 573K. At the same time the yield of hexane hydrocarbons decreases with the increase in reaction temperature. The same trend is observed for aromatic compounds, which are obtained in higher yield on Zr catalyst.

In the simultaneously recorded EMR spectra for these catalysts two different by nature signals are observed: belong to ferromagnetic/superparamagnetic FeOx for Fe/γ- Al2O3 (or

their modified by Zr forms) catalysts with effective g-factor g=2.14-3.65 and line width ΔH=110 -320 mT and paramagnetic carbon deposits with g=2.003 and ΔH= 0.5-0.7 mT. The formation of hydrocarbons is accompanied with the appearance of signals at g=2.14–2.15 and ΔH= 125–131 mT in the EMR spectra. The increase of the hydrocarbons (ethane as well as propene, propane, butenes and butanes) yields at the reaction temperatures of 553 and 573 K is accompanied by an increase of the EMR signals at g=2.14–2.15. The temperature dependence of EMR spectra of samples is investigated for catalysts with different contents active elements in the range 293-573K. It was established that the dependence of the intensity of the EMR signals on concentration of iron in samples at different temperatures of reaction is correlate with the yield of hydrocarbons. It was established that the catalytic activity of samples in ethanol to hydrocarbon conversion correlate with the concentration of magnetic particles. Active catalyst are characterized with the symmetrical ESR signal, due to super-paramagnetic particles of the size 15-20nm. The Scherrer formula was used to evaluate from diffractogram the grain size of identified phases of active elements for this catalyst (35-45 nm).

4 Conclusions

In situ EMR under flow conditions and on-line GC analysis of gas-phase products were successfully used to study the conversion of ethanol over Fe-Zr/γ-Al2O3 catalyst and constructed system can be enough effective for investigation of reaction ability, catalytic activity of magnetic particles for many other reactions.

The conversion of ethanol on Fe-Zr/γ-Al2O3 catalysts leads to formation of ethane, propane, butane, pentane, hexane – aliphatic hydrocarbons and benzene, toluene and xylene - aromatic hydrocarbons. The conversion of ethanol to aromatics increases as the Zr loading increases, which indicate that the active sites necessary for formation of aromatics is the Zr ion based structures, phases (ZrFeO3, ZrO2) in vicinity with γ-alumina acid sites that facilitate the formation of aromatic compounds. The detected ZrO2 and ZrFeO3 phases in the samples can catalyze secondary reaction of products formed initially by the acid sites of alumina. It is established that in the conversion of ethanol to hydrocarbons Zr active sites prefer the formation of aromatic compounds and FeOx species prefer the cracking reaction. At these sites, it is possible the activation and dimerization of the alkenes. The mechanism of reaction with participation of these structures and influence of Zr on the state of magnetic particles are discussed.

Keywords: nitrous oxide, ammonia, density functional theory, Pd(110), adsorption, reduction

1 Introduction

Nitrous oxide and ammonia are undesired byproducts in the catalytic reduction of NO with H_2 occurring in automotive catalytic converters. Because of the need to remove these agents, it is necessary to understand how they are formed and to know the positions of adsorbate atoms. Automotive three-way catalyst is based on Pt, Rh or Pd catalysts. The reconstructed Pd(110)-1×2 surface formed from very short close-packed terraces and edges is often used as a model for real palladium catalyst, which has rough irregular surface. Recently, several experimental studies dealing with angular distribution of desorbing products in NO reactions over palladium have been reported [1, 2]. Theoretical consideration of N_2O and NH_3 adsorbing states and direction of their vibrations promotes interpretation of the experimental data and is the required step for subsequent calculations of reaction paths for the reduction of NO over Pd(110).

In this contribution, we have performed density functional theory (DFT) calculations in order to determine the adsorption structures and stretching vibrations of the N_2O and NH_3 molecules on the Pd(110)-1×2 surface.

2 Methodology

First-principles calculations for the structure relaxations and calculations of vibration frequencies were performed using the generalized gradient approximation (GGA) of Perdew-Burke-Ernzerhof (PBE). The interactions between the ionic cores and the electrons are described by ultrasoft pseudopotentials. The simulations have been done using the PWSCF package [3].

The Pd(110)-1×2 surface was modelled by a seven-layer thick slab, and the N_2O or NH_3 molecule was adsorbed on one side of the slab. Each layer of the slab contains four atoms, except the topmost one containing two atoms. This corresponds to coverage of 0.25ML (using the symmetry of the unreconstructed surface).

3 Results and discussion

Our calculations show that adsorbed species are bound to the surface by terminal nitrogen atom of N_2O and nitrogen atom of NH_3. Four different adsorption configurations are found stable for the N_2O molecule. In the most stable configurations, the molecule is monocoordinated to a Pd atom of the topmost layer along the $[1\bar{1}0]$ and $[001]$ directions, respectively. Two two-fold bridge forms of adsorbed N_2O lying along the same directions are slightly less stable then monocoordinated on-top forms. Adsorbed NH_3 molecule occupies on-top sites over the ridge and over the side surface (facet on-top form) of Pd atomic rows (Fig.1). Small lengthening of the N-N bond and change of intermolecular vibration modes of the N_2O molecule indicate weakening of the N-N bond as a result of N_2O adsorption. A decrease in the frequency of the NH_3 symmetric deformation mode from that for free (1132 cm^{-1}) and little flattening of the molecule allow assuming a little weakening of N-H bonds of adsorbed NH_3.

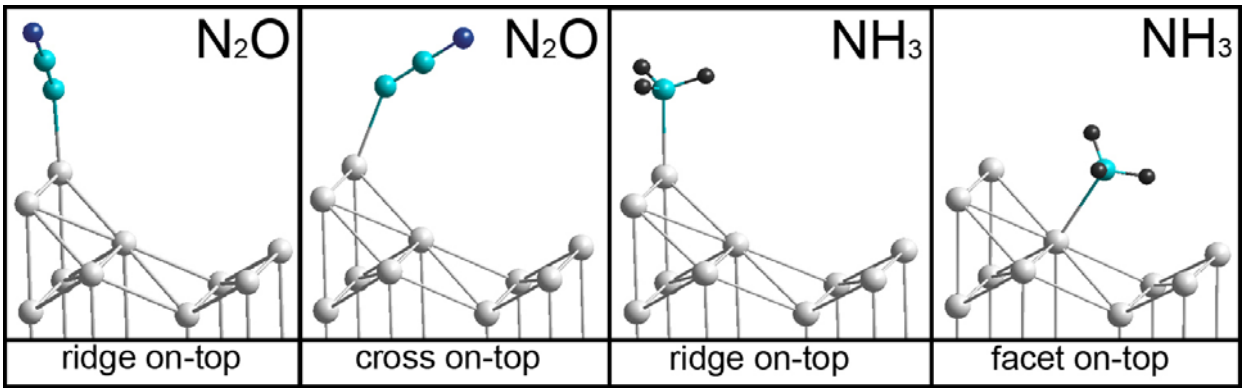

Fig. 1. Model of the most stable N_2O and NH_3 adsorption structures over Pd(110)-1×2 surface.

Table 1. Calculated energetic, structural and vibrational data of the isolated and adsorbed N_2O and NH_3.

E_b is the binding energy calculated as the total energy difference between the separated and combined systems. The $d_{Pd\text{-}N}$ label stands for the adsorbate-surface distance. The $d_{N\text{-}N}$, $d_{N\text{-}O}$, $d_{N\text{-}H}$, $d_{H\text{-}H}$, $\angle_{Pd\text{-}NN}$, $\angle_{NNO}$, $\angle_{HNH}$ labels stand for the distances and the angles between corresponding atoms. The ν_{int} and $\nu_{Pd\text{-}N_2O}$, $\nu_{Pd\text{-}NH_3}$ labels stand for intermolecular and adsorbate-surface vibrations.

4 Conclusions

DFT simulation predicts that N_2O binds weakly to the ridge of the Pd(110)-1×2 surface in two on-top an two bridge stable forms, NH_3 adsorption occurs in two on-top forms: on the ridge and on the rows' side surface of the Pd(110)-1×2. The geometry of N_2O and NH_3 is almost unchanged upon adsorption.

Keywords: supported, heteropolyacids, organic-inorganic, hybrid, acid catalysis, polyaromatic, coke

1 Introduction

Heteropolyacids (HPAs) are well defined molecular clusters possessing a very strong Brönsted acidity. Although widely used in acid catalysis, bulk HPAs have a low surface area (1 to 5 m^2/g) [1]. Supporting them on a suitable material allows a better dispersion and thus a better accessibility of their protons during catalytic reactions. Wet impregnation does not allow a precise control of the dispersion. It indeed often leads to crystalline HPA aggregates on the support's surface [1]. To address this problem, Raj *et al*. have investigated a novel strategy [2]: the hybridization of $H_3PW_{12}O_{40}$ (HPW12) with an organic surfactant (dimethyldioctadecyl ammonium bromide - DODA), and subsequent burning of the surfactant, allows obtaining highly isolated HPA entities on a HOPG surface. In our work, we have tried to apply this strategy to synthesize real HPW12/TiO_2 powder catalysts with high HPW12 dispersion. Herein, we demonstrate that the limiting factor therein is the formation of coke during the combustion of DODA, which induces a decrease of HPW12's catalytic activity.

2 Experimental/methodology

HPW12-DODA hybrids were prepared by mixing an ethanolic solution of HPW12 (0.5g HPW12/50mL) with an ethanolic solution of DODA (0.514g in 100 mL) for 2 hours at room temperature. HPW12-DODA/TiO_2 samples resulted from mixing a given volume (depending on the desired HPW12 loading on TiO_2) of the HPW12-DODA solution with a suspension of TiO_2 (2.5 g of P25 from Degussa - 50 m^2/g - in 100 mL ethanol) for 2 hours. The solid was recovered by rotary evaporation of ethanol (40°C, vacuum). Samples with different HPW12 loadings were prepared. The loading is expressed as a percentage of the amount of HPW12 that is required to form one complete monolayer on TiO_2 (%TM). DODA was eliminated by an exposure to UV-O_3 or by calcination under O_2 at 290, 350 or 450°C. Reference HPW12/TiO_2 catalysts were prepared with the same procedures but without DODA (classical wet impregnation). All samples were characterized by X-ray diffraction (XRD), NH_3 temperature programmed desorption (NH_3-TPD), FT-IR and Raman spectroscopies. Their catalytic activity was tested in the dehydration of methanol.

3 Results and discussion

XRD and NH_3-TPD show that non-hybridized HPW12 starts to form crystalline aggregates on TiO_2 at a loading of 63%TM. The latter is thus the minimum loading at which it makes sense to investigate the DODA-hybridization as a way to enhance the dispersion of HPW12. The HPW12-DODA/TiO_2 containing this HPW12 loading of 63%TM has first been subjected to various treatments in order to determine the most efficient way to eliminate the surfactant, and

so to finally isolate the HPW12 entities. According to FT-IR spectroscopy, DODA is destroyed by exposing the sample to UV-O_3 or by calcinating it for 2 hours under pure O_2 at 290 or 350°C. However, the Raman spectra after those treatments show the bands of polyaromatic coke at 1350-1600 cm^{-1} (see Fig. 1. A. for a typical spectrum). The latter hides the main peak of HPW12 at 1000 cm^{-1} and the signal of TiO_2 between 300 and 800 cm^{-1} visible on the spectrum of HPW12(63%TM)/TiO_2 prepared without DODA. Thus, although DODA has been destroyed as such, recalcitrant carbonaceous deposits are formed. This is likely due to the strong acidity of HPW12. The calcination under pure O_2 at 450°C is the only treatment leading to the complete elimination of this coke. As a counterpart, it induces the thermal decomposition of HPW12. Indeed, the FT-IR spectrum after such treatment does no longer show the fingerprint of HPW12. In the case of the three previously mentioned treatments (UV-O_3 and calcination under pure O_2 at 290 or 350°C), FT-IR spectra still show intact HPW12. The XRD patterns after those three non HPA destructive treatments do not show the diffraction peaks of HPW12 crystals, indicating that the dispersion of HPW12 has been enhanced via the DODA-hybridization. However, likely as a consequence of the formation of coke from the combustion of DODA, the catalytic methanol dehydration activity of the HPW12(63%TM)-DODA/TiO_2 sample after the various DODA-elimination procedures is always lower than the activity of the HPW12(63%TM)/TiO_2 reference sample prepared by classical wet impregnation without DODA (see Fig. 1. B.).

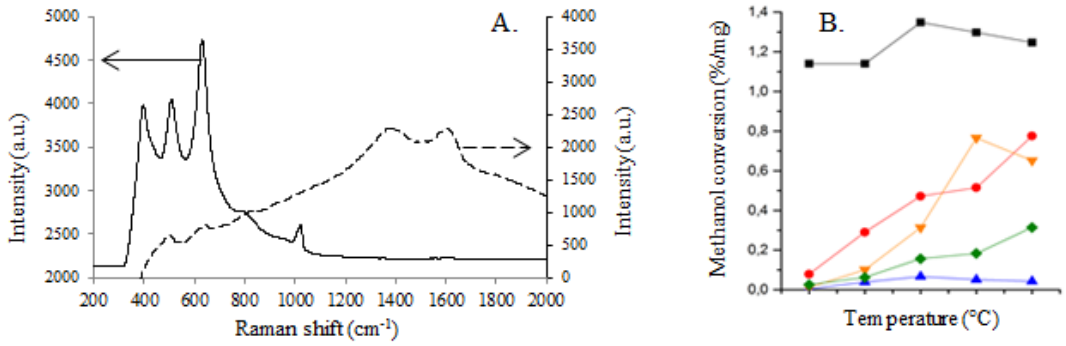

Fig. 1. (A) Raman spectra of HPW12(63%TM)/TiO_2 (–) and of HPW12(63%TM)-DODA/TiO_2 after DODA elimination trial under O_2 at 350°C (– –) / (B) Methanol conversion (%/mg catalyst) obtained with HPW12(63%TM)/TiO_2 reference catalyst (–▪–) and with HPW12(63%TM)-DODA/TiO_2 after DODA elimination trial under O_2 at 290°C (–•–), at 350°C (–▲–) and at 450°C (–▼–), and after the same treatment under O_2 at 290°C than previously followed by an exposure to UV/O_3 in addition (–◆–).

4 Conclusions

In agreement with the previous work of Raj *et al*. [2], hybridizing HPW12 with DODA prior to supporting it on TiO_2 leads to a better HPW12 dispersion. However, the aim of enhancing the dispersion, namely allowing a better accessibility of HPW12's acid sites to reactants, could not be achieved by such a DODA-based strategy. Indeed, on one hand, at HPW12-friendly temperatures, the complete elimination of DODA induces the formation of polyaromatic coke on HPW12. On the other hand, at temperatures which allow burning that coke, HPW12 is thermally decomposed and so loses acidity. Further improvements of the approach are currently under investigation.

Keywords: Cu-Mn spinel oxide, urea, combustion method, WGSR, doping effect

1 Introduction

The Water-Gas Shift Reaction (WGSR) is a well-established industrial process for hydrogen generation by conversion of CO in hydrogen-rich gas streams. The need of high-purity hydrogen for fuel cell applications stimulates a great activity in the design of novel, highly active and stable WGS catalysts. Copper is often used as an active component in low-temperature (LT) WGS catalysts. The problem with the tendency of Cu to deactivate could be tackled by development of new catalytic formulations. Recently, we have reported that the urea-nitrates combustion method is an attractive technique for preparation of Cu-Mn catalysts with favorable characteristics and catalytic properties for WGSR [1]. Catalytic measurements carried out under both idealized and realistic reformate feeds and comparison with the performance of commercial $CuO-ZnO-Al_2O_3$ catalyst demonstrated the superior performance of these catalysts. It was proposed that the catalysts' stability was related to the higher resistance of copper nanoparticles to sintering, which maintain their small size after WGS reaction. The aim of present work was to examine the effect of the nature of some doping oxides, namely, CeO_2, Fe_2O_3 and Al_2O_3 on the physicochemical properties and activity of Cu-Mn spinel oxides in the WGSR at low temperature.

2 Experimental/methodology

Doped Cu-Mn-M (M = Ce, Fe or Al) catalysts with Cu/(Cu+Mn+M) atomic ratio of 0.30 were prepared by single-step urea-combustion method. The selection of this atomic ratio was based on the results reported in a previous study [2]. The combustion synthesis involved autoignition of a mixed solution of urea with nitrates of copper, manganese and dopant (75% excess of urea) in an open muffle furnace (preheated at 400–500 ^oC) and further heating at 550 ^oC for 1 h. The catalysts were characterized by N_2 physisorption, XRD, H_2-TPR and XPS. The WGS activity was evaluated in a conventional flow reactor at space velocity of 4000 h^{-1} within a temperature range of 140–240 °C. The influence of reaction gas mixture, including idealized and realistic reformate, H_2O/CO ratio and contact time on the activity were also investigated.

3 Results and discussion

The temperature dependence of CO conversion over doped Cu-Mn oxide catalysts during LT WGSR with an idealized reformate feed is illustrated in Fig. 1. The catalytic activity of Cu-Mn oxide sample was improved in the presence of dopants. The following activity order was observed: $Cu_{0.30}Ce_{0.07}Mn_{0.63} \approx Cu_{0.30}Fe_{0.07}Mn_{0.63} > Cu_{0.30}Al_{0.07}Mn_{0.63} > Cu_{0.30}Mn_{0.70}$. The catalytic tests under a realistic reformate feed demonstrated better performance of the Fe-doped

Cu-Mn catalyst at 240 °C, whereas at lower temperature (220 °C) $Cu_{0.30}Al_{0.07}Mn_{0.63}$ exhibited slightly higher activity. The effect of space velocity on CO conversion was studied at 180 °C. The increase of water partial pressure (from 5 to 10 kPa) caused an increase of CO conversion over all catalysts and this effect was more pronounced over doped by Ce and Fe samples. It was observed that all doped catalysts exhibited good tolerance towards a high concentration of water. It is known that high H_2O/CO ratios are typical under fuel processor conditions for low-temperature shift reactors and the resistance to the presence of a high amount of steam could be considered as an important feature.

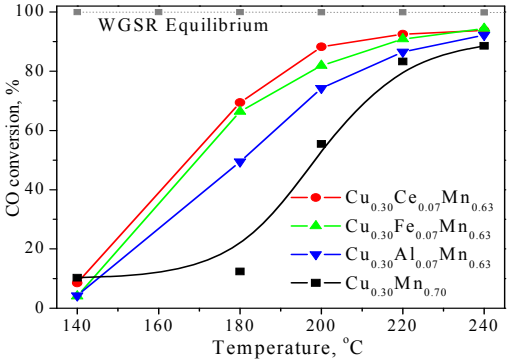

Fig. 1. Temperature dependence of CO conversion over doped Cu-Mn oxide catalysts

The measurements of BET surface area showed more significant increase of specific surface area of Fe and Al-doped samples and slight increase in the case of Ce-doped sample in comparison with undoped Cu-Mn catalyst. XRD patterns of fresh catalysts correspond to the spinel phase $Cu_{1.5}Mn_{1.5}O_4$ and Mn_3O_4/ Mn_2O_3. No detectable diffractions of third metal (except reflections of CeO_2) can be distinguished in doped catalysts most probably due to fine dispersion or/and incorporation of some amount in the spinel oxide structure. The analysis of XP spectra indicated that Mn(III), Mn(IV), Cu(II) and Cu(I) species were simultaneously present in the fresh, oxidized samples. Doping metals were presented in the Cu-Mn samples in a fully oxidized state, i.e. Ce^{4+}, Al^{3+} and Fe^{3+}. An enrichment of the surface with dopant species was also observed. The reduction profile of Cu–Mn catalyst was characterized by a broad peak centered at about 400 °C with shoulder at higher temperature side. The addition of dopants shifted the T_{max} of the peaks to lower temperature and altered their shape. Well visible shoulder was registered at lower temperature side. It was ascribed to reduction of highly dispersed copper oxide particles.

XRD and XPS measurements of the samples after catalytic tests are in progress in order to gain new insight on the effect of different dopants on WGS activity.

4 Conclusions

It was found that doping of Cu-Mn spinel oxide catalysts prepared by combustion method could be an efficient approach for design of novel, highly active and stable WGS catalysts.

Keywords: methyl lactate dehydration, acrylic acid, calcium-phosphate-silica, catalysts, structure

1 Introduction

Development of the production of multifunctional organic acids in low-cost, high-efficiency fermentation processes makes available a new route to chemical production from biomass. Lactic acid is approaching large-scale production via fermentation and show particularly excellent promise as feedstocks for catalytic conversion routes such as hydrogenation, dehydration, or condensation (Figure 1).

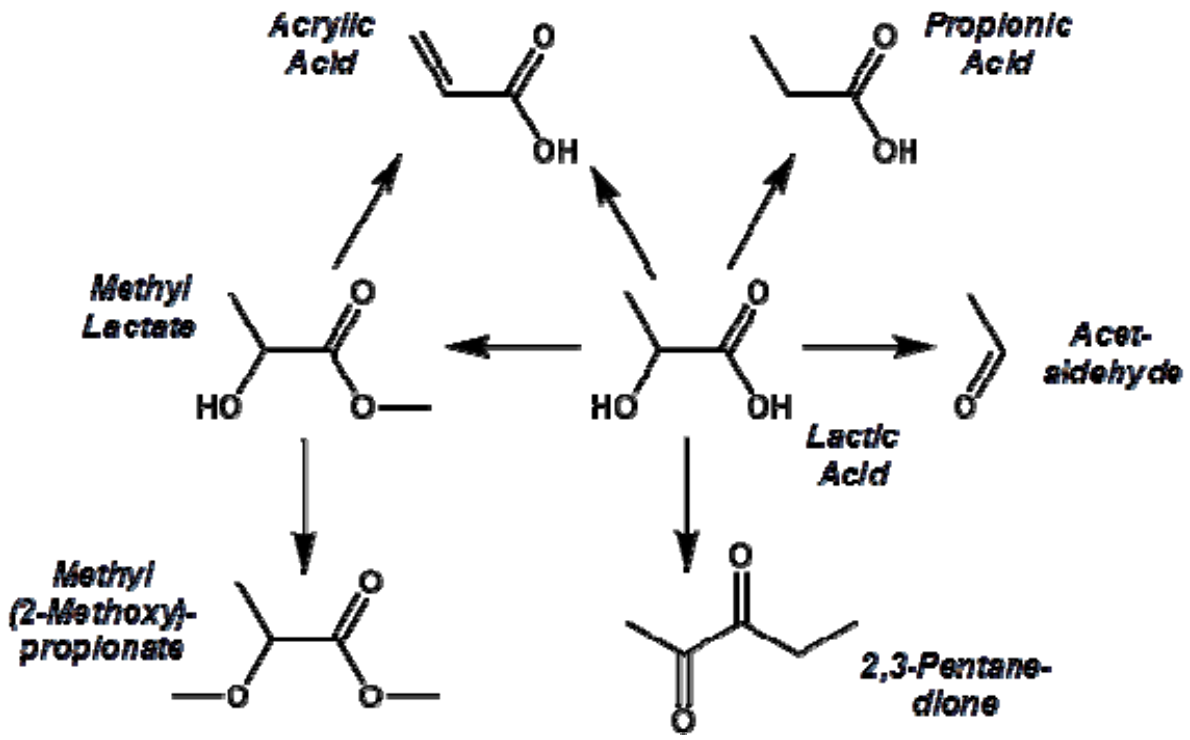

Fig. 1. Possible scheme for chemicals based on lactate feedctocks.

In particular, it looks attractive at least partial redirecting of producing conventional petrochemicals such as acrylate monomers to renewable feedstocks. A bottle neck for implementing this technology is the development of effective catalysts of lactate materials dehydration. This study investigated methyl lactate dehydration over various calcium-phosphate-silica catalysts under various conditions [1].

2 Experimental

Sampling procedures

Catalysts $Ca_3(PO_4)_2/SiO_2$, $CaHPO_4/SiO_2$, $Ca(H_2PO_4)_2/SiO_2$ и $Ca_2P_2O_7/SiO_2$ with different

ratio of corresponding calcium phosphate component vs silica (from 90/10 to 60/40 wt.%) was prepared by precipitation method followed by water rinsing to remove soluble impuritgies. Samples obtained was dried at 120°C and then calcined at 480°C in air.

Characterization and evaluation methods

Catalysts obtained were characterized by XRD and FTIR methods and the specific surface areas and pore volumes of catalysts were measured.

The dehydration of methyl lactate over the catalysts was carried out in a fixed-bed quartz reactor operated at 350-420°C and atmospheric pressure. The feedstock (20–50 wt.% aqueous solutions of methyl lactate) was pumped into the preheating zone of reactor and driven through the catalyst bed by nitrogen. Regulating the nitrogen flow rate it was maintained hold-up time 0.5-1 s.

Analysis of the products was carried out by GC and GC-MS methods.

3 Results

The data of experiments on dehydration of methyl lactate showed that, regardless of the structure of calcium phosphate component, the highest efficiency is typical for samples with ratio 'Ca-PO_x/SiO_2' = 80/20 wt.%. The methyl lactate conversion over the catalyst $Ca_2P_2O_7/SiO_2$ (80/20%масс.) at 390°C, methyl lactate content in feedstock 20 wt.% and hold-up time 1 c was 74,7% and acrylates selectivity was 48,8%.

Side reactions of condensation and polymerization lead to coke deposition, resulting in catalyst deactivation. Complete catalyst regeneration and activity recovery is achieved by calcination it in air at 480°C.

From XRD and FTIR data was found that freshly prepared catalysts based on calcium hydrophosphates decomposed during calcination to form ultimately pyrophosphate structure. During the regeneration of these catalysts as well as $Ca_2P_2O_7/SiO_2$ pyrophosphate structure is preserved.

4 Conclusions

We investigated methyl lactate dehydration to acrylates over calcium-phosphate-silica catalysts. Catalysts with ratio 'Ca-PO_x/SiO_2' = 80/20 wt.% exhibited highest efficiency.

Catalysts on base of hydrophosphate precursors passed into pyrophosphate form under preparing and perfomance conditions.

Deactivated catalysts was completely restored its activity by calcining in circulating air at 480°C.

Synthesis of Zr-BEC Zeolite Catalyst with Strong Lewis Acidity

Kots P.A.[1], Sushkevich V.L.[1], Tyablikov O.A.[1], Ivanova I.I.[1,2*]

Keywords: polymorph, degermanation, BEC, germanosilicate, Zr-Beta, Lewis acidity, FTIR, CO

1 Introduction

In past decade, use of germanium as a silicon substituent in zeolite synthesis led to a discovery of new large-pore molecular sieves structures. One of them is the polymorph C of zeolite Beta (BEC), which was synthesized for the first time by Corma et al [1]. But unfortunately, the use of such materials is strongly limited due to their low catalytic activity and poor thermal stability, because of strong tendency of Ge-O-Si bonds to hydrolyze. This drawbacks can be overcome by the replacement of Ge atoms in the framework with other atoms [2]. This contribution is aimed to elaborate post-synthetic method to incorporate Zr in framework of BEC. Zirconium-containing Beta zeolite is a perspective material possessing unique water-tolerant Lewis acidity associated with Zr atoms in framework position.

2 Experimental

BEC-type germanosilicate synthesis was performed according to previously reported procedure [3]. Stabilization of as-made BEC materials with TEOS was based on the procedure proposed by Wu et al. [4]. Stabilized materials were treated with $ZrOCl_2$ in aqueous or DMSO solutions of HCl.

3 Results and discussion

Fig. 1a shows XRD pattern of as-made BEC germanosilicate. Material obtained is highly crystalline and no impurities were detected by XRD. Based on results of Tuel et al. [5] as-made BEC could be easily degermanated under acidic pH at 70°C. But, direct treatment in the presence of $ZrOCl_2$ leads to complete amorphization (Fig. c). Treatment with $ZrOCl_2$ in DMSO also leads to significant decrease in crystallinity, but not as prominent as in the case of water. According to XRF analysis, presented in Table 1, water-treated sample losses approx. 65% GeO_2. Thus, amorphization may be coupled with germanium extraction from the framework.

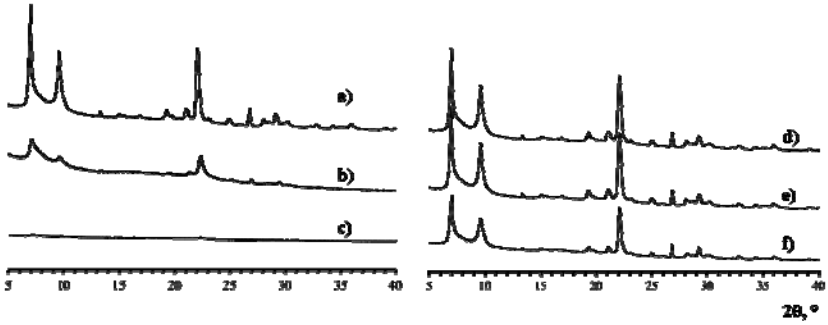

Fig. 1. XRD patterns of as-made BEC-type germanosilicate (a), after treatment with $ZrOCl_2$/HCl at 70°C for 12h in DMSO (b) and in water (c), after stabilization at 170°C with TEOS (d), subsequently treatment in $ZrOCl_2$/DMSO/HCl at 70°C for 12 h (e), after subsequent calcination in air at 550°C for 6 h (f).

Because the direct treatment was the recently established by Wu et al. stabilization procedure was chosen. XRD pattern of stabilized BEC-Si (Fig. 1d) indicate the preservation of

original crystallinity (Table 1). Stabilized samples were treated with $ZrOCl_2$ in DMSO under acidic pH and material obtained showed high crystallinity (Fig. 1e and Table 1).

Table 1. XRF data and crystallinity analysis.

Sample	Si/Ge	(Si+Ge)/Zr	cryst., %
as-made BEC	2.4	-	100
$ZrOCl_2$/water/HCl	11.5	22	20
$ZrOCl_2$/DMSO/HCl	4.9	97	50
TEOS	3.5	-	80
TEOS+$ZrOCl_2$/DMSO/HCl	4.5	55	75

As shown in Table 1 the elaborated synthetic procedure leads to highly crystalline material with high amounts of Zr ($^{Si+Ge}/_{Zr}$ =55). Changes in local structure of Si were examined via ^{29}Si solid-state NMR spectroscopy confirms the formation of Si(3Si,1Zr) domains. Lewis acidic properties of calcined Zr-BEC were examined with FTIR of adsorbed CO and acetonitrile-d_3. FTIR spectra of adsorbed CO indicates high content of strong Lewis acid sites associated with Zr^{4+} cations (band at ca. 2196 cm^{-1}) in the sample obtained. The comparison of the results obtained over novel Zr-BEC catalyst with traditional Zr-BEA samples points, that the procedure elaborated allows for much higher degrees of Zr incorporation.

4 Conclusions

The post-synthetic procedure for incorporation of Zr-heteroatom in germanosilicate with BEC structure was developed for the fist time. The procedure involves: 1) stabilization of the parent structure via solvotermal treatment with TEOS; 2) incorporation of Zr in 0.01M HCl solution in DMSO. The data obtained clearly show, that Zr-BEC in highly crystalline, thermally stable material with strong Lewis acidity. Comparing with conventional Zr-BEA sample, our Zr-BEC posses higher density of Lewis acid sites.

Bimetallic Copper Catalysts Supported on Activated Carbon Fibers for Ethanol Dehydrogenation

Ponomareva E.A.*, Tolulope O., Parastaev A.S., Egorova E.V.

Lomonosow Moscow University of Fine Chemical Technology, Moscow, Russia

* katerinaii@inbox.ru

Keywords: ethanol dehydrogenation, activated carbon, fibers, copper catalyst

1 Introduction

Copper is a well-known catalyst for the ethanol dehydrogenation reaction. However, its utility is often limited by rapid loss of activity. One of the probable reasons for deactivation of copper catalyst is sintering due to the inherently low melting point of bulk copper. Thus, instead of bulk copper, the supported copper catalyst has become prevalent in practice. Earlier it was shown that activated carbon fiber (ACF) is suitable for the role of a carrier and 5%Cu/ACF was proved to be more active compared with other copper catalysts supported on carbon materials [1]. ACF, consisting of arranged microfilaments, represents a valuable alternative to randomly packed beds of granulated carbons. It has important advantages due to a high specific surface area, low pressure drop and suppressed mass transfer limitations.

Introduction of an additional compound into copper based on carbon catalysts could bring to its higher stability. Different oxides were used for this purpose and Cr2O3 is one of the most prevalent. Moreover, some extra effects can appear. For example, Cu-ZrO2 system was proved to be selective for ethylacetate formation [2], while copper supported catalyst mainly generates acetaldehyde. In this work, activities of Cr-Cu/ACF and Zr-Cu/ACF catalysts for ethanol dehydrogenation were studied.

2 Experimental

Commercial activated carbon cloth ACF (AW1101, KoTHmex Taiwan Carbon Technology CO) was used as a support. SSABET of the carrier (measured by N2 adsorption–desorption at −196 ˚C via ASAP 2020, Micromeretics) was ~ 1050 m2/g. The catalysts were prepared by wetness impregnation with water solution of appropriate salt with following drying at 100 ˚C for 1 h. Cu(NO3)2·3H2O, Cr(NO3)3·9H2O, ZrCl4 were used as metal precursors. The loading of every metal was 5 wt%. When bimetallic catalyst prepared two technics were tested – co-impregnation and consequent impregnation. The second technic included calcination of a sample at 300 ˚C for two hours before the impregnation with copper salt water solution.

The ethanol conversion experiments were carried out at atmosphere pressure using a conventional quartz reactor. 0,5 ml of a sample was used in every test. Liquid flow rate of ethanol (93 wt%,) was 32 h-1. Received products were analyzed by gas chromatography. Prior to the reaction, every sample was calcined in situ in a stream of argon and then reduced in a stream of hydrogen.

The catalysts were characterized with help of scanning electron microscope TescanMira LMU equipped with a secondary electron detector and X-Max EDS detector. XRD analysis was carried out as well.

3 Results and discussion

Zirconium and chromium presented in the form of their oxides (ZrO2 and Cr2O3 respectively) created some areas of films on the surface of ACF, which were also observed in bimetallic systems. Without copper both components were proved to be almost inactive in the

process studied. Conversion of ethanol didn't exceed 2 %.

Activities of bimetallic catalyst compared with copper supported catalyst are represented on figure 1. It is shown that addition of Zr leads to remarkable decrease in conversion. However the maximum of conversion was observed at 375 ˚C while over the other catalysts it was reached at 350 ˚C. Such small activity of Cu-Zr/ACF catalyst can be explained by bad distribution of copper particles (fig. 2a) as well as binding of the active component (Cu) with zirconium oxide.

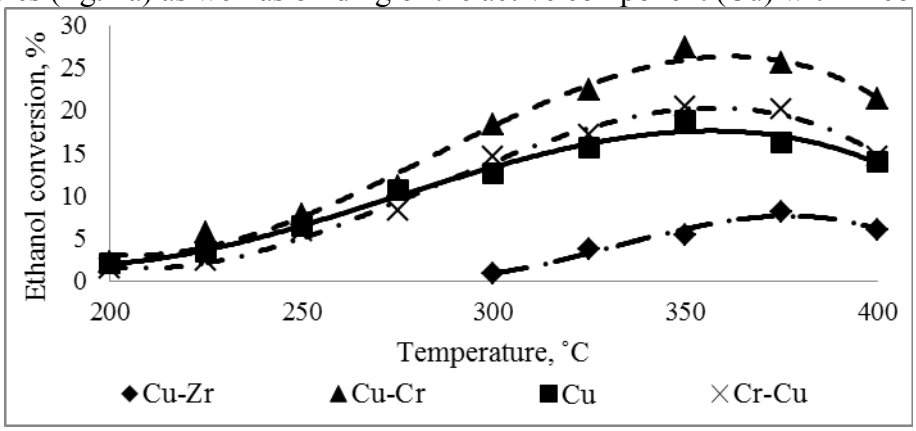

Fig. 1. Ethanol conversion over copper containing catalysts

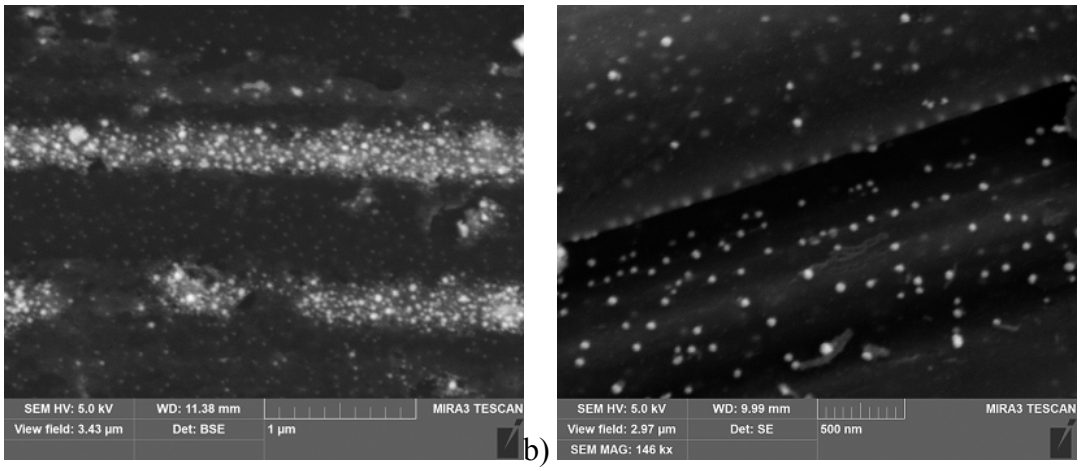

a) b)

Fig. 2. SEM images of Cu-Zr /ACF (a) Cr-Cu/ACF (b) catalysts

Cr-Cu/ACF catalyst, prepared by consequent impregnation technic (fig. 2b) shows better distribution of Cu particles, that is similar to Cu/ACF catalyst [1]. Hence Cu-Cr/ACF, prepared by co-precipitation, was more active (fig.1). Test for stability for both copper-chromium system showed an improvement compared to copper supported catalyst.

4 Conclusions

It was shown that addition of Zr to copper supported on activated carbon fibres decreases the activity of catalytic system, while addition of Cr has positive impact. Moreover, the way of preparation of a sample has an influence.

Keywords: methane activation, MnNaW/SiO_2, quantum-chemical, modeling

1 Introduction

The oxidative coupling of methane (OCM) is a promising process for direct production of ethane and ethylene. The MnNaW/SiO_2 is one of suitable OCM catalysts that show both high product yield and long-term stability. The complex reaction mechanism of OCM and multicomponent composition of MnNaW/SiO_2 catalyst complicate the elucidation of the role of different components of this catalyst. The surface cluster species WO_4 with one W=O and three W-O-Si bonds was one of the first model of the active site suggested for this reaction [1, 2]. The Mn_2O_3 species were proposed to act as the active sites responsible for the methane activation, while Na^+ and oxo anion (WO_4^{2-}, MoO_4^{2-}, SO_4^{2-}, PO_4^{3-}or $P_2O_7^{4-}$) affect the formation of the specified Mn species [3]. A modified mechanism based on two metal (W-Mn) site has been presented: activation of CH_4 is suggested to take place on W^{6+} sites while the activation of O_2 - on the Mn^{3+} sites [4]. Both Na-O-Mn and Na-O-W species were identified as active sites of the catalysts for OCM [5]. Thus, the structure of the active center for the OCM reaction is still a matter of discussion. In the present study quantum-chemical modeling of the active center of MnNaW/SiO_2catalyst were performed. To clarify the OCM mechanism the following tasks were considered: (i) optimization of structure for possible W and Mn oxide species on the surface of α-cristobalite; (ii) determination of barrier energy for the abstraction of hydrogen from methane at isolated and supported W(+6) and W(+4) species; (iii) optimization of structure for possible polynuclear W and Mn species on the surface of α-cristobalite.

2 Experimental

All calculations have been performed at the B3LYP level using the LANL2TZ(F) and 6-311G** basis sets for tungsten and lighter atoms, respectively.

3 Results and discussion

The models for active sites for the MnNaW/SiO_2 catalyst have been considered assuming (1) α-cristobalite form of the SiO_2 oxide and (2) five-coordinated W(+6) complex having single terminal W=O group bonded to the α-cristobalite (111) surface through bridged oxygen centers (≡WO(OH)). It was shown that various tungsten species (=$WO(OH)_2$,-$WO(OH)_3$,$WO(OH)_4$) on the SiO_2 surface relatively easily transform to each other due to hydrolysis of the W-O-Si bonds by water molecules. According to the energy diagram for described hydrolysis process the most stable structures are the water-coordinated tungsten species attached to the surface via one or two oxygen centers of support while adsorbed at the cristobalite surface $WO(OH)_4$ complex appears to be quite labile to migration and can achieve easily the other tungsten oxide species or manganese oxide to form a dimer.

The first step of the oxidative coupling of methane is the hydrogen abstraction.

Corresponding C-H bond cleavage includes two quite different routes - heterolytic and homolytic – which determine all further reaction steps. The abstraction of hydrogen from methane at isolated $WO(OH)_4$ to form $W(OH)_5$ is predicted to require quite high energy of about 70 kcal/mol. Surprisingly, the heterolytic dissociation at this model goes through a barrier of about 49 kcal/mol. Taking into account that the hydrogen abstraction by $WO(OH)_4$ complex requires about 50-70 kcal/mol it is concluded that oxo-center should be somehow activated to facilitate the reaction.

It is found that oxygen vacancy formation followed by W(+6)-to-W(+5) or or W(+6)-to-W(+4) reduction substantially decreases the energy required to dissociate methane at tungsten complex. The lower barrier of about 37 kcal/mol takes place for supported four-coordinated W(+4) complex without topmost oxygen ligand. The final state for this process is a six-coordinated tungsten complex having both the hydrogen and the methyl group. Homolytic methane dissociation at this center goes over a higher barrier of about 52 kcal/mol.

The activation of $WO(OH)_4$ complex through creation of the oxo-center of radical character has been considered. This is achieved by charging the $WO(OH)_4$ complex. It was found that crucial drop of CH_4 dissociation barrier to about 5 kcal/mol takes place for charged model complex $WO(OH)_4^+$, for which the terminal oxo-center (which abstracts hydrogen from C-H bond) possesses radical character as one may judge from oxygen Mulliken spin density of about 0.88 e.

To find less energetically demanding scenario of the C-H bond dissociation for OCM the investigation of polynuclear tungsten-containing complexes on the silica support has been performed. It is shown that there is a multiplicity of tungsten W-Mn polynuclear complexes (from dimer to tetramer) between two neighboring “nests” on cristobalite. Stable Mn(+5) and Mn(+3) species are predicted, coupled to support by three bridge oxygen in the neighborhood of the W(+6) complex. The Mn(+5) complex contains terminal atomic oxygen ligand with distinct radical character in the state with the spin projection of 1. It is supposed that the latter center should be as active in the C-H activation as the radical oxo-center of $WO(OH)_4^+$ complex.

4 Conclusions

The optimization of mono- and polynuclear W and Mn species on the surface of α-cristobalite has been performed and values of barrier energy for the abstraction of hydrogen from methane were determined. The barriers of the methane dissociation at oxo-centers provided by the W(+4) and W(+6) species on α-cristobalite appear to be as high as 40-70 kcal/mol. All the oxygen centers in these systems are of closed-shell configuration. Heterolytic mechanism is preferable over homolytic for such centers. Situation is qualitatively changed when oxygen center possesses radical character. The barrier of C-H activation drops to about 5 kcal/mol for $WO(OH)_4^+$ model center. Based on this result one may guess that the true OCM active center is that associated with Mn (+5) complex having terminal oxygen ligand with a radical character.

The Investigation of Structure of Biocatalyst Used in the Vegetable Oils Transesterification

Doluda V.*, Sulman E., Matveeva V., Lakina N., Burmatova O., Stepacheva A.A.

Tver Technical University, Tver, Russia

* doludav@yandex.ru

Keywords: biodiesel, magnetic, nanoparticles, lipase, FTIR, spectroscopy

1 Introduction

Last years the attention of the scientific society is forwarded to the methods of ecological fuels production. One of these types of fuels is biodiesel which is presented by fatty acids esters. The biodiesel is produced by the transesterification reaction of oils in the presence of catalyst. The most prospective catalysts are the biocatalysts on the base of hydrolytic enzyme lipase immobilized on the modified surface of magnetic nanoparticles (MNPs).

The use of MNPs as the enzyme support gives some advantages as easy biocatalyst separation from reaction media (due to magnetic properties) and simplicity of modification [1].

In this work the biocatalysts on the base of lipase immobilized on the surface of MNPs modified by sodium citrate and aminopropyltrietoxysilane were synthesized. Moreover the comparative characterization of the synthesized biocatalysts was done using FTIR spectroscopy.

2 Experimental

In this work the MNPs were used as the enzyme support. MNPs were prepared as follows. 5.2 g $FeCl_3 \cdot 6H_2O$ and 8.8 g $FeSO_4 \cdot 7H_2O$ were dissolved in 25 mL of azoted water. This mixture was drop-wise added to 250 mL of NaOH 1.5 M. The particles obtained were washed by distilled water to pH=7, than the 98% ethanol was added while the solution volume reached to 50 mL. The mixture was treated with ultrasound 10 min [1]. The synthesized nanoparticles were dried in the vacuum.

The pancreatic lipase (L3126 Type II, 100-400 un/mg) immobilization was carried out by two ways: (i) the pretreatment of 0.1 f of MNPs with sodium citrate ($Na_3C_6H_5O_7$) 0.1 mg/mL, glutaric dialdehyde (Glu) 0.01 mg/mL and lipase (Lip) 0.005 mg/mL, (ii) the treatment of MNPs with (3-aminopropyl)trietoxysilane (APTS) 0.005 mg/mL, glutaric dialdehyde 0.01 mg/mL and lipase 0.005 mg/mL.

The activity of the immobilized lipase was determined using the modified method of Ota-Yamada [2]. The investigation of the biocatalysts structure was done using FTIR spectrophotometer IR Prestige 21 equipped with direct reflection device which allows analyzing of impure samples in the spectral range 7800-350 cm^{-1} with high accuracy.

3 Results and discussion

The comparative analysis (Fig.1) of results obtained in the experiments carried out at atmospheric pressure and in the supercritical CO_2 media showed that the activity of native lipase decreased by 1.4 times, the activity of biocatalysts Fe_3O_4/APTS/Glu/Lip and $Fe_3O_4/Na_3C_6H_5O$/Lip by 1.2 and 1.3 times relatively. So it can be concluded that in the media of supercritical CO_2 the synthesized biocatalysts reserve their catalytic activity for a longer time and have better stability in comparison with atmospheric pressure.

To investigate the structure of biocatalysts samples the FTIR analysis was done. The results show the presence of covalent bonds between the functional groups of modifying agents and lipase (Fig.1).

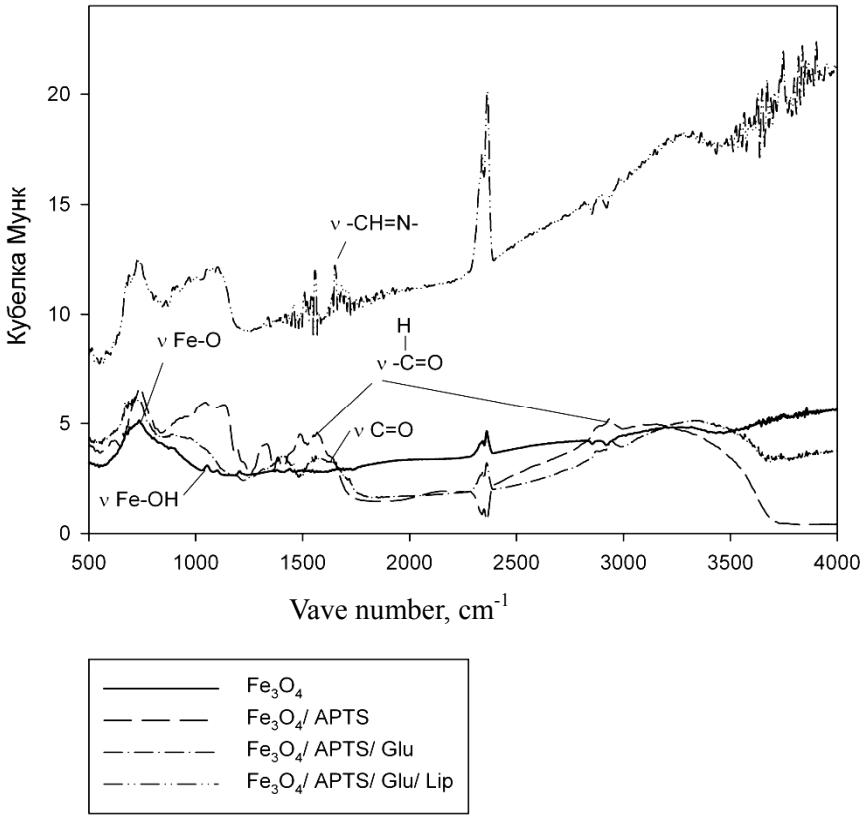

Fig.1. IR-spectra of biocatalysts samples, modified by APTS

4 Conclusions

The data obtained in the work devoted to the formation of active and stable biocatalysts used in the vegetable oils transesterification reaction shows the great prospective. The pancreatic lipase immobilization on the modified surface of MNPs passes through the covalent bonds that provides high stability of biocatalysts in supercritical CO_2 media.

Keywords: ceramic, catalysts, alumina, surface, area, wash-coating

1 Introduction

Highly porous cellular catalysts are a specific class of porous materials which consist of large cells with linear dimensions from5 mm to 10 mm and have geometry approximately corresponding to a cuboctahedron.

Highly porous ceramic structures can be produced in various forms from a variety of materials and exhibit such qualities as high porosity and good interconnectivity. Due to their specific geometry and other properties these materials can be used in a wide range of engineering problems [1].

2 Experimental

In this paper, method of polyurethane matrix replication was used for the production of highly porous cellular material. The technology involves thermal decomposition of polyurethane foam structure after its soaking in ceramic slurry. Polyurethanesample of predetermined shape is first processed by the slurry. The slurry contains alumina as filler, with addition of components imparting compressive strength, acid and alkali resistance, defoamers and other additives (2%).

Particular attention in this study is paid to increasing the surface area of the obtained samples. Ceramic carrier created by replication method from the α-alumina is processed in slurry containing γ-alumina as filler. The alternative can be precipitation of extra amount of γ-alumina from hot solution of aluminum nitrateon samples.

Presently, extensive research of samples' surface area is carried out. The obtained data confirm the absence of micro- and mesopores in samples produced from α-alumina. The data also indicate that mesopores occur after applying γ-alumina (applying methods specified above).Surface area significantly increases if a combination of methods is applied.

The next step is to apply a catalytically active component (Platinum).On this stage of the studies measurements of catalytic activity were carried out; the example can be the reaction of separation of optical isomers obtained in the ethylbenzeneformate racemisation reaction. Strength and macroporosity of the catalyst system were studied as well [2].

3 Results and discussion

By varying the composition of slurry a new catalytic system with extended surface area can be obtained. Development of optimum sintering temperature mode allows to avoid catalyst structure destruction.

One sample having platinum on the foam support is shown in Figure 1.

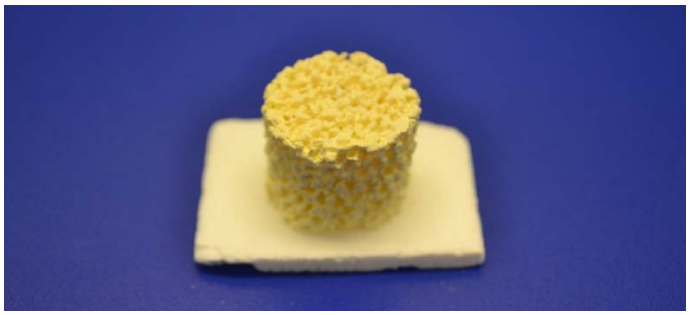

Figure 1. Alumina foam with catalytically active platinum layer at the surface

4 Conclusions

The advantages of porous catalysts are large surface area and high permeability for gas and liquid flow, which results in high rates of mass and heat transfer. This allows to produce catalyst systems of small volume.

Keywords: Pd-Au catalysts, *in-situ* XPS, CO oxidation

1 Introduction

Bimetallic systems attract the great interest of many scientific groups due to its ability to induce the significant improvement of catalytic properties compared to monometallic catalysts [1-2]. Among these systems the Pd-Au catalysts is one of the most frequently studied ones because they have exhibited high catalytic activity in a number of industrially important reactions. Although a large number of publications devoted to study of bimetallic Pd-Au systems has been published in recent years, the reasons of synergistic effects in different catalytic reactions have not be rationalized.

One of the most evident proposals, which have been supported by many researchers, is the key role of surface composition of bimetallic particles. It is well known that not only the ratio of the introduced metals, but also temperature of calcination will affect the surface composition causing the big difference between Au/Pd atomic ratios in the bulk and surface [1-2]. It is also evident that surface composition can be varied under the influence of reaction mixture due to enrichment of the surface with one of the metals. Thus the detailed study of surface structure and composition of bimetallic Pd-Au catalysts is necessary to understand the nature of active sites and help to optimize the catalyst composition for the best activity, selectivity and stability.

Success in such a study is impossible without development of procedures for synthesis of bimetallic Pd-Au catalysts with controlled particle size and Au:Pd ratio. Furthermore, low loading of the active component (< 1-2wt. %) and complex composition of the high surface area supports of a noble metal on high surface area supports in “real” supported catalysts limits the application of surface sensitive techniques. Using of model catalysts, where metal particles deposited on the planar support, could help to solve those problems and get more reliable data concerning surface structure and chemical composition of active metals depending on different treatments [3-4].

2 Experimental/methodology

XPS/STM study of the formation of Pd-Au bimetallic particles with controlled size and Au:Pd atomic ratio supported on Highly Oriented Pyrolytic Graphite (HOPG). This investigation was performed at RGBL station at the Berlin synchrotron radiation source BESSY II [5]. Then, the prepared Pd-Au/HOPG bimetallic catalysts were investigated in CO oxidation with combination of *in-situ* XPS and MS at ISISS beamline (Berlin, Germany) located also at BESSY II [6].

3 Results and discussion

Pd-Au bimetallic particles formation

Initially the set of samples with different size of gold particles supported on the HOPG surface were prepared using original three-step procedure developed by us for preparation if the Ag/HOPG model catalysts preparation [**7**]. All prepared Au/HOPG samples were characterized by STM and XPS. STM indicates that all samples are characterized by quite narrow particle size distribution (PSD) with the mean particle size of 4-7 nm depending on the sample. Then the Au/HOPG samples were used as templates for preparation of Pd/Au/HOPG bimetallic samples. The Pd amount was varied by variation of deposition time. The XPS and STM investigation shows that using this procedure a set of bimetallic Pd/Au/HOPG samples with various particle density, size distribution and Pd/Au atomic ratio were prepared. Two types of particles on the surface of HOPG in those freshly prepared samples were identified: "core-shell" bimetallic Pd/Au particles and monometallic Pd particles with smaller size.

XPS study of subsequent annealing of the samples in UHV conditions at different temperatures (from RT to 500°C) indicates that "core-shell" Pd/Au particles transform to the Pd-Au alloy ones during heating from 200 to 400°C. Annealing at 500°C sinters the particles.

CO oxidation

It was shown that the prepared Pd-Au/HOPG samples started to be active in CO oxidation reaction at 100°C. The redistribution of Au and Pd atomic concentration on the surface in the course of the reaction was investigated using *in-situ* XPS. It has been shown that the Au/Pd atomic ratio enhances when the sample is active in CO oxidation.

4 Conclusions

Formation of the model bimetallic Pd-Au/HOPG catalysts has been investigated with XPS and STM. The optimal temperature for the Pd-Au alloy formation is 400°C. Variation of Au/Pd atomic ratio on the particle surface is regulated by variation of the amount of deposited Pd and the temperature of annealing. Samples prepared using the proposed procedure is stable against sintering until 500°C.

The prepared Pd-Au/HOPG samples are active in CO oxidation reaction. The Au/Pd atomic ratio varies together with activity in CO oxidation.

Keywords: manganese oxide, zirconium oxide, solid, solution, *in situ* XRD, *in situ* XPS, reduction

1 Introduction

ZrO_2 is used as a support with high thermal resistance. Moreover, solid solutions based on ZrO_2 exhibit high catalytic activity in a number of practically important reactions. Mn-Zn mixed oxides can effectively catalyze the gas-phase oxidation of hydrocarbons or chlorcarbons. Although there is agreement that the catalytic activity of these catalysts is determined by their redox properties, the exact mechanism of these oxidation reactions is not clear yet. Mn cations can enter the lattice of ZrO_2 with the formation of solid solutions $Zr_{1-y}Mn_yO_2$, in which lattice oxygen possesses sufficiently high mobility and hence high reactivity. On the other hand, some authors suppose that the active species in oxidation reactions is mobile oxygen that is incorporated in disperse MnO_x rather than lattice oxygen of the solid solution

One of the main ways to study redox properties of catalysts is the method of temperature-programmed reduction (TPR). On the basis of its results, it is possible, to draw some conclusions about the presence in the catalysts of various forms of manganese oxides MnO_x. However, the TPR technique is an indirect method that allows monitoring only the absorption of hydrogen rather than the change in structural characteristics of catalysts or in the charge state of Mn and Zr. The aim of this work was to investigate the reduction of Mn-Zn mixed oxides by hydrogen in a wide temperature range in order to elucidate the origin of active species that catalyze the oxidation of hydrocarbons and chlorcarbons.

2 Experimental/methodology

A series of catalysts based on mixed Mn-Zr oxides with different molar ratios Mn/Zr have been prepared by coprecipitation of manganese and zirconium nitrates, calcined at 650 ^oC for 4 h.

TPR-H_2 was performed in a quartz reactor using a flow setup with a thermal conductivity detector. The flow rate of 10 vol % of H_2 in Ar was 40 mL/min. The heating rate was 10 °C/min.

Catalysts were characterized by a powder XRD technique using a D8 Advance diffractometer (Bruker). The reduction of the catalysts was studied in situ using synchrotron radiation at the Siberian Synchrotron and Terahertz Radiation Center (Novosibirsk, Russia). The in situ diffractometer was equipped with a high-temperature reactor chamber XRK-900 (Anton Paar) The heating rate was 5 °C/min; the total flow rate (H_2) was 150 mL/min.

In situ XPS experiments were performed at the ISISS (Innovative Station for In Situ Spectroscopy) beamline at the synchrotron facility of BESSY II (Berlin, Germany). The experimental station was described in detail elsewhere [1]. In these experiments, Zr*3d*, Mn*2p*, O*1s*, and C*1s* core-level spectra of sample were recorded under a H_2 flow at 140, 350, 500, 620^oC. The total pressure of H_2 was 0.5 mbar. All the spectra were obtained with a photon energy of 860 eV.

3 Results and discussion

It has been found that at low Mn/Zr ratios, when the Mn content is below 30 atom %, the catalysts are single-phase solid solutions ($Mn_yZr_{1-y}O_{2-\delta}$) based on a ZrO_2 structure. According to XPS data, manganese in these solutions exists mainly in the Mn^{4+} state. An increase in the Mn content mostly leads to an increase in the number of Mn cations in the structure of the solid solutions, but a part of manganese form Mn_2O_3 and Mn_3O_4 in crystalline and amorphous states.

Reduction of these catalysts with hydrogen was studied by a TPR, in situ XPS and XRD, 100 to 700 °C. Figure 1 shows a series of diffraction patterns recorded during the reduction of the sample with Mn/Zr=1. At room temperature, the sample contains two phases: a solid solution $Mn_yZr_{1-y}O_4$ and Mn_2O_3. The reduction of this sample leads to a change in the lattice parameter of the solid solution $Mn_yZr_{1-y}O_4$, which is indicated by the shift of corresponding peaks to larger angles. Besides, the reduction leads to transformations of manganese oxides. The XRD data illustrates the two-stage reduction of manganese: $Mn_2O_3 \rightarrow Mn_3O_4 \rightarrow MnO$.

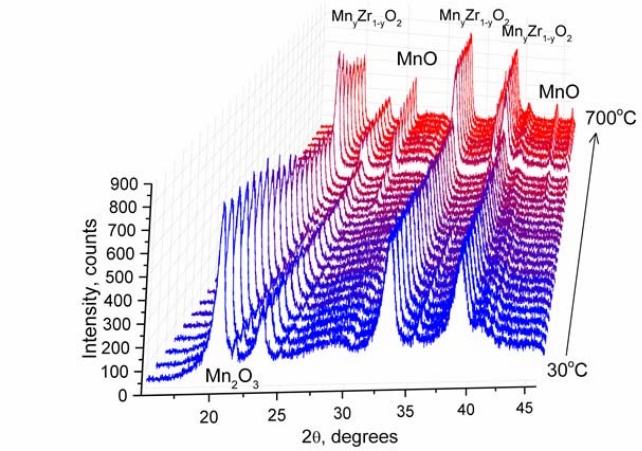

Fig. 1. Series of in situ diffraction patterns (λ = 1.0157 Å) recorded during reduction of the sample Mn/Zr=1 with hydrogen in the ranges from 30 to 700 °C

According to TPR data and to data on the change in the lattice parameter the reduction of solid solutions proceeds in two steps. In the first stage, at temperatures of 100-500°C, manganese cations undergo partial reduction to Mn^{2+}, whose presence is confirmed by XPS measurements. The lattice parameter of $Mn_yZr_{1-y}O_2$ in this case varies because of changes in the oxidation state of manganese cations in the bulk of solid solution. In the second stage, at temperatures of 500-700°C, manganese cations exit from the bulk of the solid solution and segregate on its surface. The lattice parameter at this stage increases because of the decrease in the number of Mn cations in the oxide.

4 Conclusions

Mn-Zr oxide catalysts were obtained by coprecipitation of corresponding nitrates, and their physical and chemical characteristics were studied. The reduction of mixed oxides in hydrogen was studied by in situ XRD, TPR, and in situ XPS. It has been shown that the reduction of the solid solutions proceeds in a wide temperature range 100-700 °C via two steps. At the first step, at 100-500 °C, Mn cations, which constitute a solid solution, undergo partial reduction. At the second step, at 500-700°C, Mn cations irreversibly exit to the particle surface.

Keywords: ionic liquids, aluminum chloride, benzene alkylation, 1-octene

1 Introduction

To date in the industry process of alkylation benzene with olefins is using catalyst systems based on aluminum chloride. Advantage of such systems is to use a smaller excess of benzene and the possibility to conduct of alkylation and transalkylation processes in a single reactor. However, the catalytic systems, based on aluminum chloride, have a number of disadvantages: corrosiveness, the need to remove them from the reaction mass, a large amount of wastewater.

An alternative is to use catalytic systems - ionic liquids (IL) based on aluminum chloride, including supported on solid supports.

Chemical and mineralogical composition and structure of diatomite powder - a sedimentary rock provide all the prerequisites for its use as such a solid carrier.

2 The experimental

The ionic liquid is a salt of tetramethylammonium chloride and aluminum chloride with a melting point of 50°C.

Drawing of IL on diatomite powder was carried out by impregnation of of the calcined support by an ionic liquid in medium of methylene chloride, followed by solvent removal and drying.

The degree of ionic liquid coating on diatomite powder was evaluated by the nitrogen content determined by elemental analysis, as well as in terms of bulk density.

3 Results and discussion

It is shown that with increasing amount of ionic liquid in the mixture, the nitrogen content increases in the catalyst component, and bulk density increases. It was also found that, irrespective of the mass ratio of the original IL, degree of ionic adsorption is 52-54% of its original amount.

If the content of IL increases in the initial mixture, the total pore volume and specific surface of the catalyst decrease (Table).

Table - Surface structural characteristics of the samples of catalyst - ionic liquid TMAX - aluminum chloride supported on diatomite powder.

The ratio of IL: Diatomite powder wt%	Specific surface, m^2 / g	Total pore volume cm^3 / g	Average Pore Diameter, nm
0.0:100.0	23,0	0,088	15,4
20.0:80.0	9,6	0,034	14,2
33,3:66,7	3,4	0,017	19,6
50.0:50.0	2,9	0,016	21,5

The resulting samples were used as the catalysts in the alkylation of benzene by octene-1. The temperature of the alkylation process was 80 ° C, duration - 3 hours.

4 Conclusion

The ionic liquid applied to the diatomite powder in a weight ratio of 20:80 was active in the alkylation process of benzene by 1-octene and provided satisfactory conversion of 1-octene.

Keywords: palladium, catalysts, γ- Al_2O_3, butadiene-1,3, hydrogenation

1 Introduction

The supported palladium catalysts are widely used in large industrial processes of hydrogenation of acetylene and diene compounds. These processes are realized in the preparation of monomers for the production of synthetic rubber and plastics with the usage of the imported catalytic systems. Despite sufficient activity, these catalysts do not provide a high selectivity and a long service cycle operation, so that it requires a detailed analysis of the active phase formation of supported palladium particles at all stages of catalyst synthesis. Thus, the properties of the supported metal particles in the catalyst systems are mainly determined by two factors: the size of the particles and interaction "metal - support". The latter occurs in the step deposition of the metal complex and its attachment to the acid-base surface of the alumina support. The results about the regularities of the palladium particles formation during application of palladium complex on alumina characterized by the different acid-base properties are obtained in this work. The influence of the concentration and strength of the acid-base centers on the formation of the charge state, dispersion and geometrical characteristics of the supported palladium particles on alumina is established. The obtained data will be used in the synthesis of the supported metal particles with set properties and creation of new catalysts of selective hydrogenation not conceding or surpassing in the operational characteristics of import catalytic systems.

2 Experimental

2.1 Support preparation and characterization

Modification of aluminum hydroxide was carried out by weak organic acids. It were oxalic, citric and acetic acids. This samples was calcined at 550 ^{0}C for preparation γ-Al_2O_3. Differential thermal analysis (DTA) under argon and air was performed on samples by derivatograph system «F.Paulik, J. Paulik and L. Erdey Q-1500 D» in the temperature range from 20 to 1000 ^{0}C. The phase analysis of the samples was carried out on an automatic X-ray diffractometer DRON-based serial-2 using long-wave radiation $CuK_{\alpha.}$ The surface areas of supports, pore volume, distribution of pore volume and pore diameter were determined by the ASAP 2400 analyzer company, Micromeritics AutoChem (USA). Thermo-programmed desorption of ammonia was carried out in a quartz reactor with a thermal programmable temperature rise from 100-600 ^{0}C on the instrument AutoChem Micromeritics (USA).

2.2 Catalyst preparation and characterization

The catalysts were prepared by chemisorption impregnation. The palladium was deposited onto γ-Al_2O_3 unmodified and modified by organic acids with usage 0.5 wt % solution of palladium acetylacetonate as metal precursor. The catalysts were dried for 12 h at 80 ^{0}C.

Interaction of the metal with a support was measured by means of temperature-programmed

reaction experiments in the temperature range 50-700 ^{0}C on a Micromeritics AutoChem.

2.3 Catalytic tests

Hydrogenation of Butadiene-1,3 was performed in gase phase in laboratory conditions on a flow-circulation installation of a fixed bed catalyst. One gram of catalyst initially was reduced in the reactor for 1 h under H_2 at 160 ^{0}C. Analysis of the reactants and the reaction products of hydrogenation was carried out by gas chromatography with a flame ionization detector and a thermal conductivity detector on the Chromos GCh – 1000.

3 Results and discussion

According to the data of DTA, the formation of the low-temperature modification of γ-Al_2O_3 for all samples of pseudoboehmite alumina was observed in the temperature range of 200-462 ^{0}C and the decomposition of aluminum salts in an air stream to a temperature of 531 ^{0}C. Thus for formation of alumina without organic residues was carried out heat treatment of all aluminum hydroxides at 550 ^{0}C. The formation of γ-Al_2O_3 at a given heat treatment was determined by XRF method.

According to the results of the texture analysis, modification of aluminum hydroxide with organic acids results in an increase in surface area and pore volume. The total acidity of the alumina samples estimated by the method of temperature programmed desorption of ammonia showed an increase in the acidity of the samples treated with acid approximately in 1,2 times compared with the original one. It is due to the growth of defects in the crystal oxide structure estimated by helium pycnometry. It was showed a decrease in the density of the modified samples as a result of a less dense coordination of primary crystallites of corresponding hydroxide and aluminum oxide.

On the basis of the results of the temperature programmed reduction with hydrogen the increase acidity of the supports leads to the stronger interaction of acid-base centers modified carrier with supported palladium particles. It leads to the formation of electron-deficient atoms surface of the active component.

According to the catalytic tests, the catalysts based on the modified supports showed a higher conversion of 1,3-butadiene, up to 94%, while the selectivity of 1-butene slightly decreased and amounted to 31-42%.

4 Conclusions

Thus, modification of aluminum hydroxides by weak organic acids leads to changes of texture characteristics, accompanied by an increase in surface area and decrease in pore volume; and increase in of the acidity of the supports with higher percentages of strong acid centers. The growth of 1,3-butadiene conversion probably occurs due to the high dispersivity of the metal on the surface of the acidic support and decrease in selectivity to butene-1 explained by the presence of the charged palladium particles that cause the deeper hydrogenation of 1,3-butadiene in butane.

Keywords: hydrotreating, heteropolycompounds, CoMoS, genesis, deactivation

1 Introduction

Production of clean fuels with less than 10 ppm sulfur content is one of the most important and claiming the attention problem in recent petroleum refinery. It is known that the active phases of the HDS catalysts are the MoS_2 or WS_2 nanocrystallites promoted by cobalt or nickel, deposited on a high specific surface area supports. Activation procedure such as sulfidation is an important step to improve catalytic properties of sulfide catalysts. Two different routes are commonly used for sulfidation of HDS catalysts: (i) with a H_2/H_2S mixture, carried out in gas phase and most practiced in laboratory experiments, and (ii) with spiked feedstock, in which sulfiding is mainly done by the sulfur of the organosulfide agents (also called "spiking" agents). It is known that conversion of the oxidic catalyst structure into the sulfided phase during gas or liquid phase sulfidation methods determines the final structure and performance of the catalyst. There is no consensus on which of sulfidation method is better. Thus for new precursors and HDS catalysts it is necessary to investigate both sulfidation methods. The objective of the research was to study sulfidation mechanisms of the HDS catalysts prepared with the use of Co_2Mo_{10}HPAand cobalt citrate.

2 Experimental/methodology

Catalysts were prepared by means of the incipient wetness technique via impregnating the γ-Al_2O_3 with mixed water solutions of precursors (Co_2Mo_{10}HPA and cobalt or nickel complexes with citric acid (CA)). Then the catalysts were dried at 110^0C (4 h). Catalysts were subjected to gas phase sulfidation. For this purpose, catalyst samples were placed into a separate glass reactor where sulfidizing process was carried out under a flowing H_2/H_2Smixture (85/15 v/v %, 50 ml/min, 0.1 MPa) at 20, 100, 200, 300 and 400^0C for 1 h. Samples were then cooled down to room temperature at a rate of 20–25^0C/min under the reactive mixture. Liquid phase sulfidation was carried out in bench-scale flow reactor for the $Co_3(CA)_{4.5}$-Co_2Mo_{10}HPA/Al_2O_3 catalyst. Straight run gas oil (SRGO) with DMDS (2 wt.%) was used as a feedstock. The catalysts were soaked with this sulfiding feed in hydrogen atmosphere (3.5 MPa) at 140◦C, using a liquid hourly space velocity (LHSV) of 4 h^{-1}. Then the LHSV was decreased to 2 h^{-1} (with H_2/oil = 300 NL/L) and the bed temperature was raised to 230^0C at a rate of 25^0C/h and stabilized for 8 h. The final temperature of sulfidation was 340^0C (ramping rate of 20^0C/h) and it was stabilized for 9 h. In each sulfidation experiment catalyst sample was cooled down to room temperature at a rate of 15–20^0C/min under the reactive mixture and an organic solvent. The catalysts have been studied by N_2 adsorption, XRD, HRTEM and XPS methods and tested in diesel HDT.

3 Results and discussion

The XPS and HRTEM measurements of the synthesized catalysts confirmed the formation of

multilayer slabs of type II CoMoS phase after gas and liquid phase sulfidations. Fig. 1 shows the models of genesis of the active phase of the $Co_3(CA)_{4.5}$-Co_2Mo_{10}/Al_2O_3 catalyst in gas or liquid phase sulfidation [1].

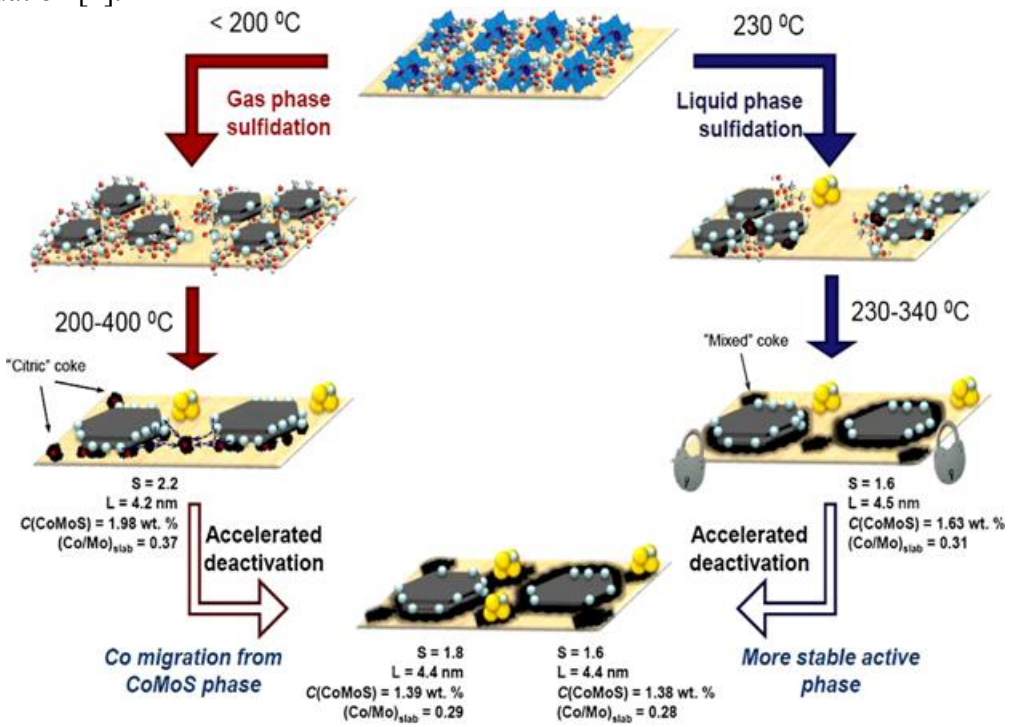

Fig. 1. CoMoS phase formation mechanisms during gas and liquid phase sulfidation of the $Co_3(CA)_{4.5}$-Co_2Mo_{10}/Al_2O_3catalyst (*S* – average stacking number, *L* – average length were found from TEM; Co content in CoMoS phase and $(Co/Mo)_{slab}$ were found by XPS).

4 Conclusions

Mechanisms of the active phase formation from Co_2Mo_{10}HPA and cobalt citrate precursors during gas and liquid phase sulfidation processes have been established. The first step of gas phase sulfidation is formation of MoS_2 nanoclusters from Co_2Mo_{10}HPAwith the deficiency of promoter atoms. The second step is destruction of cobalt citrate at higher temperatures and fixing of the Co atoms on the edges of MoS_2 crystallites. In liquid phase sulfidation, both metals (Co and Mo fromCo_2Mo_{10}HPA and Co from citrate) are sulfided simultaneously with the formation of nuclei of CoMoS phase II type at low temperature (230^0C). At high temperature (340^0C) the increase of particle size of CoMoS phase is occurred.

Gas phase sulfidation of the catalyst leads to formation of active phase with higher Co content in CoMoS and promoter ratio than liquid sulfidation. Initial activity in diesel HDT of the gas sulfided catalyst was higher than activity of the sample sulfided by the liquid phase method.

Study of behavior of the catalysts in accelerated deactivation revealed that the liquid phase sulfided sample was more resistant to the deactivation. This occurred probably due to stabilization of active phase particles by coke formed during liquid phase sulfidation. This effect prevents loss of Co atoms from CoMoS phase.

Different Preparation Method of WTi-Pillared Clay: Catalytic Application in the n-Hexane Isomerisation

Ferjani W.*, Khalfallah B.L.

Laboratoire de Chimie des Matériaux et Catalyse, Département de Chimie, Faculté des Sciences de Tunis, Tunis, Tunisie

* ferjani_wiem@hotmail.fr

Keywords: tungsten, titanium, pillared clay, isomerisation, n-hexane

1 Introduction

Pillaring layered compounds with inorganic species is a well route in preparing porous materials. The potential advantages of pillared interlayer clays lie in the possibility of achieving larger pore sizes and sufficient acidic functions: Lewis and Bronsted acid sites. Generally, metals are deposited on pillared clays by means of ionic exchange, incipient wetness, or dry impregnation of samples. The number of chemical reactions for which the potential application of pillared clay (PILC), whether as catalysts or as catalyst supports, has been evaluated and is continuously increasing [1, 2]. The Ti-pillared clays have been explored in various applications, especially those requiring acid sites [3-5]. However, the difficulties of its preparation have made its use less interesting comparing to other pillared clays. So far, there has not been any published work describing a method for the preparation of WTi-PILC or studying the effect of tungsten amounts on the physico-chemical properties of Ti-PILC nor discussing the catalytic activity of the WTi-pillared clays. For this reason, it has been interesting to investigate the effect of preparation method and tungsten amounts added to the clay during the synthesis of WTi-PILC. All the materials were characterized by different technique then tested in the n-hexane isomerisation, reaction widely utilized to evaluate the surface acidity of heterogeneous catalysts.

2 Experimental/methodology

The intercalated Ti-solution solution was prepared by slowly adding $TiCl_4$ into HCl (6M) under vigorous stirring. The tungsten solution was prepared by dissolving ammonium metatungstate $(NH_4)_6H_2W_{12}O_{40}$ in distilled water (10^{-2} M).

For the first method, the intercalated Ti-solution and W-solution were simultaneously added to the suspension of the initial clay under vigorous stirring. After 24h, the solid fraction was separated by centrifugation and dried at room temperature. The second method is the tungsten addition by incipient wetness of the intercalated Ti-clay. The samples were also dried at room temperature and finally calcined at 400 °C.

3 Results and discussion

The catalytic activity of the samples is strongly dependent of the preparation method. Furthermore, the selectivity toward isomers is mainly function of the tungsten amounts added to the clay during mixed intercalation (Fig. 1). In fact, the highest selectivity observed for tungsten-titanium-pillared clay (WTi-PILC) is directly related to the content of tungsten retained by the clay and essentially to the homogeneous pillars distribution. In all cases, products distributions revealed that mono-branched isomers form the major proportion of products while di-branched isomers were the minor products.

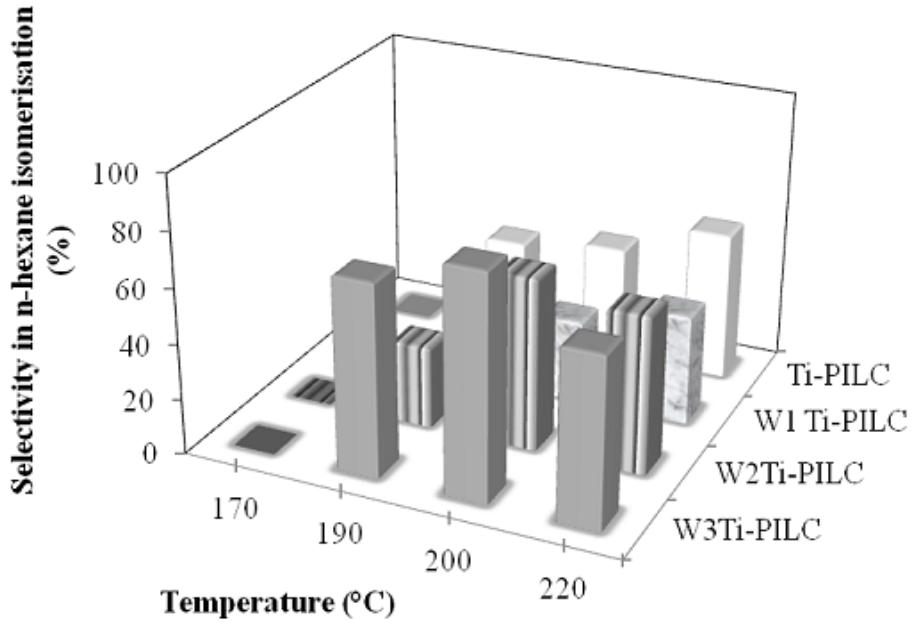

Fig. 1 : Selectivity towards isomers products at different temperature reaction.

4 Conclusions

The structural, textural and catalytic properties of tungsten-titanium pillared clay are largely influenced by the preparation method and the tungsten amounts added to the clay during intercalation process. The use of two methods induced dissimilar textural, structural and catalytic properties of the samples. Enhanced porosity by pillaring allows selective catalysis in the n-hexane isomerisation.

Keywords: vanadium, tungsten, titanium, pillared clay, SCR-NO

1 Introduction

The removal of nitrogen oxide from outgases is one of the most challenging problems of these days. So far the only process of NO removal from stationary sources used on industrial scale has been selective catalytic reduction (SCR) with ammonia. Therefore, a great deal of effort has been made for the development of new catalysts and several researchers have published reviews that cover the various range of SCR-NO by ammonia [1, 2]. The most frequently used catalyst is V_2O_5 and WO_3 or MoO_3 supported on TiO_2 [1]. However, the use of TiO_2 as support is limited by the fact that it possesses low specific surface area and porosity, only Lewis acid sites and low resistance to sintering compared to Titanium pillared clay (Ti-PILC), characterized by large surface area, high porosity, good thermal stability, a sufficient amount of Bonsted with Lewis acid sites. Recently, considerable effort has been made to investigate layered clays and their SCR behaviour [3]. In our previous work, we have compared Ti-PILC and sulphated Ti-PILC either unpromoted or promoted with V_2O_5 [4-6]. We have also demonstrated that the promoting effect of tungsten in the presence of sulphate was not found [7]. For this reason, it has been interesting to investigate SCR-NO by ammonia over vanadium supported on WTi-PILC prepared in absence of sulfate. To the best of our knowledge, this is the first report of vanadia supported on WTi-PILC prepared with different amounts of tungsten and vanadium then tested in the SCR-NO by ammonia.

2 Experimental/methodology

The tungsten solution, prepared by dissolving ammonium metatungstate $(NH_4)_6H_2W_{12}O_{40}$ in distilled water (10^{-2} M), was simultaneously added with the intercalated Ti-solution to the clay suspension under vigorous stirring. After 24h, the solid fraction was separated by centrifugation and dried at room temperature. Vanadium supported on mixed WTi-pillared clay were prepared by incipient wetness impregnation of the support with a solution of ammonia vanadate NH_4VO_3 (0.1M) dissolved in water acidified by oxalic acid. All the samples were dried at 80°C.

3 Results and discussion

Textural, structural and catalytic properties of WTi-PILC supports are largely influenced by the tungsten content incorporated in the clay and essentially by the amount of vanadium added to the support. The SCR activities of the investigated supports doped with 2% of vanadium are shown in Fig. 1. The V/WTi-PILC catalyst that exhibits better activity between 200°C and 400°C is the sample having homogeneous distribution of pillars, good porosity and an adequate total acidity.

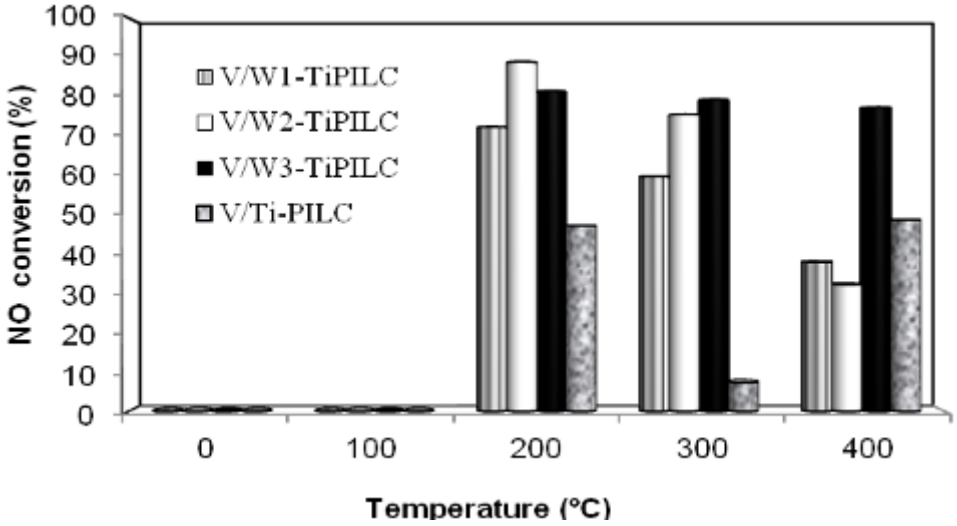

Fig.1: NO conversion for SCR-reaction.

4 Conclusion

The efficiency of vanadium supported on mixed WTi-PILC catalyst is related to essentially the homogenous pillar distribution in the support. Based on the results, it can be concluded that the incorporation of an appropriate amount of tungsten on Ti-PILC is a key factor for obtaining a good support of vanadium to catalyze the SCR-NO reaction by ammonia.

Isomerization of Light Hydrocarbons over the ZSM-5 Zeolites

Velichkina L.*, Kanashevich D., Vosmerikov A. , Fedushchak T.[1]

Institute of Petroleum Chemistry, Siberian Branch of the Russian Academy of Sciences, Tomsk, Russia

* mps@ipc.tsc.ru

Keywords: ZSM-5, modification, n-alkanes, gasoline, isomerisation, coke

1 Introduction

According to the current literature, isomerization of light hydrocarbon raw materials follows two main routes: over the chlorinated [1] or sulphated [2] oxide catalysts, both having numerous disadvantages. On the other hand, it is much more reasonable to use zeolites that allow to converting n-alkanes under extraordinary conditions, i.e., without feeding the hydrogenous gas to the reaction medium at atmospheric pressure and without any use of noble metals and superacid additives, which would favor cost reduction of the final product [3-5].

The aim of this work is to investigate the catalytic activity and stability of the pentasil zeolite with the silica modulus 40 and its nickel-containing analog in the course of a hydrogen-free isomerization of C_5-C_8 n-alkanes and straight-run gasoline oil fraction.

2 Experimental/methodology

The high-silica ZSM-5 zeolite with SiO_2/Al_2O_3 molar ratio of 40 was manufactured by hydrothermal synthesis. Modification of ZSM-5 with a nanosized nickel powder obtained by the gas-phase method in the amount of 0.5% by weight of the nickel oxide was carried out by dry mixing in a vibrating mill for 2 hours, followed by compressing the resulted mixture into pellets, refinement of 0.5-1.0 mm fraction and its sampling. The average particle size of nickel nanopowder was 50 nm.

The catalytic activity of the initial and the Ni-containing zeolite was studied in the conversion reactions of normal pentane, hexane, heptane and octane, an artificial mixture of n-pentane: n-hexane = 1: 2, and straight-run gasoline fraction (low-boiling fraction boiling out at a temperature of 90 °C). The tests of catalytic activity of zeolites were carried out in a flow installation at the reaction temperatures of 280-360 °C, volumetric feed rate of 2 h^{-1} and atmospheric pressure. The dynamics of deactivation of zeolite catalysts was investigated in the course of conversion of the hydrocarbon raw materials under study during 16 hours of their continuous operation at 320 °C and 2 h^{-1}. The amount and nature of the coke deposits were determined by differential thermal analysis. The composition of the initial feedstock and its conversion products were analyzed by gas chromatography.

3 Results and discussion

The gaseous products of conversion of all types of the hydrocarbon raw materials under study over zeolite catalysts are mainly presented by C_1-C_4 alkanes, whose largest fraction are propane, n- and isobutanes. As the process temperature increases from 280 to 360 °C, the conversion of the initial feedstock also increases, thus resulting in a higher intensity cracking reaction and gives rise to an increased yield in the gaseous products, whose hydrocarbon composition varies slightly.

The major liquid products of isomerization over zeolite catalysts under study are n- and isoalkanes, C_4-C_8 alkylbenzenes, and a minor amount of olefins and naphthenes. An increase in the process temperature from 280 to 320 °C results in the increased total yield of hydrocarbons with isometric structure, while further increase in temperature to 360 °C – in the reducing of

their concentration. The dependence of the individual isoalkane yield on the process temperature is identical to that of the total yield – the maximum amount of C_4, C_6, C_7 and C_8 isoalkanes is also formed at a temperature of 320 °C and that of C_5 isoalkanes only at 340 °C. The fraction of hydrocarbons with isometric structure having number of carbon atoms 9 and 12 in a catalyzate increases with a rise in process temperature.

The content of gaseous alkenes increases over the entire temperature range in the course of zeolite modification with a nickel nanopowder. Their maximum is reached at 300 °C, while the yield in C_1-C_4 alkanes, n- and C_{5+}iso-alkanes is slightly decreased. It is important to note that the yield of catalyzates with a prevailing content of isometric hydrocarbons significantly increases during the conversion over Ni-ZSM-5 zeolites.

Noteworthy is also the relationship between the type of hydrocarbon raw materials and the yield in catalyzate resulting from its processing over the zeolite catalyst: the lighter are the hydrocarbon raw materials, the lower is the yield of liquid product but it is typical only for the use of individual hydrocarbons. In the case of use of pentane-hexane mixture the yield of liquid product increases considerably compared with the individual hydrocarbons.

The highest selectivity towards a formation of isoalkanes for 16 hour's reaction is observed for the Ni-ZSM-5 sample and it remains practically unchanged during the whole period of operation of the catalyst.

The maximum amount of carbon deposits with a dense structure is formed during the conversion of n-octane, while the minimum amount – n-pentane, which is due to the greater thermodynamic stability of alkanes with lower molecular weight.

The nickel-containing zeolite catalyst exhibits a higher stability during conversion of various hydrocarbons and their mixtures as compared to the initial sample, which is due to the presence of nickel-containing active centers in this catalyst system. Their involvement into the hydrogenation-dehydrogenation reactions results in a decreased rate of formation of condensed molecules being coke precursors. The catalyst deactivation is thus slower compared to the initial zeolite.

4 Conclusions

The use of different types of hydrocarbons in the course of isomerization of unmodified and nickel-containing ZSM-5 zeolites allowed to reveal the main trends in the distribution of the reaction products and to determine the optimal reaction conditions for the formation of the maximum amount of iso-alkanes and the minimum amount of coke.

Keywords: density, functional theory, nanostructured, ceria, silver, cluster, oxygen, adsorption

1 Introduction

Ceria supported transition metals (TM) are known for activity in catalytic oxidation reactions. In this relation active sites on surface of nanosized cerium oxide particles are of particular interest. To characterize such structural features we considered localization of monomer, trimer and tetramer silver species on a $Ce_{21}O_{42}$ cluster (Fig. 1, [1]). Effect of support on these TM species is quantified via adsorption of O_2 probe molecule. All calculations are done using PW91+4 pseudopotential density functional approximation [1].

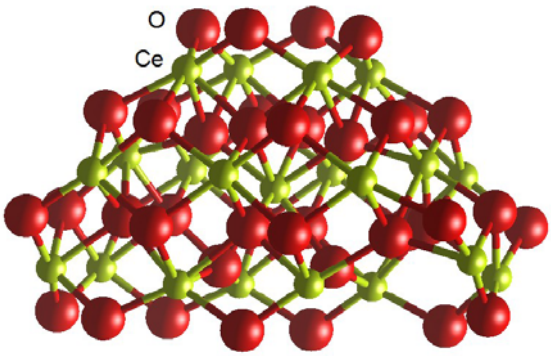

Fig. 1. Nanosized particle $Ce_{21}O_{42}$

2 Results and discussion

Surface of the $Ce_{21}O_{42}$ particle exposes small (111) and (100) facets as well as edge sites at their intersections. There are three- and two-coordinated oxygen atoms, O^{3c} and O^{2c} centers, and six- and five-coordinated cerium atoms, Ce^{6c} and Ce^{5c} centers. On interaction with ceria surface Ag_n moieties are oxidized. Each Ag and Ag_3 adsorbates donate to the substrate particle one electron. Ag_4 clusters in rhombus and tetrahedron configurations donate one and two electrons, respectively. Each donated electron is localized on just one cerium center, reducing it from Ce(IV) to Ce(III). Such centers are recognized via their magnetization of generally ≥0.7 μB and via increment of involved average Ce-O bond lengths by ~10 pm. Somewhat more stable structures are formed when donated electrons are localized on Ce^{6c} atoms.

Most stable $Ag_n/Ce_{21}O_{42}$ complexes are formed for adsorption on (100) facets, via interaction with O^{2c} atoms. The binding (adsorption) energies of Ag, Ag_3 and Ag_4 are calculated to 2.2, 2.9 and 3.0 eV, respectively. Silver atom in the most stable isomer of $Ag/Ce_{21}O_{42}$ system is in a hole position and interacts with four O^{2c} atoms (the so-called O_4-pocket [2]). Silver trimer in the $Ag_3/Ce_{21}O_{42}$ complex is in upright position. An $Ag_3/Ce_{21}O_{42}$ isomer with parallel to (100) facet orientation is ~0.5 eV less stable. The most stable $Ag_4/Ce_{21}O_{42}$ complex features tetrahedral structure of silver tetramer. The isomer with parallel to (100) facet silver rhombus is ~0.7 eV less stable. Still less stable is isomer with upright orientation of silver rhombus.

Ag_n adsorption on the (111) facets results in less stable complexes with binding energies of ~1.2 eV for $Ag/Ce_{21}O_{42}$, 1.7–2.5 eV for $Ag_3/Ce_{21}O_{42}$ and 1.6–2.0 eV for $Ag_4/Ce_{21}O_{42}$. In the $Ag/Ce_{21}O_{42}$ complex silver atom is localized in a hollow position between one O^{2c} and two O^{3c} atoms. In the most stable $Ag_3/Ce_{21}O_{42}$ complex on (111) facet, silver trimer is in upright position with O^{2c} and O^{3c} atoms bound to two silver atoms in the base of the Ag_3 triangle. $Ag_3/Ce_{21}O_{42}$ complexes with parallel to (111) surface Ag_3 plane are 0.3–0.4 eV less stable. Binding energies for $Ag_3/Ce_{21}O_{42}$ complexes with upright silver trimers bound to two O^{3c} atoms are calculated to 1.7–1.9 eV. Binding energies for complexes with Ag_4 located on (111) facet are calculated to be 2.0 and 1.6 eV with tetrahedral and rhombus silver tetramers, respectively.

Binding of O_2 molecule on the discussed above supported silver species are strongly dependent on the nature of supporting surface site. O_2 binding energies to silver atoms supported on (100) facets are small, 0.2–0.3 eV. In contrast, binding to silver atoms localized at (111) facets is rather strong, 0.7 eV for terminal adsorption mode and 1.3–1.4 eV for bridging adsorption mode. Molecular and dissociative O_2 adsorption on silver trimer supported at the (100) facet are calculated to be 0.2 and 0.4 eV, respectively. Binding energies for molecular and dissociative adsorption on silver trimer supported on (111) facets are slightly larger: 0.6 and 0.7 eV, correspondingly. O_2 binding energies for molecular adsorption on silver tetramers supported on (100) facets are 0.4–0.6 eV. Molecular adsorption on tetrahedral isomer of silver tetramer supported on (111) facets is again 0.5 eV more profitable than for such isomer on (100) facets.

For Ag_4 complexes on (100) facets O_2 binding energy for dissociative adsorption is in a range 1.2–1.5 eV. So, binding energy for molecular and dissociative adsorption on $Ag_4/Ce_{21}O_{42}$ is much more different than for $Ag_3/Ce_{21}O_{42}$ complexes.

Results for molecular silver clusters on $Ce_{21}O_{42}$ are compared with those calculated for similar clusters on MgO [3,4] and SiO_2 surfaces [5,6].

Quantum-Chemical Investigation Ligand-Stabilized Gold Clusters in Oxidation Reaction

Golosnaya M., Pichugina D., Kuz'menko N.*

M.V. Lomonosov Moscow State University, Moscow, Russia

* mashagolosnaya@gmail.com

Keywords: gold catalysis, gold-protected nanoclusters, phosphine, ligands

1 Introduction

Gold (Au) nanoparticles have been found to be capable of catalyzing a variety of reactions, such as selective oxidation and hydrogenation [1]. The main problem in the preparation of metals NP is that they are unstable in solution and tend to agglomerate to form larger aggregates. For stable NPs to provide there must use stabilizing agents, namely organic ligands, which are adsorbed on the particle surface, prevent their association.Ligand-protected gold nanoclusters have been widely studied due to their interesting optical, electronic, and charging properties, as well as potential applications in catalysis, biomedicine, and nanoelectronics[2].

Studying and revealing the well-defined atom packing structures of metal nanoclusters is of critical importance for understanding the quantum size and shape effects in nanoclusters. The synthesis of metal clusters with phosphine ligands has been extensively researched since the 1960s [3]. However, the structures, which was provided, were difficult to identify. In the past decades, because of the development of computational techniques, the number of synthesized and successfully identified nanoclusters is significantly increased. Over the past few years, a number of thiolate-protected gold nanoclusters gold atoms have been reported. However, with respect to phosphine-protected gold nanoclusters, much fewer have been attained [4]. We have analyzed the structural stability and electronic properties of the recently reported structurally known tetranucleargold cluster with phosphine ligands - $Au_4[P(CH_3)_2PCH_3(CH_2)_2P(CH_3)_2]_2^q$(q=+2, -2, 0), by using density functional theory. The cluster has synthesized and defined recently by NMR spectroscopy and X-ray spectroscopy [5]. It was shown, that the cluster exhibit size-specific physical and chemical properties, including photoluminescence, which are not observed in bulk metals.

Despite significant progress in the area catalytic properties of clusters, mechanism of formation as well as the phosphine ligands influence on the catalytic properties of have not been fully understood. Therefore, the main goal of this study is quantum-chemical study catalytic properties of gold-based catalysts, namely ligand-stabilized, in oxidation reactions.

2 Methodology

Geometry optimizations was performed within the spin-polarized approach (PBE functional) [6]. The Priroda program [7]was used for the all-electron calculations within the scalar-relativistic approach, which was based on the full four-component one-electron Dirac equation with separation of the spin-orbit effects.

2 Results and discussion

In present work we investigated the structure and electronic properties of cluster $Au_4[P(CH_3)_2PCH_3(CH_2)_2P(CH_3)_2]_2^q$(q=+2, -2, 0) as well as the catalytic activity of this cluster toward molecular oxygen adsorption.The high value of the HOMO-LUMO gap energy is typical for the cationic cluster. The charge strongly influences on the structure of the cluster. Gold atoms in the cationic cluster formed an elongated rhombus. The neutral model is

characterized by distortion of the structure. In addition, we observed breaking of Au-Au bonds in the anionic structure(fig. 1). The structure of the cationic cluster is in good agreement with X-ray data [1]. The modelling of oxygen adsorption on $Au_4[P(CH_3)_2PCH_3(CH_2)_2P(CH_3)_2]_2^q$ have indicated that molecular type of oxygen adsorption is most favourable in the cluster.

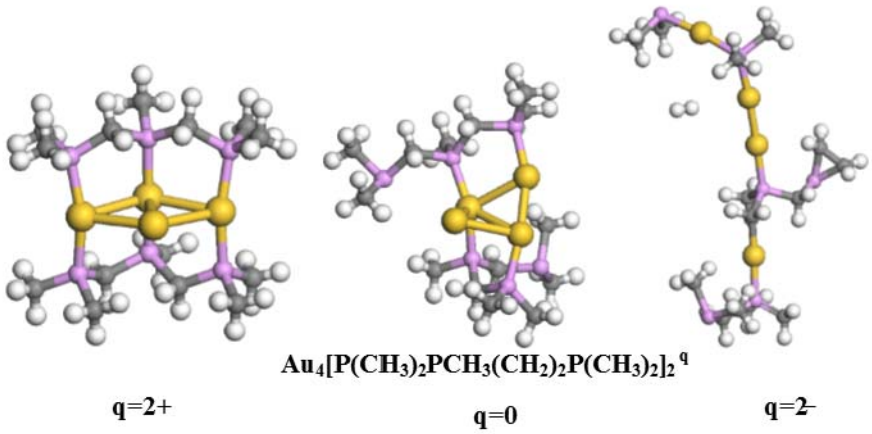

Fig. 1. The structure of $Au_4[P(CH_3)_2PCH_3(CH_2)_2P(CH_3)_2]_2^q$cluster (color labels: violet = P; yellow = Au; white = P; grey = C).

3 Conclusions

In summary, we have analysed the structural stability and electronic properties of a newly crystallized cluster $Au_4[P(CH_3)_2PCH_3(CH_2)_2P(CH_3)_2]_2^q$ by using DFT. The study of the cluster has provided much important information concerning the stability, structure and physical properties of phosphine protected metal clusters with ultra-small metal cores.

Keywords: rhodium, supported catalysts preparation, size control, nanoparticles

1 Introduction

Nowadays catalysts play a major role in modern industrial and economic structures. Noted, that more than 80% of the petrochemical products and chemicals produced by industry with heterogeneous catalysis and therefore with supported catalysts. The main advantage of using heterogeneous catalysts is that they can be removed easily from the reaction products. Furthermore, high thermal stabilities and high activities of supported nanoparticles allow to utilized them in many industrial processes. It is well known that supported catalysts may be successfully used not only in heavy industrial chemistry like synthesis of NH_3 or petrochemistry but also in fine chemistry for asymmetric hydrogenation for instance. The heterogeneous catalyst preparation methods include co-crystallization, ion-exchange or impregnation result in formation of metal particles dispersed on an oxide support such as Al_2O_3, SiO_2 or TiO_2. Subsequent oxidation and/or reduction steps can cause aggregation of the supported metal nanoparticles, resulting in changes in particle size and thus in size-dependent properties such as activity and selectivity.

Nowadays rhodium typically used for the production of automotive catalysts. Careful attention should therefore be paid during catalyst preparation to produce highly efficient catalysts with low metal loading, high metal dispersion and a long lifetime without deactivation. Different impregnation methods are available for catalyst preparation such as wet, incipient-wetness and dry impregnation or impregnation with interactions (e.g. ion exchange and adsorption methods). . Generally for the preparation of metal supported catalysts the final metal loading and the metal dispersion depends on the preparation technique used and on the final treatments to bring the catalyst in the active form [1, 2].

2 Experimental/methodology

The commercially available $RhCl_3*3H_2O$ was used as the start material for rhodium catalyst preparation. The catalysts were prepared via wet impregnation of Al_2O_3 or TiO_2 support with rhodium nitrate or acetic aqueous solutions.

Rhodium hydroxide was prepared by precipitation of $RhCl_3$ with sodium hydroxide. Rhodium precursors were obtained by dissolution of rhodium hydroxide in HNO_3 or HOAc. As a result, rhodium nitrate (III) solutions with varying relative concentrations of nitric acid and Rh were prepared. Next, both rhodium nitrate solution and rhodium acetic solution were used for the supported rhodium catalysts preparation.

To determine the influence of temperature pretreatment on the active component dispersion level, and therefore particle size distribution, the reduction of catalysts by hydrogen at 300 °C for 3 hours was performed after calcinations at different temperatures (400 °C for 4 hours, 600 °C for 2 hours).

3 Results and discussion

The procedure of supported rhodium catalysts (Rh/TiO_2 and Rh/Al_2O_3) preparation by using rhodium nitrate and acetate precursors was shown. It was found that the sizes of rhodium nanoparticles are strongly dependent from the preparation procedure and it allows to receive supported rhodium nanoparticles with particles size from 1 to 10 nanometers, that was examined by CO-chemisorption, TEM and XPS methods. It was found that the major mechanism for control of dispersion degree of the active component is the nature of the rhodium complexes (precursors). It was shown that the utilization of nitrite-nitrate complexes of rhodium leads to formation of highly dispersed rhodium (1-5 nm) nanoparticles, whereas usage of rhodium acetic complexes causes formation of relatively big metal particles up to 5-10 nm. The support pre-treatment is also highly important. It was shown, that modification of the TiO_2 or Al_2O_3 with HOAc solution leads to enlargement of Rh particle size for Rh/TiO_2 and Rh/Al_2O_3 supported catalyst.

It was shown that rhodium supported catalysts with different particle sizes are very active in heterogeneous hydrogenation of propylene to propane. Based on previously reported results demonstrating that metals supported on titanium oxide (TiO_2) generally exhibit higher levels of parahydrogen-induced polarization effects compared to other oxide supports, a number of metal catalysts supported on TiO_2 were tested in heterogeneous gas phase hydrogenation of propene with parahydrogen. All Rh/TiO_2 catalysts studied were very active in heterogeneous hydrogenation of propene to propane and, importantly, produced strongly polarized as detected by high-resolution NMR spectroscopy. The maximum signal at 9.4 T was observed with 1.6 nm particles. This catalyst yielded polarized propane with significant signal enhancement compared to the thermally polarized propane. Therefore, this catalyst was selected for further MRI studies [3].

4 Conclusions

Preparation methods for size selective synthesis of supported rhodium nanoparticles were developed. It was shown that the nature of rhodium precursors, calcination temperature and support modification may significantly effect on the sizes of rhodium nanoparticles. All supported rhodium catalysts are very active in heterogeneous hydrogenation of unsaturated gaseous compounds and lead to formation of strong polarization when parahydrogen was used.

The Nature of Carbon Supports Action on the Palladium Electronic State and Catalytic Properties

Kochubey D.I.[1*], Smirnova N.S.[2], Temerev V.L.[2], Iost K.N.[2], Tsyrul'nikov P.G.[2], Radkevich V.Z.[3], Khaminets S.G.[3], Samoilenko O.A.[3], Kriventsov V.V.[1]

Keywords: carbon supports, electronic state of palladium, XANES, CO oxidation

1 Introduction

Carbon supports may have great differences in the structure and electrophysical properties. It is known that carbon materials are narrow band semiconductors, so the effect of strong metal-support interaction may be observed on them. Previously this effect was actively studied for the metals supported on the transition metal oxides. Often strong interaction metal-metal oxide leads to the metal nanoparticles decoration with metal suboxides. This decoration may lead to almost total encapsulation of active compound nanoparticles and decrease of their catalytic activity. But for the suboxides with electro conductivity exchange of the electrons between metal and support becomes possible which could lead to increase of catalytic activity. This effect was observed for rhodium catalyst on titanium suboxide [1]. For the carbon supports that effect takes place even without decoration. Moreover, modification of the electron configuration for Pt catalysts on carbon support, due to transition of part *d* electrons into *p* or *s* states was observed [2].

2 Experimental

The influence of the carbon supports, including graphite-bearing material (sibunit) and carbon-base fibers (busofit, karbopon), on the electronic state of palladium and catalytic activity Pd/C systems were studied in this work. 1%Pd/busofit and 1%Pd/karbopon catalysts were prepared by means of the ion exchange method from H_2PdCl_4. The 1%Pd/sibunit catalysts were prepared via impregnation method. Prepared catalysts are dried in He for 1 h. and reduced in H_2 at 300^{o}C 2h.

3 Results and discussion

The NIR-VIS spectra (fig.1) were measured for supports. Forbidden band width was calculated from spectra derivative using Tauc theory [3]:

$$d[\ln(D(h\nu)*h\nu)]/d(h\nu)=k/(h\nu - Eg)$$

(D - optic density; hν - optical photons energy; Eg - forbidden band width).

The maximums at 0.8 and 1.0 eV are needed additional analysis. Spectra analysis has shown two forbidden bands with width of 1.3 and 2.0 eV for busofit, one forbidden band with 1.2 eV for carbopon, sibunit don't have forbidden bands with width more than 1 eV (fig. 1a).

According to HREM data the average Pd particle size for all catalysts is 1.7 nm. Radial distributions of atoms (RDA) around Pd have Pd-Pd distance for metal and Pd-C distance from carbon atoms of support was observed. The coordination numbers for first Pd-Pd distance in metal determined from EXAFS data are too low. The structure distortion due to support action may be reason of that.

Catalytic activities for 1%Pd/sibunit, 1%Pd/busofit and 1%Pd/karbopon were determined in the CO oxidation reaction (dry reaction mixture (0,3 vol.% CO in air), 5,5 mg of Pd in catalyst

loading, 3300 h^{-1}). Experiments results have shown increase of catalytic activity with the increase of forbidden band width (fig.1).

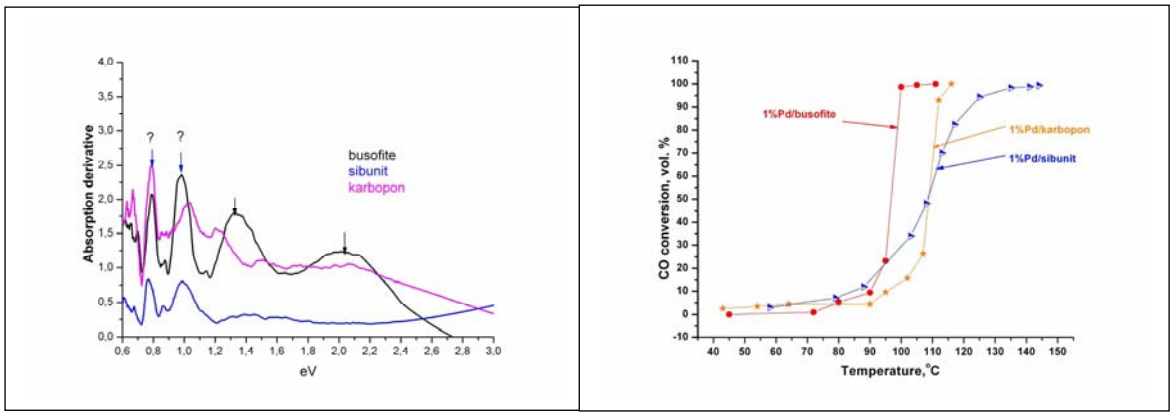

Fig. 1. a) The width of forbidden bands for carbon supports b) Catalysts activity in CO oxidation reaction

Additional information was obtained from XANES spectra. The shift of the spectrum edge in the region of greater energy indicate the increase of electron deficiency on the metal nanoparticles. Catalytic activity of the samples with greater electron deficiency is higher was determined (Table 1).

Table 1. Edge position for Pd catalysts

Catalysts	1%Pd/ busofit	1% Pd/ karbopon	1%Pd/sibunit
E, keV	24.3938	24.3914	24.3926

4 Conclusions

The correlation of the Pd catalysts activity in CO oxidation reaction and forbidden band width of the carbon supports was determined. Catalytic activity also correlated with electron deficiency metal Pd nanoparticles. Nanoparticles with greater electron deficiency are more active.

Mössbauer Spectroscopy Investigation of Iron-Cerium Oxide Systems as Catalyst in the Reaction of the Methylbutene Dehydrogenation

Bochkov M.A.[1*], Kharlampidi Kh.E.[1], Akhmerov O.I[1], Pyataev A.V.[2]

Keywords: iron oxide, cerium, Mössbauer spectroscopy, dehydrogenation

1 Introduction

Investigations of dehydrogenation catalysts are carried out for a long time. However a question about a nature of catalyst active component is still discussed. Also, there is no consensus on the phase and chemical transformations in the system of iron – oxygen that occur during this system synthesis and working.

2 Experimental/methodology

Samples of iron oxide and iron-cerium oxide systems as catalysts for the dehydrogenation reaction of methylbutenes are studied by Mössbauer spectroscopy method. Samples were prepared by initial magnetite (S_A / S_B ~ 1,1) solution impregnation of cerium salt (III), followed by drying, molding and burning in air at 650 ° C. The formed granules of polycrystalline samples were placed in the reactor as a catalyst in the dehydrogenation reaction of methylbutenes. The catalytic activity of the samples in the reaction of isoprene synthesis from isoamylenes was determined on flow microcatalytic laboratory setting under the conditions of catalyst loading amount of 1 cm3, molar feed steam dilution 1:20, at the temperature of 580ºC. Analysis of the reaction products was carried out by chromatography.

3 Results and discussion

Mössbauer transmission spectra of obtained samples were largely similar to spectra of standard model of α-Fe_2O_3 in the parameters of hyperfine interactions. In case of magnetite the yield of isoprene for decomposed hydrocarbons (YD) is 77%. The introduction of cerium into the magnetite composition increases the selectivity of catalyst, i.e. YD to 84%. To elucidate the mechanism of interaction between the catalyst system and the reaction medium, Mössbauer measurements were carried out after the catalyst system staying in the reactor in transmission geometry at room temperature. The spectrum of the oxide system after the reactor is a magnetite like system which is characterized by parameters of hyperfine interactions close to founded in chemically pure Fe_3O_4 samples. The ratio of the partial areas S_A / S_B ~ 1,9.

4 Conclusions

During the catalytic reaction in oxide system conversion from α-Fe_2O_3 to Fe_3O_4 like system occurs which is attended with the changes in A and B positions populations in the spinel structure in the direction of S_A / S_B ratio increasing with respect to the initial magnetite. By Mössbauer spectroscopy method insignificant role of cerium in the formation of magnetic microstructure in initial iron-cerium oxide system and in the system after working in the reactor was revealed. Increasing of the catalyst selectivity is apparently connected with the formation of the respective solid solutions on the surface of the iron oxide polycrystallites. These results

require further investigations of granules thin surface layer composition and its changes during the reaction.

Keywords: surface, oxygen, radicals, oxides, EPR, DFT

1 Introduction

Long-distance separation of electron-hole pairs is usually assumed to be the first stage of various thermal and photochemical processes resulting in the formation of ion radicals on the surface of oxides. A common feature of all such processes is the generation of isolated paramagnetic species with S=1/2 stabilized on the surface, which can be detected by EPR [1]. However, long-distance charge separation with participation of the conductivity or valence bands is unlikely for wide band-gap dielectrics, such as MgO with the band gap 7.8 eV. Still, the experiments show that the radicals can be effectively generated under illumination with soft UV light with 4.1 eV (303 nm) photon energy [1, 2]. A viable alternative to the physical charge separation mechanism is a "chemical" mechanism ascribing the generation of the ion radicals to the formation of mobile radical species [2, 3]. Radicals H• and OH• formed from the fragments of chemisorbed water H^+ and OH^-, respectively, are the most likely candidates for such species.

In this communication we shall demonstrate that the chemical and spectroscopic properties of O^- radicals formed as hole and electron sites seem to be exactly same. This is possible only if these species are not charged and are formed due to the homolytic splitting of chemisorbed water molecules. Quantum-chemical simulations supporting this hypothesis will be discussed.

2 Experimental/methodology

ESR experiments were conducted in our high-vacuum EPR "in situ" installation. The standard sample pretreatment included alternating oxygen-vacuum treatments at 500°C in a vacuum line with a trap cooled by liquid nitrogen. ERS-221 spectrometer was used for registration of X-band ESR spectra at variable temperatures. The EPR samples were subjected to the illumination directly in the spectrometer cavity. A monochromator used made it possible to study spectral characteristics of the photoreactions in the energy range of 1 - 5 eV.

The Mg_9O_9 cluster was used as a model of an MgO nanoparticle, see Figure 1, left. The energetics of the processes was estimated using spin-polarized density functional theory (DFT) b3lyp/6-31g(d) in the Gaussian 09 quantum-chemical package. Steps and kinks on the surface of MgO particles are common surface defect sites. For these we adopted MgO (410) facet shown in Figure 1, right. The energetics and optimal structures were obtained by spin-polarized PW91 DFT functional. Plane-wave basis set restricted to kinetic energies below 25 Ry. Core electrons were approximated using ultrasoft pseudopotentials. Periodic structure calculations were carried out using Quantum Espresso 4.3 package.

3 Results and discussion

MgO illumination by UV light in the presence of N_2O was shown to result in the formation of spectroscopically indistinguishable O^- radicals both on electron and hole sites. So the total

concentration of such radicals proved to be higher than after illumination in oxygen when such radicals are formed only on hole sites. Chemical properties of the O^- radicals formed on the electron and hole sites in reactions with O_2, CO and ethylene were found to be the same as well. This is possible only if these species are formed by the transfer of uncharged radical species formed from homolytic splitting of water.

The oxygen radical O^- obtained after UV-illumination and O^- produced due to N_2O decomposition on electron-rich F-centre according to our scheme are almost the same species, see Fig. 1, left. So, it is not surprising that their EPR spectra have no differences at all. According to quantum-chemical simulations, the homolytic water dissociation on the oxide surface has the energetic barrier 2.75-3.39 eV, depending on the nature of radical stabilization sites. Thus, it becomes clear why soft UV illumination with photon energy about 4 eV is sufficient for generation of the radicals. Note that complete water removal is feasible under experimental conditions, for example, by heating the sample up to 1200 K. Molecular oxygen or nitrous oxide are able to stabilize radical sites by shifting the equilibrium towards further production of the oxygen radicals as it is shown by our DFT calculations.

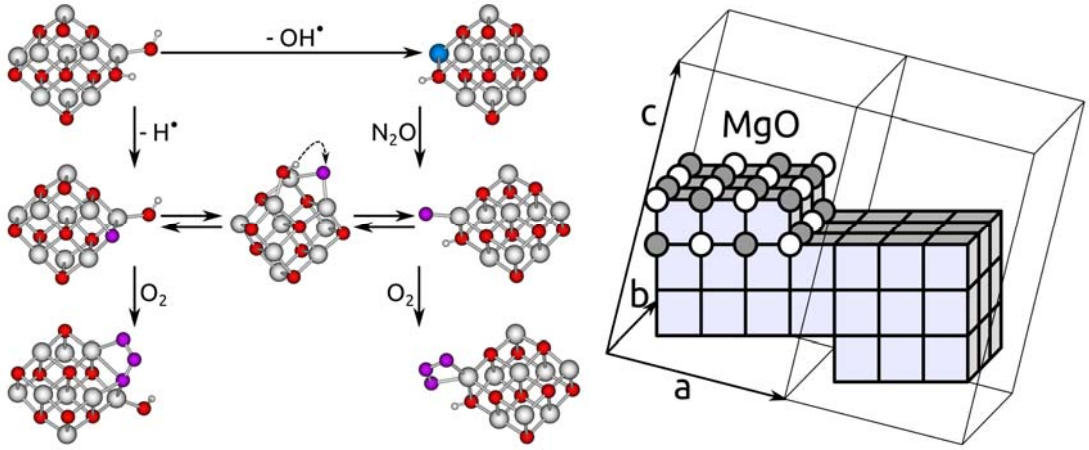

Fig. 1. Quantum-chemical models of radicals on the MgO surface simulated using the molecular cluster approach (left) and the MgO step simulated using a periodic MgO (410) surface slab (right).

4 Conclusions

In conclusion, let us emphasize that under real experimental conditions the surface of oxides always contains some chemisorbed water. So, generation of ion radicals on partially hydroxylated oxide surface due to homolytic dissociation of chemisorbed water seems to adequately describe the mechanisms of many thermal and photostimulated processes resulting in the formation of ion radicals on oxide surfaces.

Keywords: aminomethylphosphine, copper(I), P,N-ligands

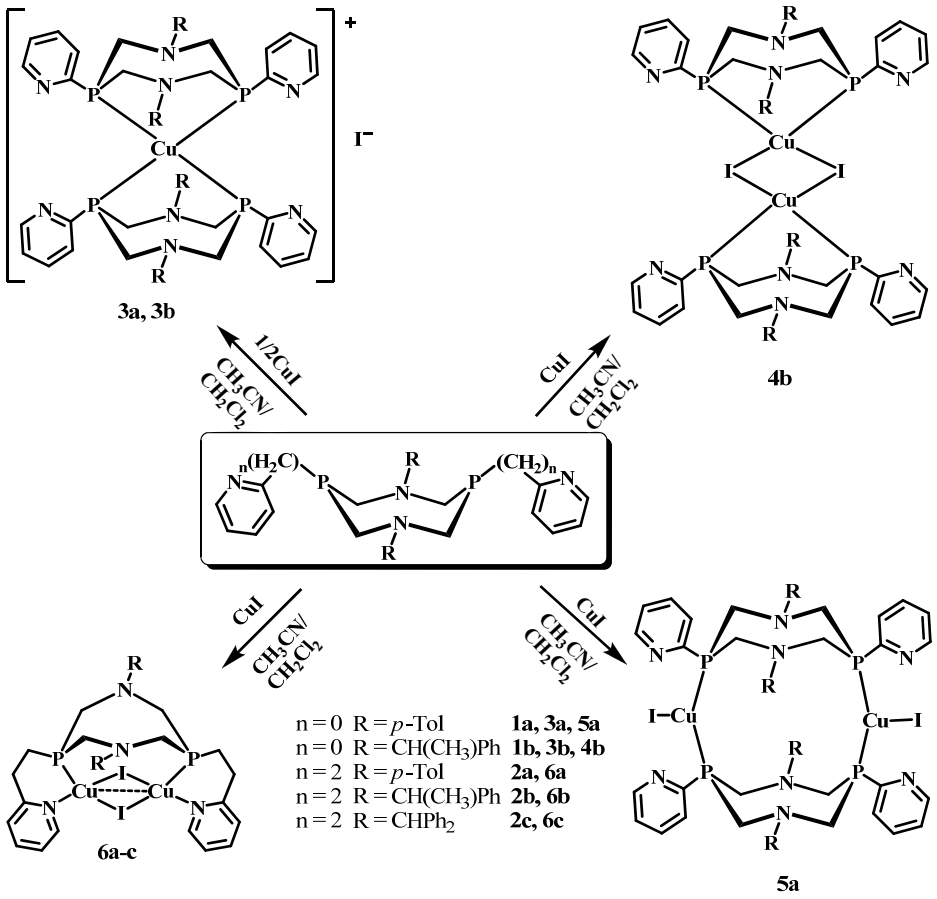
1 Introduction

Coordination systems based on copper halides show a remarkable structural diversity, [1] which arises from the many possible variation of coordination numbers (two, three and four) available for copper(I) and for the geometries that can be adopted by the halide ions and phosphine ligands. The development of the catalytic systems based on phosphine copper(I) complexes is not so intensive as for palladium complexes, but it still presents a perspective area due to the cheapness and availability of the first one [2]. Mostly these catalysts show moderate activity, which is generally surpassed to complexes based on "hard" N and/or O donors. Thus in several years a row of the works dedicated to the catalytic properties of the phosphine copper(I) complexes for the C-N bond formation [3], hydrosilylation [4] and ketalization [5] reactions were published. The system based on the R_2P-N-PR_2 ligand showed the best activity for the amination reactions among the Cu(I) phosphine complexes [3]. The effectiveness of these copper(I) complexes with the additional nitrogen donor center for the C-N cross-coupling reactions motivated us for the construction of the row of novel copper(I) complexes on the basis of pyridylsubstituted 1,5-diaza-3,7-diphosphacyclooctanes coordinated in P,P-bridge, P,N- or P,P-chelate modes and containing at least one uncoordinated nitrogen atom.

2 Results and discussion

New 1,5-diaza-3,7-diphosphacyclooctanes **1-2** were smoothly obtained in the good yields by the condensation reaction of corresponding primary pyridylphosphines, paraformaldehyde and primary amines. The following interaction of **1-2** with copper (I) iodide in dichloromethane at ambient temperature (Scheme 1) readily led to the complexes **3-6.** The ligands steric effect determinates the formation of complexes with various structure. Thus the reaction of **1a** with CuI (1 eq) leads to the P,P-bridged complex **5a**, while the same reaction of **1b** with the bulky chiral α-methylbenzyl substituents gives the dimeric P,P-chelate complex **4b**.

It should be mentioned that the ligands with the *ortho*-pyridyl substituents directly linked to phosphorus atoms show P,P-coordination modes (**3a,b, 4b, 5a)**, while the insertion of the linker between phosphorus atoms and pyridyl groups allows to reach P,N-chelate coordination of the metal (**6a-c**).



Scheme 1.

All obtained complexes have donor atoms in the secondary coordination spheres, which are localized nearly to the metal core, which makes them perspective as catalysts of the hydrosilyilation or amination reactions. Compounds **3-6** will be tested in the C-N cross-coupling reactions in the near future.

3 Conclusions

The row of novel aminomethylphosphines copper(I) iodide complexes with various coordination modes were obtained. It was found that the steric effects of ligands determinates the copper complex structures.

SiO_2 Modified with ZrO_2 as a Complex Support for Cr-Containing Catalysts for Dehydrogenation of Hydrocarbons

Litvyakova N.N., Bugrova T.A., Mamontov G.V.*

Tomsk State University (TSU), Tomsk, Russia

* GrigoriyMamontov@mail.ru

Keywords: complex supports, chromia-containing catalysts, hydrocarbons dehydrogenation

1 Introduction

Many industrial catalysts are composed of one or more active components supported on the surface of support. State and dispersion of active components influence on catalytic properties and depend on many factors. The introduction of the active component on the support surface is the determinative step of the catalyst preparation. Distribution of active component on the surface of support and its state may be controlled by changing of properties of support surface, porosity, the precursor nature and amount of the component introduced.

Silica is one of the most widely used supports for heterogeneous catalysts because of its high specific surface area and pore volume. However, the application of silica supports is limited by complexity to stabilize active component in desirable state. Therefore, the modifying of silica by transition metal oxides with suitable surface properties is one of the ways to improve the properties of catalysts.

The aim of this work is to study the distribution of zirconia modifier and active component CrO_x on the surface of silica, depending on the amount of oxide introduced, silica pre-treatment conditions as well as activity of prepared Cr-containing catalysts in the isobutane dehydrogenation. Silica with wide mesopores (10-50 nm) was used as a primary support, providing the desired porous structure of catalyst, while zirconium oxides were used as a secondary support, providing the required functional properties for active component stabilization.

2 Experimental

Mesoporous silica (KSKG) was used as a primary support. A series of $nZrO_2/SiO_2$ supports where n was 0.5, 1 or 2 monolayers (one monolayer corresponds to 5 Zr atoms per nm^2 of support) were prepared by impregnation method using aqueous solution of $ZrO(NO_3)_2*2H_2O$ stabilized with citric or hydrochloric acids. Then the samples were dried at 80°C for 12 hours and calcined at 600°C for 4 hours. Cr-containing catalysts were prepared by impregnation of initial silica and ZrO_2/SiO_2 supports by aqueous solution of H_2CrO_4 and KNO_3 (Cr/K molar ration was 5/1). The content of chromium oxides was 1 monolayer (5 Cr atoms per nm^2) that corresponds to 6.1-7.0 %wt. of Cr_2O_3. CrO_x/ZrO_2 catalyst was prepared as a reference.

Pore structure of the supports and catalysts was studied by low-temperature N_2 sorption. Chemical state of Cr was studied by electron diffuse reflectance spectroscopy (UV-vis), TPR, XRD and XPS. Catalytic properties of the prepared catalysts were measured in isobutane dehydrogenation in a bed fixed reactor at ambient pressure.

3 Results

On the basis of N_2 sorption results it was shown that the nature of acid (citric and hydrochloric) stabilizing the zirconia precursor influence on its distribution in pores of silica. A series of ZrO_2/SiO_2 mixed support with specific surface area of 100-120 m^2/g and pore volume

of 0.6-1.0 cm^3/g had mesopores with sizes of 2-60 nm.

Formation of α-Cr_2O_3 particles was observed by XRD and UV-vis for CrO_x/SiO_2 catalyst. Addition of ZrO_2 onto silica surface led to decreasing of Cr_2O_3 loading and increasing of amount of Cr(VI) species.

Results of catalytic tests are shown in Fig. 1. The activity of Cr/ZrO_2 (rate of isobutene conversion per 1 mol of chromium) is higher in comparison with the one of CrO_x/SiO_2 catalyst. Addition of zirconia in CrO_x/SiO_2 catalyst led to significant increasing of catalytic activity. It was associated with increasing of amount of Cr(VI) species in the presence of zirconia (UV-vis and TPR).

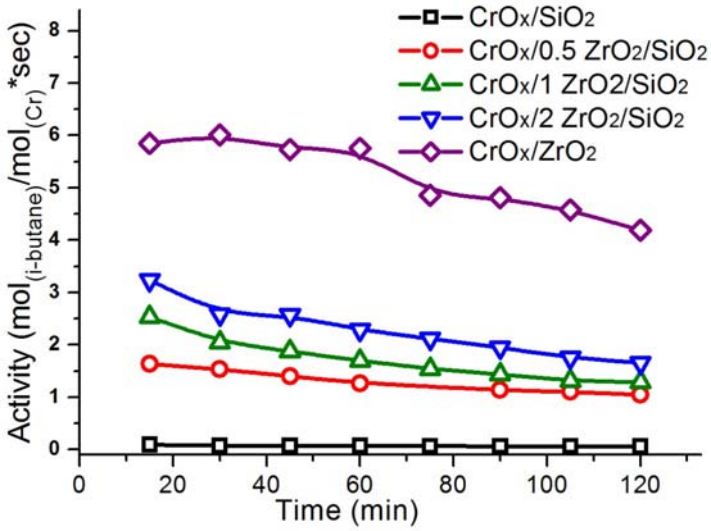

Fig. 1. Activity of Cr-containing catalysts in isobutene dehydrogenation

4 Conclusions

Thus, new approach to develop mixed ZrO_2/SiO_2 supports for Cr-containing catalyst for dehydrogenation of hydrocarbons was suggested. It was shown that ZrO_2/SiO_2 supports with high specific surface area and porosity may be prepared by simple impregnation technique and used as supports for Cr-containing catalyst. Elevated activity of $Cr/ZrO_2/SiO_2$ catalysts is associated with increasing of amount of Cr(VI) species stabilized by ZrO_2 surface.

Keywords: ceria, alumina, rhodium, catalytic partial oxidation, natural gas, syngas

1 Introduction

The catalytic partial oxidation (CPO) of CH_4 to syngas is an exothermic process that achieves high CH_4 conversion and selectivity to syngas at short contact times and autothermally [1]. However, the harsh reaction conditions may lead to catalyst deactivation. A lot of efforts have been devoted to develop active and stable catalysts also reducing the formation of hot spots [2]. Rh is the most active metal and its performances are related to the support and preparation route. γ-Al_2O_3 shows large specific surface area, making it possible to obtain highly dispersed metallic particles. On the other hand, its acidic character promotes carbon formation and it suffers from phase changes at high temperatures, leading to the sintering and deactivation of the catalyst. The stabilization of γ-Al_2O_3 by addition of Ce is well-known [3] and the chemical role of Ce in the evolution of CPO was reported [4]; however the modification of the performances due to the changes in surface area and Rh dispersion could not be investigated. In this work, we studied the role of Ce content (0, 5, 10 and 20 wt.%) on chemical-physical and catalytic properties of Rh-CeO_2-Al_2O_3 catalysts (0.25 wt.% Rh) under harsh CPO reaction conditions.

2 Experimental/methodology

Precursors of Rh-CeO_2-Al_2O_3 catalysts were prepared by coprecipitation at constant pH (9.5) of an aqueous solution of $Ce(NO_3)_3$, $Al(NO_3)_3$ and $Rh(NO_3)_3$. Catalysts were obtained by calcination at 900ºC for 12h and were labelled Rh*x*CeAl_2O_3, where x is the Ce wt.% (0, 5, 10 and 20 wt.%). Samples were characterized by PXRD, N_2 adsorption/desorption, Micro-Raman Spectroscopy, TPR, HRTEM, XPS and Cyclohexane Dehydrogenation (CHD) test reaction.

CPO tests were performed, after catalyst reduction, with a natural gas mixture (90 % v/v CH_4, 7 % v/ C_2H_6 and 3 % v/v C_3H_8) at 1.2-1.4 bar, τ= 5 ms and C/O = 1. The oven temperature (T_{oven}) was set at 500 and 750ºC, modifying the gas mixture ($C/O_2/N_2$= 2/1/20 and 2/1/4 v/v).

3 Results and discussion

A mixture of γ-, η- and δ-Al_2O_3 phases were identified in Rh-Al_2O_3; while Rh*x*CeAl_2O_3 samples contained both Al_2O_3 and CeO_2 fluorite-type phases. The intensity of CeO_2 lines increased with the Ce loading; but their broadness suggested a high CeO_2 dispersion in the Al_2O_3 support. Nevertheless the presence of large amounts CeO_2 reduced the surface area, it decreased from 142 to 116 m^2g^{-1} in 5 and 20 wt.% Ce-loaded samples, respectively.

Three different Rh species were identified by TPR in $RhAl_2O_3$: segregated Rh_2O_3, well dispersed Rh^{3+} species, and rhodium aluminate. Rh*x*CeAl_2O_3 samples showed the reduction profile characteristic of CeO_2-Al_2O_3 based catalysts, with H_2 consumption peaks related to the reduction of Rh^{3+} species, surface and bulk CeO_2, and formation of $CeAlO_3$. The higher the Ce loading, the more intense the $CeAlO_3$ peak and the higher the reduction temperature.

The presence of a small amount of Ce (5wt.%) increased the number of available Rh^0, as evidenced by CHD. Moreover, HRTEM images indicated the formation of Rh nanoparticles in

all reduced samples, although the size slightly increased with the Ce loading. XPS confirmed the formation of Rh^0 during the catalyst pretreatment. On the other hand, the oxidation state of Ce depended on its content, while in $Rh20CeAl_2O_3$ reduced sample both Ce^{3+} and Ce^{4+} species were identified, XPS suggested that in $Rh5CeAl_2O_3$, Ce^{4+} was completely reduced to Ce^{3+}.

CPO tests evidenced that the differences in chemical-physical properties of the samples determined the catalytic performances (Fig. 1). In the initial test, T_{oven} = 500ºC and 2/1/20 v/v mixture, similar conversion values were achieved with $RhAl_2O_3$ and $Rh5CeAl_2O_3$ samples, while increasing the Ce content the activity decreased. The differences were smoothed during tests at 750ºC with a concentrated 2/1/4 v/v mixture; however, conversion was still lower over $Rh20CeAl_2O_3$ and this sample deactivated with time-on-stream. Selectivities in H_2 and CO were high and followed a similar trend than conversion.

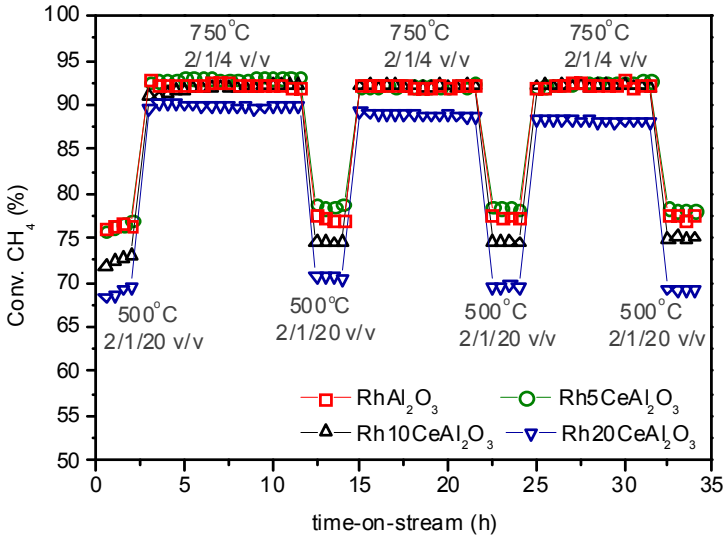

Fig. 1. Evolution of conversion of CH_4 with time-on-stream for all the catalysts studied

The characterization of spent catalysts revealed that the transition from metastable Al_2O_3 to α-Al_2O_3, taking place in $RhAl_2O_3$, was inhibited in all the Ce-containing catalysts. CeO_2 was not detected by XRD, while $CeAlO_3$ was only identified in the highest Ce-loaded sample. A loss of area occurred in $RhAl_2O_3$ and $Rh20CeAl_2O_3$, while for the 5wt.% Ce sample surface area values before and after tests were quite similar. Lastly, Raman spectroscopy confirmed the presence of carbon only in the $RhAl_2O_3$ and the full reduction of CeO_2 during CPO tests.

4 Conclusions

CeO_2 was dispersed in Al_2O_3 modifying the surface area, Rh dispersion, γ-Al_2O_3 stability and catalytic performances. A high Rh dispersion and catalytic performances, can be achieved by addition of 5 wt.% Ce, also avoiding both carbon deposition and α-Al_2O_3 formation. Contrarily a further increase in the Ce content affected negatively to the chemical physical properties and catalytic performances.

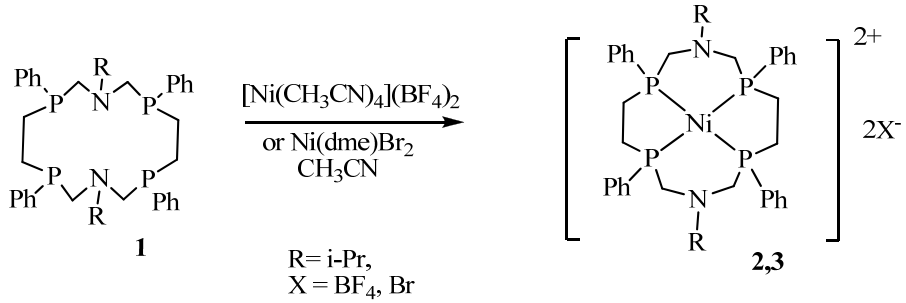
Keywords: dissociation, acid catalysis, Ni(II), complexes, P,N–ligands, cyclic aminomethylphosphines

1 Introduction

The expanded use of energy from intermittent renewable energy sources such as solar and wind will require the ability to efficiently convert electricity to chemical energy for storage as fuels. [1] Nickel and cobalt diphosphine complexes that incorporate a positioned base in the ligand have been found to be active electrocatalysts for hydrogen production in acidic acetonitrile solutions.[2] The amine base positioned near the metal center has been proposed to function as a proton relay that facilitates the formation or cleavage of the H-H bond. Ni(II) complexes of 1-aza-3,6-diphosphacycloheptanes were found to be very effective catalysts for hydrogen production.[5]

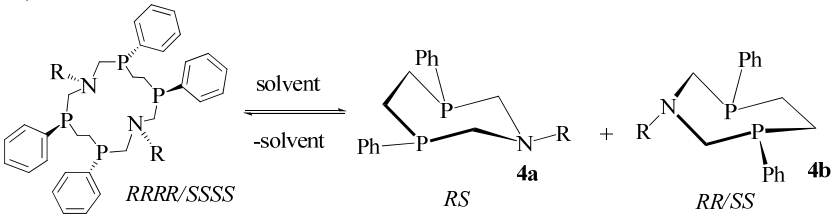
2 Results and discussion

Here we report the synthesis of novel seven-membered cyclic P,N-ligands with alkyl substituents on the nitrogen atoms and their Ni(II) complexes. Unexpectedly reaction of the bis(phenylphosphino)etane with formaldehyde and iso-propylamine gives 14-membered 1,8-diaza-3,6,10,13-tetraphosphacyclotetradecane (**1**) [4,5] instead of expected 7-membered 1-aza-3,6-diphosphacycloheptanes. However macrocyclic Ni(II) complexes of **1** (Scheme 1) did not show the noticeable catalytical activity for the electrochemical hydrogen oxidation or production.



Scheme 1 Synthesis of complexes **2**, **3**

We found that 14-membered aminomethylphosphine **1** was unstable in the solution and underwent nearly quantitative the interconversion to desired 1-aza-3,6-diphosphacycloheptanes 4**a**, 4**b** (Scheme 2).



Scheme 2 The dissociation of 14-membered aminomethylphosphine **1**

We supposed that the rate of the dissociation of **1** will be increased by an acid catalysis. Indeed if 10 mol% CH_3PhSO_3H was added the rate of dissociation increased. Under the acid-free conditions the dissociation proceeds during 650 hours (Fig.1a), while the acid-catalyzed dissociation reached the final point after 150 hours (Fig.1b).

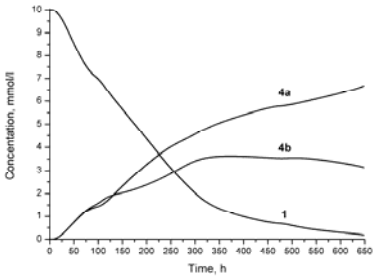


Fig.1a Dissociation in normal conditions

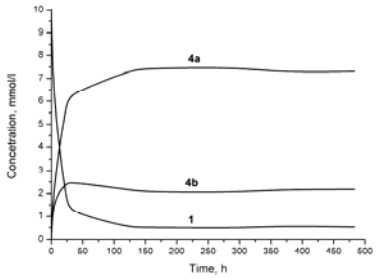

Fig.1b Dissociation with addition of CH_3PhSO_3H

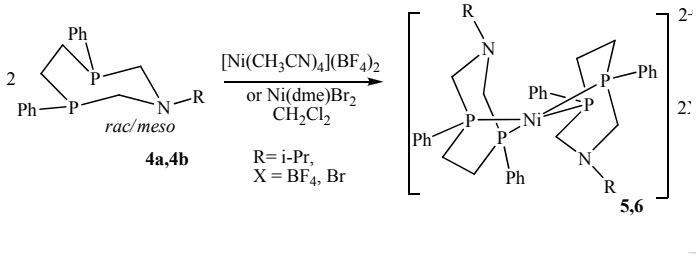
The complexes **5**, **6** were obtained by the reaction of 7-membered aminomethylphosphines **4a, 4b** with Ni (II) complexes (Scheme 3) in dichloromethane. The structure of the complex **5** was established by X-ray diffraction analysis (Fig.2)



Scheme 3 Synthesis of complexes **5**,**6**

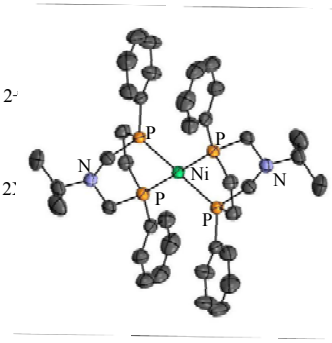


Fig. 2 Complex **5** cation

It should be mentioned that structure of obtained complexes **5** and **6** are similar to that of described effective potential catalysts of electrochemical H_2 production [3].

Keywords: Cu-ZSM-5, hollow particle, core-shell particle, nanoscale, Kirkendall effect

1 Introduction

In the past decade zeolites with different morphology are considered as matrix for stabilization of oxide and metal nanoparticles of transition and noble metals, e.g., Cu, Ag, Au and others [1, 2]. Nanoparticles are known to possess unique optical, magnetic, redox and catalytic characteristics.

Current communication is devoted to study of oxidation processes of metal (Cu, Ni, Co) nanoparticles supported on ZSM-5 zeolite, aiming to find correlation between structures of metal-oxide particles, such as core/shell, hollow and bulk, and oxidation conditions. The TPR-H_2, XRD in situ, HRTEM, XPS, UV-Vis DR, and the optical spectra modeling were used to confirm the hypothesis about the structure of metal-oxide particles over zeolite. The CO and NO oxidation as well as NO SCR by propane were employed to examine catalytic characteristics of different metal-oxide particles.

2 Experimental

The Cu-, Ni- and Co-containing ZSM-5 samples were reduced in hydrogen-containing mixture at 200 - 700^{o}C; and then subjected to oxidation at 25, 100, 300, 500 и 700^{o}C in air, dry oxygen or moist oxygen stream. Metal content was 2.5 wt%.

The TPR-H_2 experiments were conducted with mixture 10% H_2 in argon and heating rate 10^o/min, before and between experiments the samples were pretreated in situ in oxygen at the temperature specified above. DR UV-Vis spectra were obtained at room temperature using a "Shimadzu" UV-2501 PC spectrophotometer equipped with a diffuse reflectance accessory (ISR-240 A). HRTEM images were obtained using a JEOL Model JEM-2010 electron microscope with an accelerating voltage of 200 kV and a lattice resolution of 0.14 nm. Chemical composition of sample surface were studied using a photoelectron spectrometer (SPECS Surface Nano Analysis GmbH) equipped with a high-pressure cell that allowed us the heating of samples at 200 - 400^{o}C in H_2 or O_2 containing mixtures. The sample XRD composition during Reduction/Oxidation were registered on the station of time-resolved diffraction (station ''5b'' at the VEPP-3 storage ring, BINP, Novosibirsk).

CO (0.1 vol%) and NO (400 ppm) oxidation tests were carried out as TPR mode. Heating rate was 10^{o}C/min. Selective catalytic reduction of NO (NO-SCR) by propane (320 ppm NO, 1500 ppm C_3H_8, 3.2 vol.% O_2 in N_2) was studied using a flow reactor at 42000 h^{-1} and temperatures 200–550 ^{o}C.

3 Results and discussion

Nanoscale Kirkendall effect is illustrated with reference to 2.85%Cu-ZSM-5 sample (Fig.1). The phenomenon was revealed at low-temperature (up to 100^{o}C) oxidation of 10-20 nm Cu^0

particles located on a surface of zeolite crystallites. Hollow metal-oxide nanoparticles (Fig.1B) are formed from core/shell nanoparticles containing the 3-5 nm Cu_2O layer on a surface of a copper nanoparticle (Fig.1A) due to different diffusion coefficients. At oxidation temperatures 300°C and above, bulk CuO particles near 40 nm are only formed (Fig.1C). When size of Cu^0 particles is 40-50 nm and higher, the core/shell nanoparticles are resistant to further oxidation. The Cu^0-Cu_2O-CuO transformations are identified by XRD in situ and XPS.

The core/shell, hollow and bulk Cu-oxide particles have different optical, redox and catalytic properties. DR UV-Vis spectra showed a shift of plasmon absorption from 17500 to 15800-16500 cm^{-1} at oxidation of Cu^0 to core/shell particles. A fundamental absorption edge (FAE) of Cu_2O nanoparticles (22200 cm^{-1}) and an adsorption bands corresponding d-d transition (13000-15700 cm^{-1}) and a ligand-metal charge-transfer (CTB) of square-planar copper(II)-oxide clusters (29500 cm^{-1}) were observed in spectra of samples with hollow CuOx particles. The 40-50 nm CuO nanoparticles are shown blue-shift of optical band gap compared with bulk CuO phase (2.3-3.1 against 1.85eV).

The core/shell and hollow CuO_x particles are more reducible in H_2-TPR experiment compared with CuO nanoparticles and CuO phase, 165 – 185°C against 235°C.

Catalytic performance of the core/shell and hollow CuO_x particles supported on ZSM-5 in oxidation of CO, NO and propane are found to correlate well with their redox behavior. While in NO-SCR by propane the core/shell and hollow CuO_x particles supported on ZSM-5 were less active in comparison with the Cu-substituted ZSM-5.

Similar nanoscale effects are also observed during oxidation of the Ni and Co nanoparticles supported on ZSM-5 zeolte. Kirkendall effect for Ni nanoparticles was detected at low-temperature oxidation, while the core/shell and hollow CoO_x particles were formed at higher temperatures.

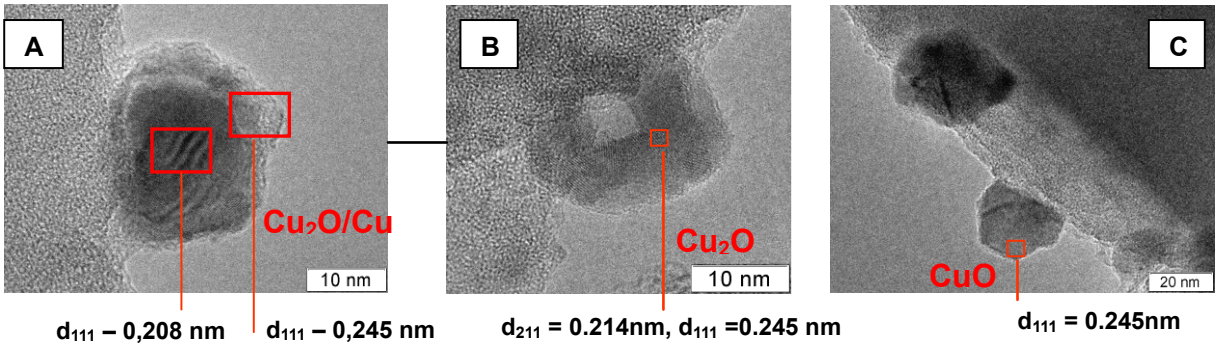

Fig.1. TEM images of copper nanoparticles formed during oxidation of 10-20 nm Cu^0 at different temperatures: core/shell Cu^o/Cu_2O-CuO (A), hollow Cu_2O (B) and bulk CuO (C).

4 Conclusions

2D and 3D metal-oxide nanoparticles are formed at oxidation of nanoparticles of Cu, Ni and Co. Their structures and properties are found to significantly depend on oxidation temperature.

Keywords: Co supported catalyst, multi-wall carbon nanotubes, internal field, ^{59}Co NMR

1 Introduction

Over the last few years, the interest to carbon nanostructures has grown enormously that mostly relates to the numerous searches of possible industrial applications. Among large variety of carbon nanomaterials, carbon nanotubes (CNTs) attract a special attention. Due to unique mechanical properties, large specific surface area, high electrical and thermal conductivity, and chemical stability, CNTs can be considered as a key component in different composites, in various electrochemical devices (lithium-ion batteries, supercapacitors) and for different applications in catalysis as supports. CNTs could be utilized as supports for various catalytic processes. For instance, one of the promising directions is Fischer-Tropsch synthesis (FTS) in the form of cobalt catalysts supported on CNTs [1]. High thermal conductivity of MWCNTs makes them also attracting as supports for the development of new catalysts of FTS avoiding overheating of the catalyst bed. In the present work, the structure of cobalt systems based on the perspective carbon supports, functionalized multi-wall carbon nanotubes (MWCNTs), has been investigated. The special attention has been applied to characterize Co species fixed on the surface of MWCNTs by the internal field (IF) ^{59}Co NMR.

2 Experimental/methodology

MWNTs were synthesized by CVD of ethylene decomposition over the bimetallic Fe-Co catalysts at 680°C. We have used functionalized MWCNTs containing surface carboxylic groups (0.76 groups per 1 nm^2) produced via boiling concentrated nitric acid (denoted as MWNT-Ox-NA) [2]. Co-containing samples were prepared by impregnation of MWCNTs (surface area of 305 m^2/g, average particle diameter of 9.4 nm) with the aqua solutions of Co (II) salts followed by calcination under an inert atmosphere and reduction in a stream of hydrogen at the temperature of 350°C. The samples with Co concentrations: 3.5, 7.3, 11.7 and 14.5 wt. % were obtained. The structure and morphology of pure and Co-containing MWCNTs was monitored by TEM. The structure of the cobalt metal in the catalyst after the reduction was investigated by IF ^{59}Co NMR providing information about the structural (FCC, HCP, and stacking faults - sfs) and magnetic (magnetic domains and domain walls) features.

3 Results and discussion

The sample 3.5% Co/MWCNT-Ox-Na mainly contains Co-oxide particles within the channels of MWCNTs of 3-5 nm in the size. The particle size is not increased after the reduction in hydrogen. The increase of Co content (within the range 3.5 up to 14.5 wt. %) leads to the growth of Co^0 particle sizes from 5-10 nm to 50-80 nm. The studied samples show both types of Co metal particles as inside the MWCNTs with certain diameter of 5 nm as maximum and various lengths, and Co metal particles located on the surface.

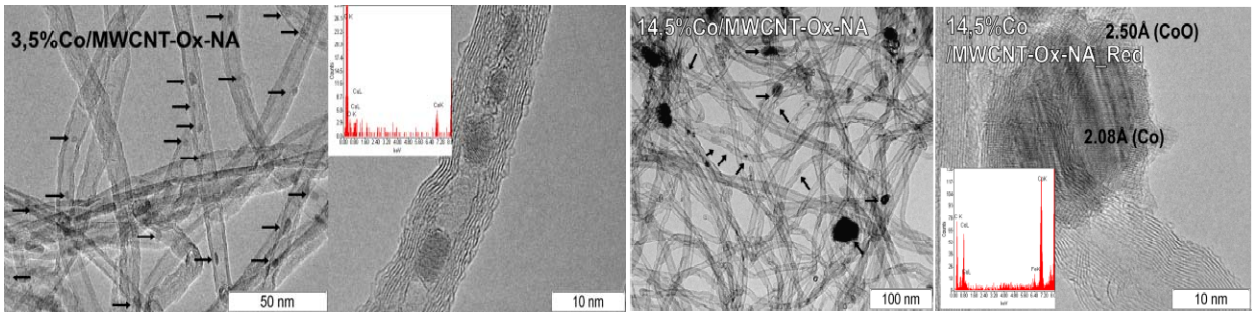

Fig. 1. TEM images of 3.5 and 14.5 wt.% Co/MWCNT-Ox-NA, correspondingly. Arrows show Co particles inside and outside nanotube channels.

The IF ^{59}Co NMR data shown in Fig 2 allow to discern 5 different signals in spectra (2D distribution helps determining the number of resonances) from HCP and FCC Co metal stacking, magnetic domains and domain walls (d.w.). The d.w. resonances state the existence of large Co particle of more than 70 nm in size [3]. Returning to the present work, the d.w. reflects filled with Co metal MWCNTs where diameter is restricted by internal tube size (~5 nm), however the length reaches 100 nm.

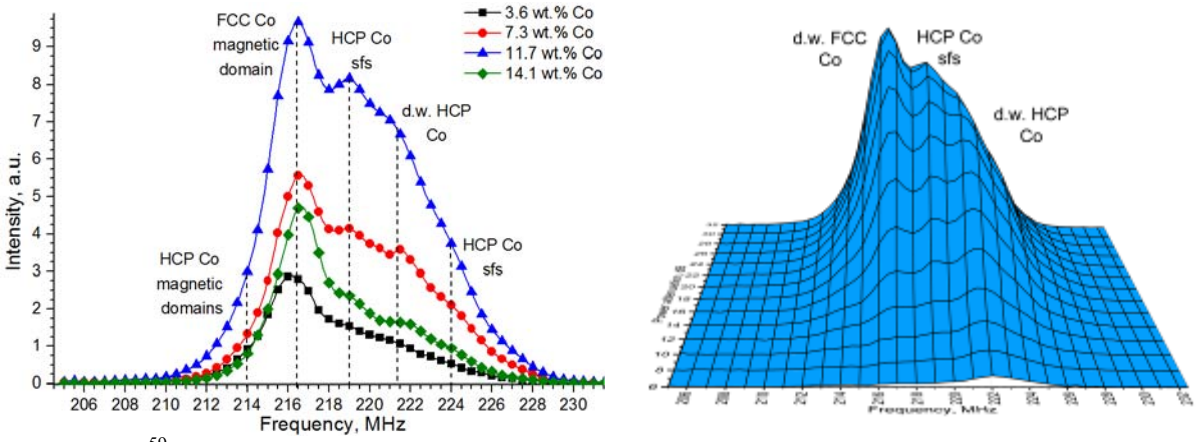

Fig. 2. IF ^{59}Co NMR spectra of studied samples (left) and 2D spectrum (right).

4 Conclusions

Varying the deposition conditions gives cobalt particles both inside the internal channels of the tubes and on the external surface. Co particles inside the channels of MWCNTs have an elongated and rounded shape and the average diameter of 2–3 nm. IF ^{59}Co NMR gives five different types of metallic Co particles. The increase of Co concentration leads to the decrease in the relative content of Co in a cubic stacking, resulting the increase of the HCP/FCC ratio from 1.0 to 1.7. The increase of the portion of magnetic domain walls of HCP suggests the presence of elongated particles up to 100 nm inside the MWCNTs.

Keywords: paraffins, dehydrogenation, olefins, carbon, dioxide, gallium oxides catalysts

1 Introduction

Gallium supported oxides are effective catalysis for dehydrogenation of light paraffins. Side processes, such as cracking and coke formation, decrease yield of olefins. Silica framework using as support is characterized by good resistance to coke formation. This work devoted to the comparison of gallium catalysts prepared by wet impregnation on silica and direct one-pot synthesis embedding Ga species in the siliceous mesoporous framework of MCM-41 for process of propane dehydrogenation. The process was also studied in the presence of CO_2 which can interact with hydrogen, forming at propane dehydrogenation, what results in the shift of reaction equilibrium, and partly oxidizes coke and catalyst surface.

2 Experimental

Catalysts were prepared by wet impregnation of silica (KSKG) from water solutions of gallium nitrates and direct one-pot synthesis embedding Ga species in the siliceous mesoporous framework of MCM-41. Catalysts under investigation are contained 5.0-40.0%Ga on SiO_2 and 1.0-3.0%Ga in MCM-41. Catalyst structure and adsorption properties were controlled by X-ray diffraction, N_2 adsorption, TPR-H_2 and FTIR. Long-duration tests of catalysts were carried out in a flow reactor at 600°C, volume space velocity 200 h^{-1}, atmospheric pressure and at initial reaction composition (%, vol.): (C_3H_8) (15), CO_2 (30), N_2 (55). Before the reaction all catalysts were activated in O_2 flow at 600°C for 6 hours. The reaction products were analyzed by GC methods using two columns – molecular sieves 5A (H_2, N_2, CH_4, CO) and Porapak-Q (CO_2, hydrocarbons C_1-C_3). After each experiment the catalysts were regenerated in O_2 flow at 600°C for 10 hours. Unstationary phenomena were investigated using the transient response method in the flow reactor of small volume connected with mass-spectrometer. Relaxation curves describing a transition of the system to a new steady state were obtained by a jump change of the corresponding concentrations. The partial pressures of C_3H_8 and CO_2 were changed in the limits 0.125-0.33 and 0.30-0.75 atm., respectively, temperature was 600°C. Some adsorption-desorption tests of the reaction components and experiments on replacement of C_3H_6 by CO_2 and opposite had been also done at 200°C. For all the experiments the relaxation time was lower than the turnover time. Thus, it allows characterizing all observed relaxations as own ones.

3 Results and discussion

Results of investigations on propane dehydrogenation in the presence of CO_2 over studied catalysts showed (Fig. 1) that catalysts prepared by one-pot method demonstrate considerably more high specific activity and stability in propene formation than the catalysts made by wet impregnation. According to TPR-H_2 data, catalysts Ga-MCM are characterized by high dispersity. It was shown in [1] that high metal dispersity (Ni) in silica framework is accompanied by an intense decrease of coke formation. We observed the analogical effect. One of reasons of it can be a decrease of possibility for interaction between adsorbed olefins and further growth of chain because of an increase of distance between centers of their adsorption.

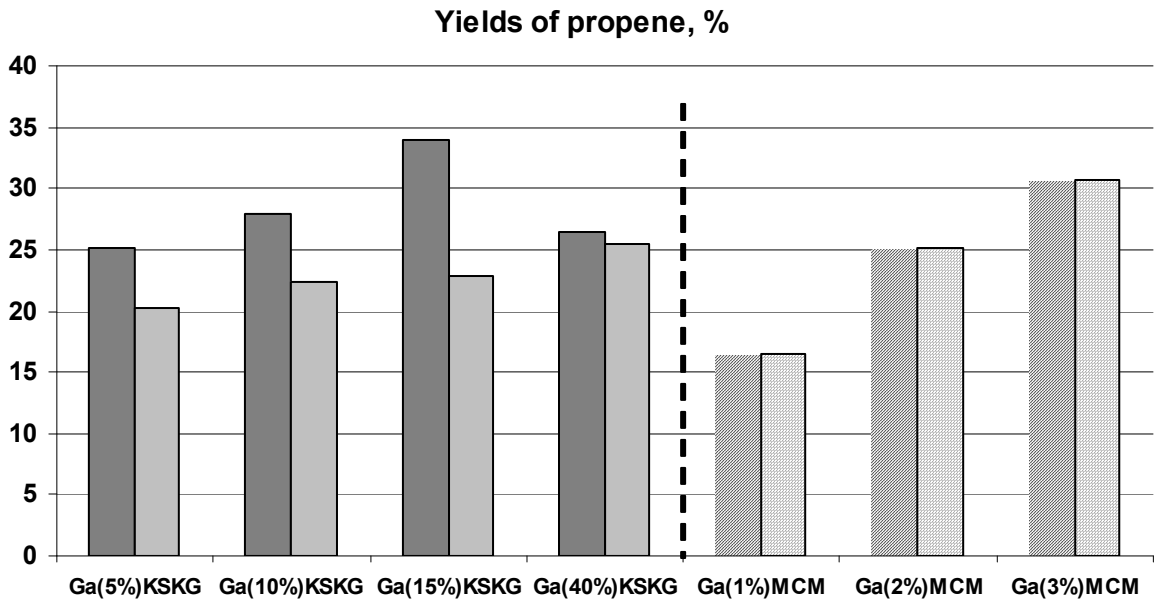

Fig. 1. The initial yields of propene (d after 300 min of work ( ) at dehydrogenation of propane over Ga-catalysts prepared by different methods

Dehydrogenation of propane over gallium catalysts proceeds through heterolytic dissociation reaction pathway with the formation of Ga-hydrides [2]. In this case CO_2 would have the negative influence on this process due to its oxidized properties and can inhibit the hydride formation. Really, this effect is detected in stationary and unstationary experiments: the propene yield was more high in the CO_2 absence for all studied catalysts.

The comparison of responses $(He+C_3H_6)/(He+CO_2)$ and $(He+CO_2)/(He+C_3H_6)$ at 200°C per the time of replacing one component by another showed that CO_2 is tied more firmly than C_3H_6. It was shown that amounts of cracking products are decreased in CO_2 presence also over all catalysts. Also it is shown that the delay of C_3H_6 appearance in gas phase is increased in the following row of responses: $[He/(C_3H_8+He)] < [He/(C_3H_8+CO_2)] < [(He+CO_2)/(C_3H_8+CO_2)]$. Thus, CO_2 precludes the interaction of propane with an active surface.

4 Conclusions

The advantages of Ga-catalysts, prepared by direct one-pot method before catalysts obtained by wet impregnation, are demonstrated in this work. The specific activity and stability of Ga-MCM catalysts are higher but coke formation is less because of high dispersity and strong bond of active phase with the support.

It was shown that the use of CO_2 at paraffin dehydrogenation is limited because of it precludes an interactions of paraffins with active centers reducing an yield of olefin.

Keywords: palladium nanoparticles, nanocapsules, catalysis, viologen

1 Introduction

The results of last years show that the nanosized metal particles demonstrate higher catalytic activity compare to bulk metal due to larger surface to volume ratio. It involves many researches to create new catalytic nanosystems with different shape and properties. [1] The most promising systems showing high stability and catalytic activity are nanocomposites on base of polymer and metal nanoparticles. [2]

In this presentation, we will demonstrate our last results concerning the creation of new catalytic hybrid nanocomposites of palladium nanoparticles stabilized on the surface of polymeric nanocapsules.

2 Experimental/methodology

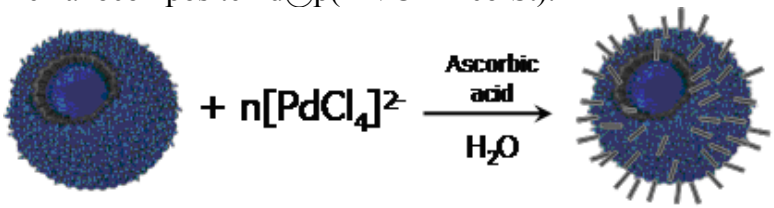
Polymeric nanoparticles was synthesized as described in [3]. The nanocomposite Pd@p(MVCA^{8+}-co-St) was obtained using the modified method [4]. Pd@p(MVCA^{8+}-co-St) was characterized by the physical and chemical method of IR-, NMR- spectroscopy, transmission electron microscopy (TEM), scanning electron microscopy (SEM), Energy-dispersive X-ray spectroscopy (EDX), dynamic light scattering DLS.

NMR spectroscopic experiments were carried out with an Avance 600 spectrometer (Bruker, Germany) equipped with a pulsed gradient unit capable of producing magnetic-field pulse gradients in the z direction of about 56 Gcm^{1}. D_2O was used as a solvent in all experiments. Chemical shifts were reported relative to HDO (d= 4.7 ppm) as an internal standard. UV/Vis spectra were recorded with a Perkin–Elmer Lambda 25 UV/Vis spectrometer. Fluorescence emission spectra were recorded with a Cary Eclipse fluorescence spectrophotometer (USA). Imaging of the polymer nanocapsules with and out palladium nanoparticles probe microscope (Veeco). The morphology of the implanted structured silicon surfaces were characterized in plan-view by scanning electron microscopy (SEM) using high-resolution microscope Merlin Carl Zeiss combined with ASB (Angle Selective Backscattering) and SE InLens (Secondary Electrons Energy selective Backscattering) detectors, which was also equipped for energydispersive X-ray spectroscopy (EDX) analysis with AZTEC X-MAX energy-dispersion 5 spectrometer from Oxford Instruments.

3 Results and discussion

For the creation of new catalytic nanocomposite, the polymeric nanoparticles decorated with viologen groups (p(MVCA^{8+}-co-St)) were chosen. p(MVCA^{8+}-co-St) effectively binds with negative charged metal complexes $PdCl_4^{2-}$ due to electrostatic forces. The soft reduction of $PdCl_4^{2-}$ leads to the formation of Pd nanoparticles stabilized with p(MVCA^{8+}-co-St)

(Pd@p(MVCA^{8+}-co-St)) (Scheme 1). The TEM image (Fig. 1A) show that Pd nanoparticles with the size about 10 nm decorate the surface of the polymer nanoparticles p(MVCA^{8+}-co-St) to form the flower like nanocomposite Pd@p(MVCA^{8+}-co-St).



Scheme 1. Synthesis of p(Pd@MVCA8+-co-St).

The catalytic properties the nanocomposites were examined on the reaction of reduction of *p*-nitrophenol by $NaBH_4$ in water. The reduction of *p*-nitrophenol is a conventional reaction for the evaluation of catalytic activity. [5] The results show that Pd@p(MVCA^{8+}-co-St) shows very high catalytic activity. Six nanomoles of palladium in Pd@p(MVCA^{8+}-co-St) is enough for the completely reduction of nitrophenol during 10-15 minutes.

The synthesis, characterization and catalytic properties of Pd@p(MVCA^{8+}-co-St) nanocomposited will be discussed in the presentation.

A B

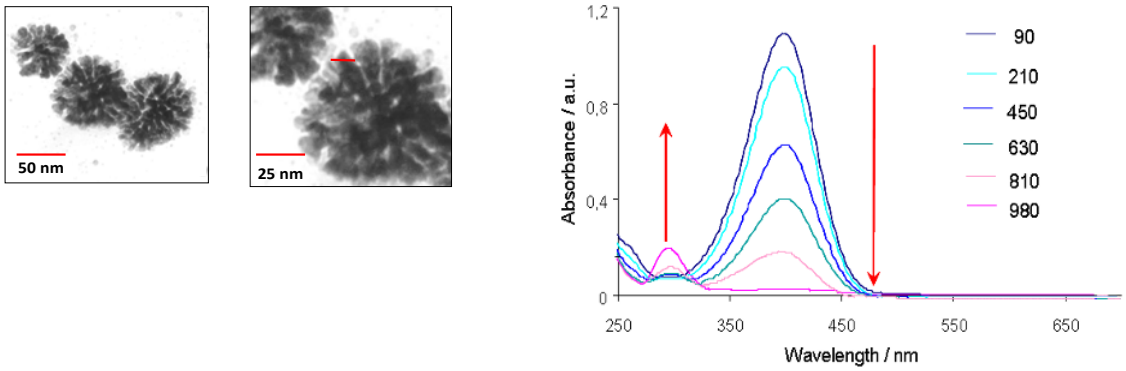


Fig. 1. A) TEM images of Pd@p(MVCA^{8+}-co-St). B) UV−vis spectra of Pd@p(MVCA^{8+}-co-St) at various reaction times.

4 Conclusions

We demonstrated a new method to prepare new hybrid nanomaterials. The Pd@p(MVCA^{8+}-co-St) obtained, exhibits a high catalytic activity. In the future, we plan to investigate this catalyst in other reactions.

Cu(111) Chlorination on Atomic Scale: Adsorption, Diffusion, and Desorption

Pavlova T.V.*, Zhidomirov G.M., Eltsov K.N.

A.M. Prokhorov General Physics Institute RAS, Department Of Technologies And Measurements On Atomic Scale, Moscow, Russia

* pavlova@kapella.gpi.ru

Keywords: reaction, dynamics, thermal desorption, atomic structures, chlorination, DFT

1 Introduction

In heterogeneous catalysis, 3d metals are often used as catalysts and halocarbons - as promoters. After dissociation of adsorbed halocarbon molecules, all steps of surface transformations for molecule radicals and halogens are needed to understand. In particular, halogens desorption process is rather interesting. For copper as catalyst and for chlorine as promoter, we have contradictory information about desorption process. Conclusion that chlorine desorbs as atoms is made on the base of thermal desorption spectroscopy (TDS) experiments [1] and Density Functional Theory (DFT) calculations [2]. On the other hand, only cooper chloride was detected in thermal desorption spectra for chlorinated Cu(111) and Cu(100) in [3,4]. Taking into account that chlorinated cooper surface is catalyst in 1,2-dichloroethane production as a part of industrial oxychlorination reaction, the resolution of this contradiction is important.

2 Calculation details

To understand surface processes at the atomic level, we carried out detailed *ab initio* theoretical study of different steps of Cu(111) chlorination: Cl_2 adsorption, Cl and Cu atoms diffusion, surface structure transformations, and thermal desorption of reaction products. All DFT calculations were carried out with Vienna Ab initio Simulation Package (VASP) [5]. Energy barriers are evaluated with Nudged Elastic Band (NEB) method [6]. Range of chlorine coverage on Cu(111) was used from separate atoms to saturated monolayer. In contrast to the previous study [2], we consider Cl atoms not only on perfect Cu(111) surface, but also near defects like Cu adatoms and step edges. All atomic structures were modeled in accordance with experimental STM images obtained in [3]. Several scenarios have been tested.

3 Results and discussion

The most energetically favorable adsorption sites for chlorine are steps, where the Cl atom is attached to two Cu atoms on the step edge, directly above one Cu atom from terrace. On terraces, Cl adsorption is preferred at surface defects like adatoms. Ideal (111) surface is occupied by Cl in fcc sites, coupled Cl in fcc-hcp sites in the form of chains, and Cl in the ordered $(\sqrt{3}x\sqrt{3})R30°$ structure that undergoes a continuous uniaxially compression with domain walls formation at Cl coverage increasing up to saturated submonolayer. Our analysis shows that the latter structure is thermodynamically most stable followed by CuCl film, in a good agreement with experimental observations [3,7]. In contrast to the previous theoretical work [2], we report about a variety of thermodynamically stable structures on Cl/Cu(111).

Figure 1 shows activation energies for Cl_2 adsorption, Cl and Cu adatoms diffusion, and desorption of different species (Cl, Cl_2, CuCl, Cu). It was found that Cu(111) have strong catalytic effect on Cl_2 dissociation canceling the activation barrier at both perpendicular and parallel orientations of the molecule axis. Cooper and chlorine atoms have negligible small diffusion barriers on Cu(111), allowing effective surface structure transformations at T > 30 K.

However, modification of step edges is possible at significantly higher temperatures, T > 282 K.

At Cl/Cu(111) annealing to remove chlorine, CuCl molecules desorb first from step edges, with activation energy of 2,47 eV (T ~ 802 K). It is in accordance with the TPD experiment [4], where CuCl molecules were detected in mass-spectrometer at around (700 - 850) K with peak maximum at 800 K. Even after chlorine removing from step edges, this sites will be almost immediately occupied by Cl due to the energetically gain in adsorption energy in combination with small diffusion barrier of Cl atoms. This highlights the important role of step edges as the most active sites on Cu(111).

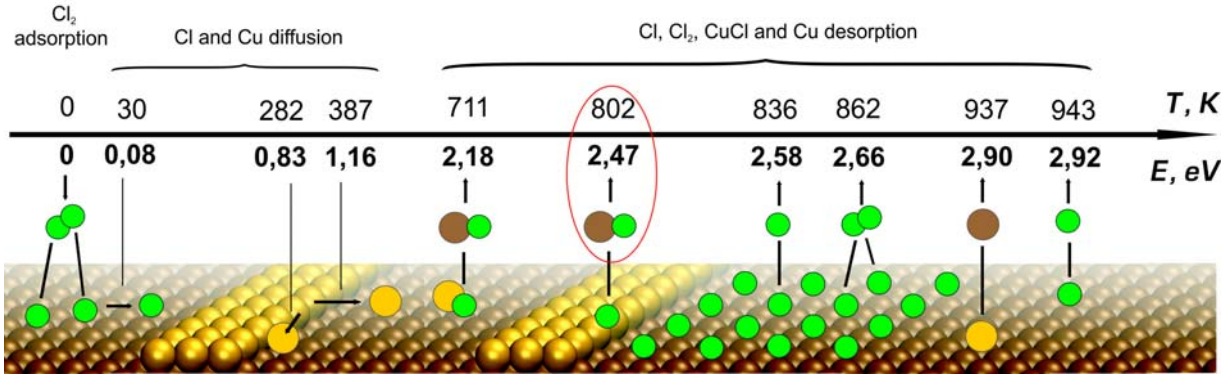

Fig. 1. Activation energies for Cl_2 adsorption, adatoms diffusion, and desorption of different species. Temperatures were evaluated from activation energies by Polanyi-Wigner equation.

4 Conclusions

We have computationally studied the reaction of cooper chlorination on ideal and defective (111) surface. The consistent theoretical description of the whole reaction allows us to make following conclusions:

- Cl_2 dissociation occurs spontaneously;
- Cl atoms prefer to be adsorbed at step edges;
- Cl atoms easily diffuse on surface via bridge positions;
- CuCl molecules are desorbed species;
- CuCl molecules are desorbed from step edges.

Keywords: perovskite, catalyst, organometallic precursor, self propagating, high-temperature synthesis

1 Introduction

Complex oxides with a perovskite structure are known to be catalysts for a wide range of redox processes. They are characterized by a high activity, considerable oxygen mobility, thermal stability of their structure, a unique diversity of their properties and chemical compositions. Volume combustion synthesis (VCS) [1] based on igniting gel-like (viscous) organometllic precursors prepared by concentrating aqueous solutions of metal nitrates and organic compounds (amino acids, urea, citric acid and others) has been the most wide-spread method of their preparation. But this method requires a stage of a prolonged high temperature (~1000^{o}C) calcination of the resulting product to decompose the thermo-stable phases of lanthanum carbonates and to complete the formation process of the perovskite phase.

This study has been undertaken for an improvement of the glycine-nitrate combustion method which would allow to obtain easily dryable and grindable solid organometallic complex precursors and to conduct the perovskite synthesis both in the VCS regime and in the course of self-propagating high-temperature synthesis (SHS). An analysis of the combustion products of the organometallic precursors depending on the combustion regime is given and an energy-efficient approach to perovskite synthesis is proposed. It should be noted that there are only few studies devoted to SHS synthesis of perovskites and to comparison of combustion products from VCS and SHS regimes.

2 Experimental/methodology

The organometallic precursors of the perovskites (OMPP) – LaMGlyOx (M–Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+} and others, Gly–glycine, Ox–oxidant) were prepared by interacting aqueous solutions of glycine and nitrates in the presence of sodium hydroxide (series I) or ammonia (series II) using stoichiometric quantities. The synthesis was conducted at room temperature, under continuous stirring and gradual addition of the base. The solvent was removed in a rotary evaporator after which the complexes were dried in a vacuum box and ground.

Combustion synthesis of the perovskite was conducted in VCS and SHS regimes. In the case of VCS a quartz glass with a thin layer of OMPP powder was heated at 500 ^{o}C for 5–10 min. Its combustion produced a loose solid residual. In the case of SHS a pellet of OMPP was ignited with a lighter. The lighter was removed as soon as the burning started. As the reaction went on "serpentines" of the layered perovskite growing in lengths were formed [2].

Physicochemical methods of investigation: TGA, IR, FTIR, XRD, X-ray fluorescence, S_{BET}, HR TEM, differential dissolution [2].

3 Results and discussion

The formation of OMPP in the presence of alkali was studied. Alkali addition to the glycine-nitrate mixture was found to promote glycine coordination to the metal which results in the formation of a neutral solid compound whose structure contains an oxidant (series I–$NaNO_3$, series II–NH_4NO_3). According to IR and thermal analysis data this oxidant does not exist as a

separate phase but is chemically bound to the ligand and enters into the structure of a complex X-ray amorphous complex compound. The presence within the structure of the synthesized OMPP along with the fuel component (glycine) also of an oxidant makes them able to undergo exothermal decomposition and combustion. It was shown that the nature of the transition d-metal cation and the oxidant together and the regime of the burning are the most significant factors determining the process of their decomposition.

The OMPP of series I was found to be little acceptable for perovskites synthesis because of the higher temperatures required for their decomposition (Fig.1) as well as the presence of impurities of sodium compounds in the final product. On the contrary, the burning of OMPP of series II proceeds efficiently in both regimes (VCS, SHS) with a high degree of gasification at lower initiation temperatures. Phase composition of the perovskites from both combustion regimes has been investigated (IR (Fig.2), XRD, TGA, XRD, TEM (Fig.3), S_{BET}, differential dissolution). The combustion regime of the precursor plays an important role in the resulting phase composition, dispersion and crystallinity of the product. It was found that in the SHS regime the perovskite content in the combustion product was as high as 90% without the additional stage of calcination. The observed phase homogeneity and high crystallinity degree of the resulting perovskites may indicate that a higher combustion temperature has been reached in the SHS regime. Under such conditions, the lanthanum carbonate phase decomposes and the formation of carbonaceous residues becomes unlikely. This observation was common for all OMPK of series II studied.

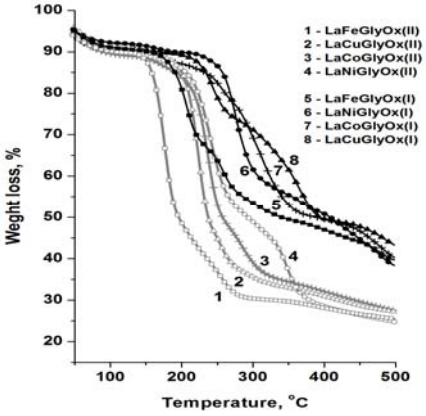

Fig. 1. TG curves of OMPP of I and II series.

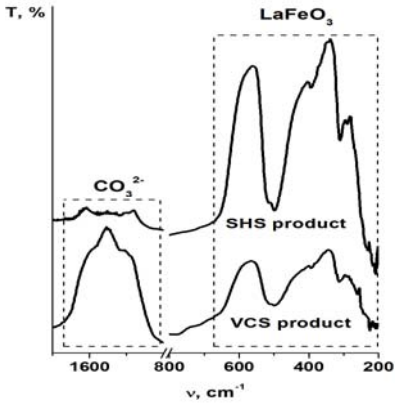

Fig. 2. FTIR spectra of products of VCS and SHS from LaFeGlyOx(II).

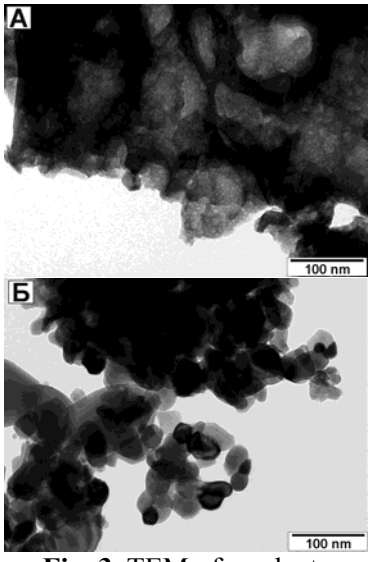

Fig. 3. TEM of products of VCS (A) and SHS (B) from LaFeGlyOx(II).

4 Conclusions

Thus, solid organometallic complex precursors of perovskite catalysts have been synthesized which are capable of forming perovskite phase in the energy-saving self-propagating high-temperature synthesis without the additional stage of calcinations.

Keywords: supported Ziegler-Natta type catalysts, XPS

1 Introduction

The supported Ziegler-Natta type catalysts of α-olefin polymerization represent catalytic systems of the composition $(Me_x^{(n+)}L_y)/MgCl_2$, where Me - transition metal, usually Ti, in degree of oxidation from (2+) to (4+), L - Cl, OR-groups. The most effective support for an active component of the catalyst is «the activated» waterless (hydrophilic) magnesium chloride with the developed surface, modified by various additives (electron donor or acceptor compounds). The features of composition and structure of polymerization catalysts possessing high sensitivity to H_2O, O_2 and other polar compounds demand use of the inert atmospheres at all stages of work with these systems: synthesis, research of an active component, test in polymerization reaction.

One of the most used physical methods allowing obtain information about electron state of the active centers of the catalysts is the XPS method. However, for studying the systems that actively interact with atmospheric gases (oxygen and water vapor), its facilities are very limited. Working with such materials requires special chambers with controlled atmosphere, the glove box, and transport of the samples to the spectrometer is an important problem because the ordinary commercial devices involve loading the samples in contact with atmospheric gases. In this work, the samples were loaded into the spectrometer using a specially designed glove box docked to the XPS spectrometer (Fig. 1).

2 Experimental

XPS spectra of supported Ziegler-Natta type catalysts were obtained on a SPECS (Germany) photoelectron spectrometer as described in [1]. Powder samples were fixed on a sample holder using a double-side conductive adhesive tape. Samples were loaded in the spectrometer via fast entry lock system. XPS measurements were carried out in a UHV analyzer chamber at a base pressure of 5×10^{-9} Torr.

Figure 1. Download the sample into the SPECS spectrometer using «home made» glove box.

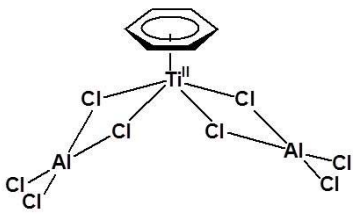

Figure 2. [η^6-Benzene$TiAl_2Cl_8$]

Before the measurements, the binding energy (BE) scale was calibrated against the characteristic lines of metallic gold and copper — $Au4f_{7/2}$ at 84.0 eV and $Cu2p_{3/2}$ at 932.6 eV, respectively. To take into account the charging effect appeared for non-conducting substances as a result of photoemission under MgK_α irradiation, the C1s line with the BE of 284.8 eV was used as internal reference.

3 Results and discussion

In the study of divalent titanium complex of [η6-BenzeneTiAl2Cl8] composition (initial compound for preparation of TMC with Ti(II)), in the XPS spectra, the lines corresponding to Ti(+2) as well as Ti(+3) were observed in the region of Ti2p. After recording the spectra, the sample was moved into lock chamber of the spectrometer that was filled atmosphere. After this procedure, the spectra of all the regions were recorded again as for the initial sample. As can be seen in Fig 3 (a), the lines corresponding to Ti(+2) and Ti(+3) were disappeared and the line corresponding to Ti(+4) was observed at the spectrum (Fig 3 (b)). At the same time, the intensity of the Ti2p line increased by an order.

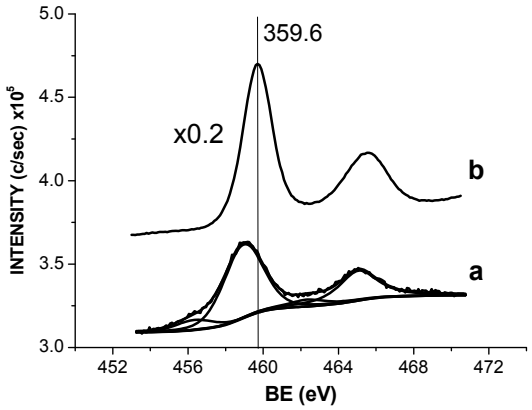

Figure 3. Ti2p core-level spectra of samples: initial (a) and after exposure to air (b).

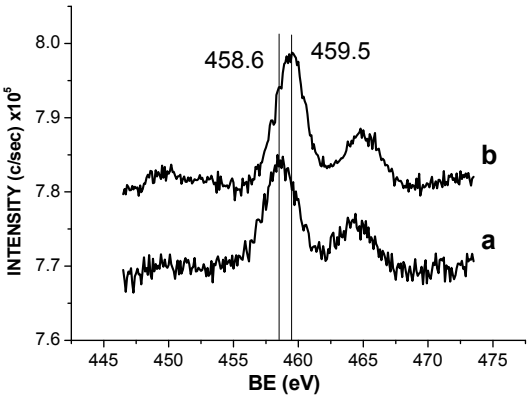

Figure 4. Ti2p 4f core-level spectra of the $Ti/MgCl_2$ samples: initial (a) and after exposure to air (b).

The samples with low concentration of supported titanium (at. ratio Ti/Mg = 0.02) were also studied. As for the previous sample, spectra were recorded for the initial sample and for the sample after exposure to the atmosphere. It is seen from the spectra in the region of Ti2p (Fig. 4) that in the initial sample, oxidation state of titanium corresponded to (+3) and after oxidation treatment, the surface of the sample contained Ti(+4).

4 Conclusions

It has been shown that the «home made» glove box system developed in Boreskov Institute of Catalysis allowed to study the supported Ziegler-Natta type catalysts by XPS effectively.

New Possibility for Investigation of Supported $Pt/MgAlO_x$ Catalysts by XPS with Use of Monochromatic AgL_α Irradiation

Keywords: platinum supported Pt/MgAlOx catalysts, XPS, monochromatic AgLa

1 Introduction

The capabilities of XPS to study heterogeneous catalysts are severely restricted for supported $Pt/MgAlO_x$ catalysts. When XPS spectra from these catalysts are taken with the standard AlKα or MgKα irradiations, the Pt4f doublet line is masked by a strong Al2p line as well as by the additive lines-satellites from Mg2s line. A possible solution of this problem could be the use of AgLα irradiation with the photon energy of 2984.3 eV for excitation of $Pt3d_{5/2}$ and Al1s lines.

2 Experimental

All measurements were performed with a SPECS (Germany) photoelectron spectrometer equipped with two X-ray sources. One source with a double Al/Mg anode works without a monochromator, whereas another source, with a double Al/Ag anode, was used with a monochromator. Application of the monochromator narrows essentially the energy width of the exciting irradiation and, hence, the width of the photoemission lines. For each sample, spectra were recorded using non-monochromatic MgKα (hν = 1253.6 eV) and monochromatic AgLα (hν= 2984.3 eV) irradiations.

3 Results and discussion

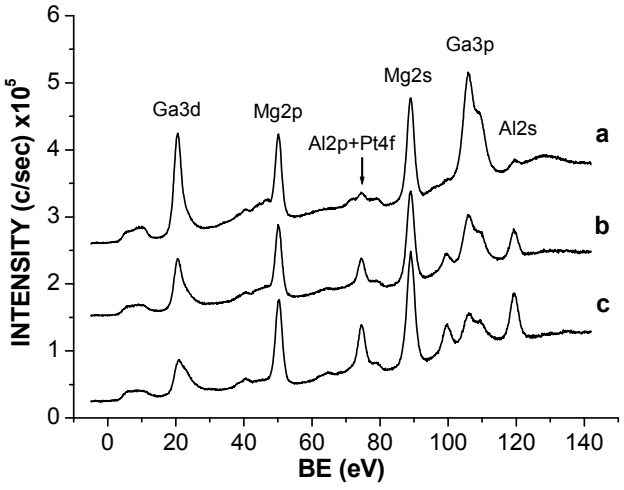

Figure 1. XPS spectra of Pt/MgAlO*x* catalysts with various Ga/Al ratios in support: 10% Al (a); 50% Al (b); 70% Al (c).

A Full Width at Half Maximum (FWHM) is an important characteristic of photoelectron spectra. The smaller is the FWHM, the better is the spectra resolution and, therefore, the more accurate is the determination of the positions and areas of spectral components belonging to different chemical states of an element.

FWHM of the $Pt3d_{5/2}$ line in the studied compounds and catalysts is higher than that of the MgKα-excited $Pt4f_{7/2}$ line by approximately 1.5 eV. The higher value of the $Pt3d_{5/2}$ FWHM makes this line less useful for the characterization of most platinum containing substances than the Pt4f line. Nevertheless, the use of AgLα irradiation for measurement of the $Pt3d_{5/2}$ spectra might be very helpful for the Pt/Al_2O_3 catalysts and many other particular systems where the Pt4f doublet line is strongly screened by the Al2p line, so the researchers have to analyze the broad $Pt4d_{5/2}$ line (FWHM of 4.5 – 5.0 eV) instead.

When AgLα irradiation is used for study the supported $Pt/MgAlO_x$ catalysts, need arises, as well as when the conventional X-ray sources are used, the calibration of the spectral lines because of their shift due to surface charging. Usually, for supported catalysts, as a standard the internal standard is used that is the value of binding energy of the line of the support, for example, Al2p, Mg2p and others as well as the value of binding energy of C1s line from residual organic contaminents on the surface of samples. In this case, under transition to a more hard X-ray irradiation region (hν=2984.3 eV) than traditional sources, the intensity of Al2p, Mg2p lines significantly reduced. This is due to two factors, namely a decrease in the photoionization cross sections for these levels compared with AlKα or MgKα irradiations and an overall reduction in the intensity of the X-ray source as AgLα source is used only in monochromatic regime.

In this work, the following method of calibration was used. Firstly, the values of binding energies of the most intense lines (O1s, Mg1s, $Ga2p_{3/2}$) were calibrated relative to C1s line (284.8 eV). Then, these lines were recorded also at AgLα irradiation along with the lines for Pt3d, Al1s, Mg1s and others. This procedure allows to create a specific set of internal standards for different oxide supports using proposed radiation.

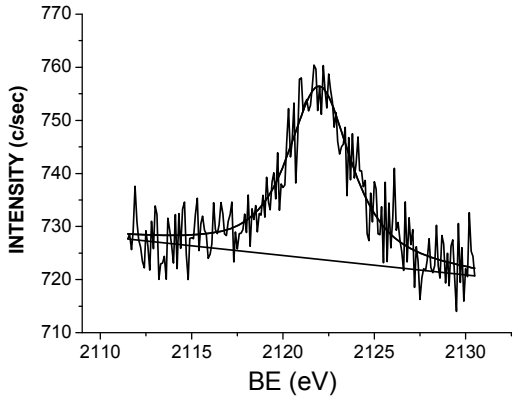

Figure 2. $Pt3d_{5/2}$ core-level spectra of $Pt/MgAlO_x$ (2% wt. Pt).

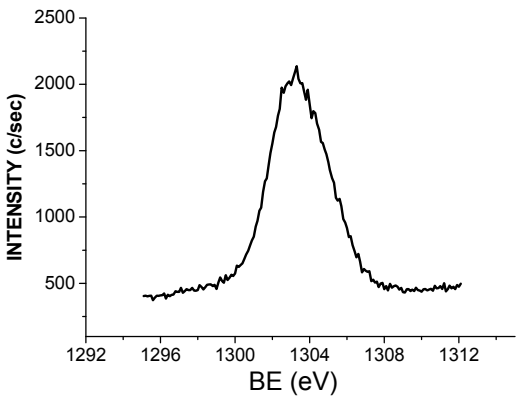

Figure 3. Mg1s spectra of Pt/MgAlO*x* catalysts.

4 Conclusions

AgLa irradiation is an useful tool for investigation of supported Pt-alumina catalysts. The values of $Pt3d_{5/2}$ binding energy can be used for determination of the oxidation state of platinum in supported $Pt/MgAlO_x$ catalysts and other systems containing both platinum and aluminum.

Keywords: sol-gel, boria-alumina, response surface methodology

1 Introduction

Recently, nanostructured metal oxides as catalyst support materials have gained much attention for their unique physicochemical properties like high surface area, high pore volume and high pore size [1].

Alumina-based mesoporous materials are well suited catalytic materials. Alumina is an amphoteric metal oxide and has a wide range of applications in heterogeneous catalysis both as catalysts and supports. The acidity on the alumina surface can be tuned by surface modification with supported oxides. Among alumina-based materials, boria-alumina mixed oxides have been considered as important acid catalysts in many industrial applications such as catalytic reforming, cracking and hydrotreating reactions [2,3,4]. Boron addition to the alumina support is known to increase Bronsted acid sites and improves catalytic performance by decreasing metal-support interaction [5,6,7].

In literature, B_2O_3-Al_2O_3 mixed oxide catalyst supports are mostly prepared by impregnation on γ-alumina with boric acid [1,7] and precipitation technique using ammonium hydroxide [3,8]. The design, synthesis and modification of binary oxide materials need to be well controlled. For this purpose, the sol-gel route seems convenient since it allows the formation of the active phase directly in the catalyst lattice [9,10].

In this study, a sol-gel process was used to prepare mesoporous B_2O_3-Al_2O_3 supports with high BET surface area around 500 m^2/g. Response surface methodology (RSM) has been studied in order to optimize the process variables like boria content and hydrolysis ratio to achieve high surface area and mesoporous structure. For the characterization of sol-gel prepared binary oxide supporting materials XRD, BET, FTIR, TPD, SEM and TEM techniques were used.

2 Experimental/methodology

The sol-gel precursors for Al_2O_3 and B_2O_3 are aluminum isopropoxide (AIP) and sodium tetraborate decahydrate, respectively. Desired amount of precursors were dissolved in 1-propanol and well stirred to prepare a medium for hydrolyzing step. Sodium tetraborate decahydrate was dissolved in given amount of water which was then used to complete hydrolysis at 85 ^oC under reflux. All prepared samples were aged for 2 days to grow the network encapsulating the solution and dried in an oven at 100 ^oC for 24 hours. Calcination step was done at 500 ^oC for 3 hours in a muffle furnace.

3 Results and discussion

Optimum sol-gel process parameters to synthesize B_2O_3-Al_2O_3 (1-5 wt% B_2O_3) catalyst supports are defined by utilizing response surface methodology approach. Due to the face centered composite design, four parameters and their experimental values are summarized in Table 1. According to experimental design points, 30 runs were performed which included 6 repeating runs on the centered levels. BJH adsorption/desorption isotherms and pore size distributions of the samples were investigated by structural and catalytic point of view. TEM images and XRD patterns were interpreted to analyze the crystalline size using Scherrer equation. The acidity of boria-alumina supports with increasing B_2O_3 content were defined by TPD and FTIR results. The effect of aging, drying and calcination process to the textural properties of final product were also discussed.

Table 1. Experimental design points

Name	Units	Low Actual	Mean	High Actual	Low Coded	High Coded
HNO_3	mol HNO_3/mol AIP	0,1	0,5	0,9	-1	1
AIP	Molarity	0,4	0,7	1	-1	1
R	mol H_2O/mol AIP	15	57,5	100	-1	1
B_2O_3	% weight	1	3	5	-1	1

Maximum BET surface area of the sol-gel prepared boria-alumina support has been reached 538 m^2/g under the conditions listed in Table 2. It was concluded that the addition of boria to the alumina support at low hydrolysis ratio was increasing total surface area by effecting the pore structure slightly.

Table 2. Experimental conditions

Keywords: perovskite, planar, defects, XRD, HRTEM, oxidation

1 Introduction

Complex oxides $La_{1-x}Ca_xMO_{3-\delta}$ (M = Mn, Fe, Co) with perovskite-type structure intensively studied over the years, due to the unique combination of magnetic and electronic properties. In particular, the compounds of this class are used in catalysis in high temperature oxidation processes. The catalytic properties of these solutions depend on the preparation methods and the degree of substitution of calcium cations. Increasing of Ca^{2+} content enhances the mobility of the O^{2-} anion, which positively influences on the catalytic activity of the samples, but in some cases, limits the region of existence of the solid solutions and may cause decomposition of the solid solutions in high-temperature processes.

This work studies the characteristics of the formation of the microstructure of perovskite oxides of $La_{1-x}Ca_xCoO_{3-\delta}$ by XRD and HRTEM methods and compare the microstructure features of solid solutions $La_{1-x}Ca_xCoO_{3-\delta}$, with the previously studied series of $La_{1-x}Ca_xMO_{3-\delta}$(M = Mn, Fe).

2 Experimental/methodology

The samples $La_{1-x}Ca_xCoO_{3-\delta}$ were synthesized by dissolving in water the corresponding nitrate salts in the appropriate ratio followed by evaporation and annealing of the product at 900° for 4 hours (the Pechini method). High resolution electron microscopy (HRTEM) images were obtained on a JEM-2010 (Japan) with resolution 1.4 Å. X-ray microanalysis (EDX) of elemental composition of the samples was carried out using energy-dispersive spectrometer with a Si-(Li) detector with an energy resolution of 130 eV. In situ XRD experiments were carried out at the "High Precision Diffractometry" station at Siberian Synchrotron and Terahertz Radiation Center (Novosibirsk, Russia). The diffractometer was equipped with high temperature chamber Anton Paar HTK2000 and position sensitive parallax-free linear OD-3M detector. X-ray wavelength of 1.01 Å was set by a single reflection from flat perfect crystal monochromator Si(200).

3 Results and discussion

According to XRD, in a series of $La_{1-x}Ca_xCoO_{3-\delta}$ the presence of morphotropic transition R-3c ($0 \le x \le 0.2$) → Pm3m ($0.3 \le x \le 0.4$) reported, associated with a gradual increase of the content of Ca cations. Samples with $x \ge 0.5$ are multiphase, the main component of those is based on the perovskite phase $La_{0.6}Ca_{0.4}CoO_{3-\delta}$. According to HRTEM samples with $x \le 0.5$ are almost single-phase solid solutions with the perovskite structure, while containing a small proportion of simple oxides CaO and Co_3O_4.

Application of the samples as the CH_4 oxidation catalysts at 600T^oC (?) leads to partial phase decomposition of solid solutions and formation of planar vacancies in the perovskite structure in the direction of the planes (101). An interesting feature is the presence of irregularities in the crystal structure of the perovskite matrix. Thus, formation of alternating perovskite-brownmillerite structures are occurred after performing of methane oxidation reaction(Fig. 1). Also, as the result of reaction partial formation of nanostructures in orthorhombic perovskite matrix are occurred. Apparently, this nanostructures lead to the further formation of brownmillerite structure in perovskite.

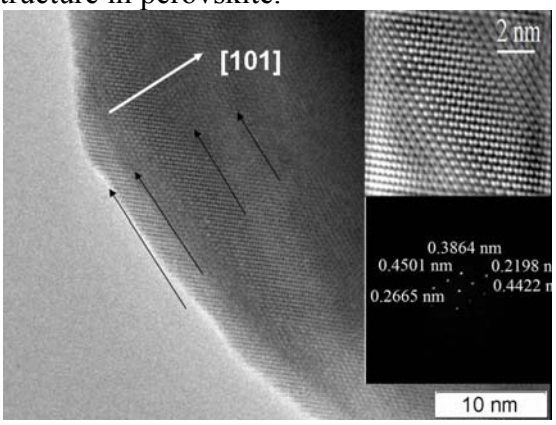

Fig. 1 HRTEM image of $La_{0.6}Ca_{0.4}CoO_{3-\delta}$ microstructure after CH_4 oxidation reaction. In inserts FFT image and Fourier–cleaned image are shown.

To examine the thermal stability of the solid solutions *in situ* testing of samples was performed in the high temperature chamber using synchrotron radiation. Calcination of the samples in air has virtually no effect on the structure and microstructure of $La_{1-x}Ca_xCoO_{3-\delta}$ solid solutions. Heating of perovskite oxides under vacuum, conversely, results in a partial decomposition of the solid solutions. For example, in $La_{0.6}Ca_{0.4}CoO_{3-\delta}$ there is an allocation of oxides CaO and Co_3O_4 on the surface of $La_2Co_2O_5$, wherein the particle sizes of formed phases are in the range of 50 - 100 nm.

4 Conclusions

In this work the solid solutions $La_{1-x}Ca_xCoO_{3-\delta}$ synthesized by polymerized complex precursor (Pechini) method were studied. XRD and HRTEM show the formation of X-ray single-phase solid solutions in the range of replacement parameter $0.5 \geq x \geq 0$. According to XRD, structure of the samples seemed to be almost unaffected after the CH_4 oxidation reaction, but HRTEM data indicate the formation of nanoheterogeneous sites on perovskite surface. Increase of the substitution parameter (x = 0.2, 0.4) lead to formation of simple oxides of Co and La particles on the surface of the initial phase. Furthermore, there is a formation of planar defects in the direction of the crystallographic planes (101). As a result of the reaction medium in the sample $La_{0.6}Ca_{0.4}CoO_{3-\delta}$ areas are formed with alternating elements of the perovskite structure and brownmillerite.

It is shown that the calcination in air samples does not change the structure of the sample, and calcination in vacuum conversely leads to separation of the solid solutions. Whereby it can be concluded that the decomposition of the solid solution caused by the partial removal of oxygen.

Keywords: molybdenum catalyst, organic hydroperoxide, hydrogen peroxide, deactivation, epoxidation

1 Experimental/methodology

Thermal stability of catalysts was studied on change of concentration of the dissolved molybdenum in the range of temperatures 90 - 120 ° C, using the ampoules method. Concentration of the dissolved molybdenum was defined by titration method [1].

Oxidation was carried out in the reactor of the manometrical installation allowing to fix change of oxygen volume absorbed during reaction as function of time. Catalyst PMKZh was allocated in a firm look, and dissolved in a dimetilformamid (DMFA).

2 Results and discussion

As a result of experiments it is established that at temperatures close to working temperatures in the industrial reactor of epoxidation of GPEB propylene (110 ºC), there is a fast decrease in the content of the dissolved molybdenum in catalysts.

The catalysts, synthesized on organic hydroperoxides, CMC and MC are losing 85% of the dissolved molybdenum at temperatures of 110, 120 ºC already through 15 minutes, and ~45% initial metal are remained in PMCZh.

It is known that derivatives of ortovanadiyevy acid thermally are decomposed by the radical way [2] since compounds of molybdenum and vanadium behave similarly in epoxidation reactions and decomposition of hydroperoxides,, it is possible that the compounds of molybdenum which are a part of catalysts also are decomposed by the homolytic way

The fact of decomposition substance with free radicals can be detect experimentally to acceleration a radical chain reaction. In this work we used standard reaction of liquid-phase oxidation of styrene oxygen, kinetic characteristics by which are repeatedly checked and described in literature [3].

Styrene mixed with DMFA oxidised very slowly. In the presence of a molybdenum catalyst, the rate of oxidation of styrene is increased depending on the temperature on the order of 2-4 (at T=80°C with $8{,}97 \cdot 10^{10}$ to $5{,}39 \cdot 10^{6}$ mol/l·c). Moreover, the oxidation begins immediately without the induction period.

3 Conclusions

Thus, it is experimentally proved that the molybdenum catalyst deactivation begins with homolytic decomposition. Based on this fact, as well as based on the composition of products of decomposition molybdenum catalysts, are proposed scheme of the mechanism of deactivation.

Keywords: plasma-arc synthesis, low-temperature CO oxidation, composite, Pd/CeO_2, Pd/SnO_2

1 Introduction

Catalysts based on cerium oxide and palladium are among the most promising catalysts used for oxidation of carbon monoxide and other harmful gases. The development of new effective catalysts for neutralization of carbon monoxide is tightly bound with necessity to form highly dispersed states of active components Pd and CeO_2. These states are required to be stable in a wide temperature range and under the action of reaction medium. Perspective way to create new effective catalysts of CO oxidation is an application of nanocomposite precursor materials prepared by plasma-arc synthesis (PAS). This method is based on sputtering of the separate components as a highly dispersed nanoparticles forming complicated nanostructured composites. During the subsequent calcination in air the burning of carbon occurs which facilitate the transformation of the composite precursors to dispersed metal-oxide catalytic systems [1]. For the implementation of this new approach, in this work the composite Pd/CeO_2-SnO_2 catalysts were prepared from PdCeSnC composite precursors obtained by PAS. The step-by-step calcination of this PdCeSnC composite allowed us to investigate the process of the component phase transitions and to obtain highly active CO oxidation catalysts.

2 Experimental/methodology

In the presented work, the PdCeSnC composite precursors were prepared by PAS for the first time. The synthesis of Pd/CeO_2-SnO_2 catalysts was carried out in two steps: step 1 – direct synthesis of the PdCeSnC composite in the plasma-arc chamber, and step 2 – calcination of the composite in air at 450°C - 1000°C resulting in carbon burning from composite material and formation of the catalyst. HRTEM, XRD, XPS, Raman spectroscopy were used to investigate the microstructure, composition and electronic state of the composite components after the high-temperature calcination step. The catalytic testing was performed by the temperature programmed reaction in $CO+O_2$ (TPR-$CO+O_2$) using plug flow reactor with mass-spectrometric analysis of the gas mixture.

3 Results and discussion

Figure 1a shows that the high activity (low T_{10} and T_{50} values) is observed for the 1%Pd/CeO_2 catalysts after calcination at 600-800°C, while calcination at T = 900°C results in decrease of activity with the further dramatic deactivation after calcination at 1000°C. Introduction of Sn to the catalyst composition results in better catalytic performance compared to Pd/CeO_2. As it can be seen from Fig. 1b the Pd/CeO_2-SnO_2 catalyst is characterized by

excellent activity after calcination at 600-900°C. Calcination at 1000°C results in increase of T_{50} value, but this deactivation effect is less pronounced compared to Sn-free sample. These data demonstrate the strong thermal activation effect and the high thermal stability of catalysts doped by tin. HRTEM and XRD data indicate extremely high dispersed states of palladium and other components of modified catalysts.

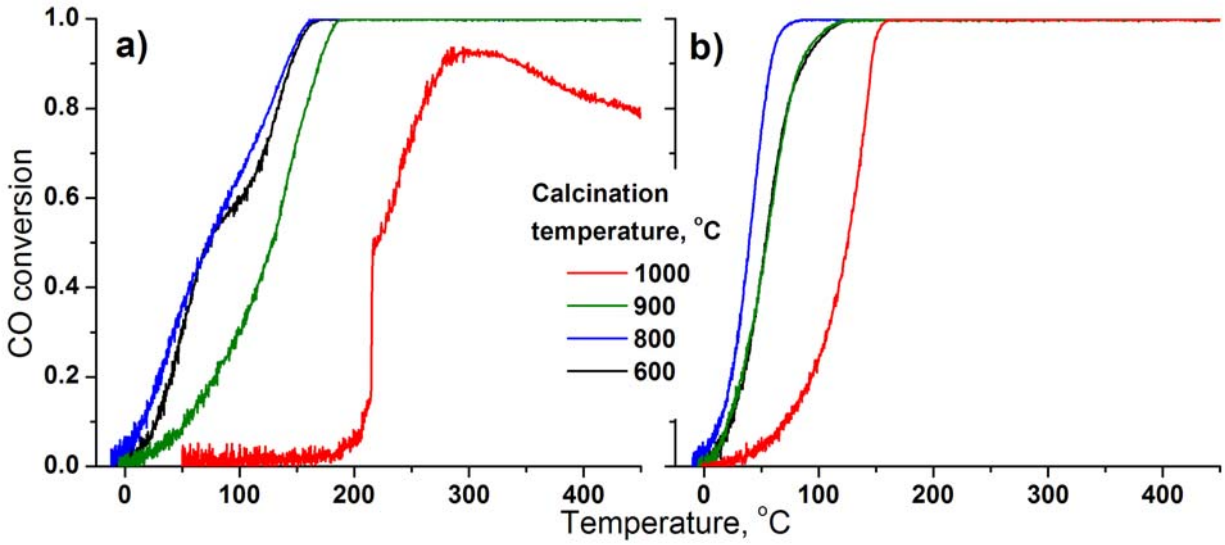

Fig. 1. Temperature dependences of CO conversion for CO oxidation reaction using 1%Pd/CeO_2 (a) and 1%Pd/CeO_2-SnO_2 (b) catalysts calcined at 600°C-1000°C.

The XPS data show the presence of sp^2- and sp^3- carbon nanostructures which are mixed with the components in the initial PdCeC or PdCeSnC composites. These carbon nanostructures play a key role in the formation of the high-defect solid solution of palladium in the CeO_2 structure ($Pd_xCe_{1-x}O_{2-\delta}$). Introduction of tin to the initial composite leads to formation of small SnO_2 nanoparticles after calcination. Together with the residual carbon structures the SnO_2 nanoparticles prevent sintering of $Pd_xCe_{1-x}O_{2-\delta}$ particles during calcination.

4 Conclusions

The plasma-arc method was applied to synthesize the PdCeC and PdCeSnC composites which can be effectively used as precursors for preparation of Pd/CeO_2 and Pd/CeO_2-SnO_2 catalysts with high activity in CO oxidation reaction. The obtained Pd-ceria based catalysts modified with tin represent a very promising catalytic system, which has a unique combination of high thermal stability and activity in CO oxidation starting at low temperatures.

Catalytic Performance of MFI Zeolite Synthesized with Cetyltrimethylammonium Cation as SDA

Campos A.F.P., Borges D.G., Cardoso D.*

Universidade Federal de São Carlos, São Carlos, Brazil

* dilson@ufscar.br

Keywords: MFI zeolite, cetyltrimethylammonium cation, transesterification reaction

1 Introduction

An alternative to overcome diffusional restrictions relative to application of zeolite materials is by using in the form of nanocrystals (crystal sizes below 100 nm). These zeolites can be synthesized through the use of specific structure-directing agents, such as bifunctional surfactants [1]. Based on this concept, several studies have explored the ability of cationic amphiphilic surfactants commonly used to obtain mesoporous materials as zeolite structure-directing agents, for example, alkyltrimethylammonium surfactants ($C_nH_{2n+1}N^+(CH_3)_3Br^-$, n = 6, 8, 10, 12, 14 e 16) [2,3]. In this study, we have evaluated the performance of cetyltrimethylammonium cation as structure-directing agent to obtain zeolites, as well as, the activity and catalytic stability study of these zeolitic materials in the catalytic transesterification.

2 Experimental/methodology

The chemical composition of the reaction mixture used to synthesis of zeolites was 1 SiO_2: 0,125 Na_2O: 0,01 Al_2O3: 0,05 CTMABr: 40 H_2O[2]. The syntheses were conducted at temperature of 150 ºC and different hydrothermal treatment time (1-6 days). The zeolites were characterized through X-ray diffraction, scanning electron microscopy (SEM), thermogravimetric and chemical analysis. The catalytic tests were performed using the catalytic transesterification between methanol and ethyl acetate (2:1). The catalytic reactions were conducted in the presence of 4 % (w/w) catalyst at 50 ºC and 0,5 hours of reaction time. After the reaction, the catalysts were filtered, dried and reused several times. The conversion of ethyl acetate was quantified by gas chromatography.

3 Results and discussion

As shown in Figure1-a, the XRD patterns of the materials synthesized with $CTMA^+$ cation from hydrothermal treatment of 2 days are of MFI structure.

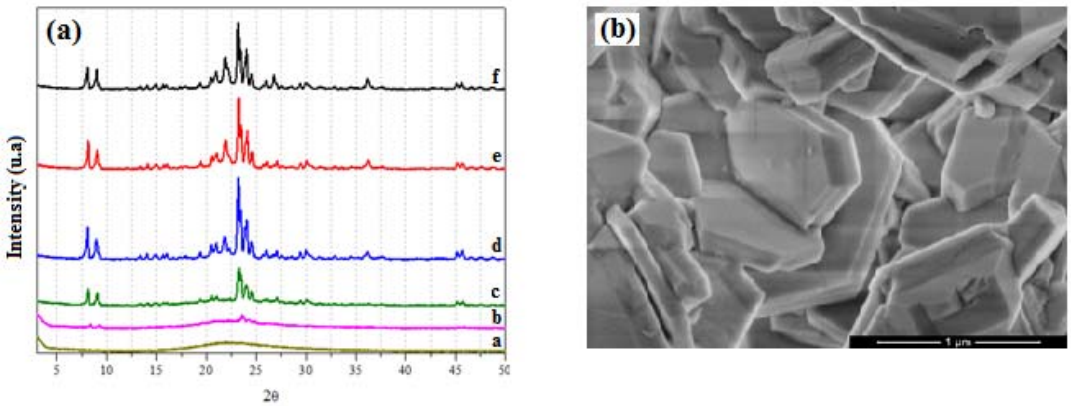

Fig. 1. (a) XRD power patterns of materials obtained from CTMA+ cations at 150 ºC after (a) 1, (b) 1,5, (c) 2, (d) 3, (e) 4 and (f) 6 days. (b) SEM image of MFI formed after 6 days at 150 ºC.

The elongated cations $CTMA^+$ affected the morphology of the MFI crystals and after 6 days it was obtained hexagonal plates crystals (Figure 1-b). These cations fit within ten-membered ring straight channels of MFI structure and it should restrict the growth of crystals in direction of straight channels [1].

Due to the presence of the cations inside the zeolite channels, these as-synthesized materials exhibited catalytic activity to transesterification reaction (Fig. 2-a). The organic cations present in these zeolites are associated to siloxy anions ($\equiv SiO^-$) and the catalytic reaction takes place through these anions present on the surface of catalytic material [4]. The loss of catalytic activity as function of catalytic uses is related to leaching of organic $CTMA^+$ cations associated to these siloxy anions. These assumptions are supported by the thermal analysis (Figure 2-b).

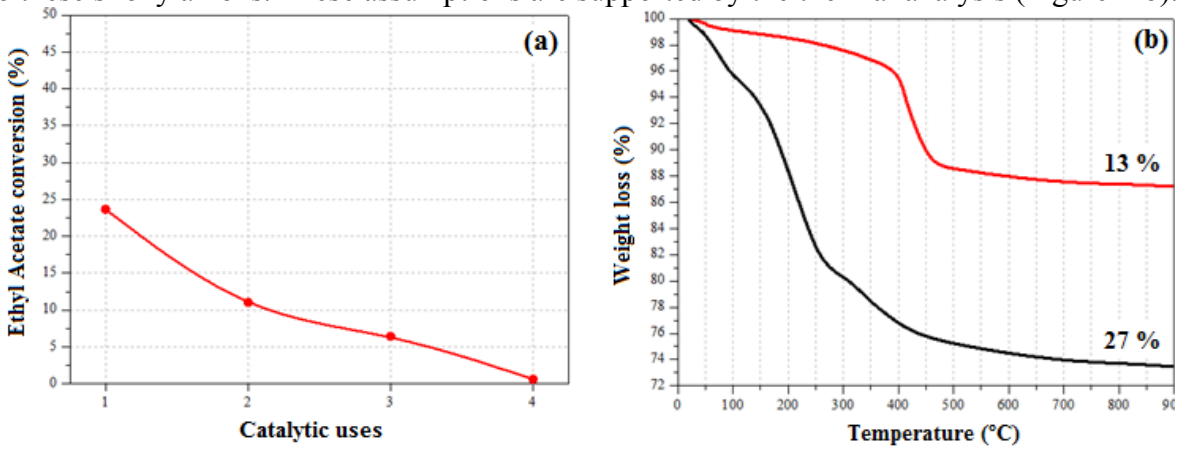

Fig. 2. (a) Ethyl acetate conversion as function of catalytic uses and (b) thermal analyses of the MFI-zeolites before (black line) and after successive catalytic uses (4th use – red line).

Figure 2-b presents the thermal analyses of the zeolites before and after successive catalytic uses (4th use). Before the material was used catalytically, there was a weight loss of 27 % that can be attributed to the following events: (1) below 100 ºC, the desorption of water molecules and (2) between 100 and 300 ºC, the combustion of organic CTMA+ cations. After the fourth catalytic use of the zeolite, the weight loss was only 13 %, associated mainly to the decomposition of organic CTMA+ cations.

4 Conclusions

The results confirmed the formation of MFI-type zeolite through organic $CTMA^+$ cation from 2 days at 150 ºC. The zeolitic materials obtained were catalytically active for the transesterification reaction and it is believed that the low catalyst stability is related to leaching of $CTMA^+$ cation present on the surface of these materials.

New High Porosity Endogas Production Catalyst on Foam Substrate for Low-Carbon Steel Heat Treatment

Makarov A.A.*, Fotin D.V.

ECAT Company, Perm, Russia

* makarov@ecocatalysis.com

Keywords: catalyst endogas, porous catalysts, steel carbonization

1 Introduction

Carbonization is one of the most widely used methods of friction and high-load metal parts performance characteristics improvement. This process involves diffusion saturation of low-carbon steel in controlled atmosphere with a mixture of carbon oxide and hydrogen (**endogas**) derived from natural gas and air mixture. Reactions of partial oxidation of hydrocarbon (including endogas production) proceed on solid nickel or platinum catalyst. Specialized cementation furnaces with premixed ($CO:H_2$) atmosphere or furnaces with built-in **endogas** generator are used for carbonization [1].

The challenge of low-carbon steel carbonization and endogas generation is the difference in process temperatures. Low-carbon steel (18ХГТ/HGT grade of alloy structure steel with 0.17-0.23% C, 0.17 – 0.37% Si, 0.8-1.1 Mn, up to 0.3% Ni, up to 0.035% S, up to 0.035 P, 1 – 1.3% Cr, 0.03 – 0.09 Ti and up to 0.3% Cu content) carbonization proceeds at temperatures of 850-950°C, while endogas generation occurs at 1020-1050°C. Carbonization velocity in most cases is 0,1mm/h with process time amounting to 8-12 hours. These conditions have a negative impact on overall carbonization process cost. From the chemical performance prospective, GIAP type catalysts currently in use allow to generate atmospheres with relatively high carbon residue content (2-3% vol.), which leads to low process performance timing-wise and easy decomposability of microcrystalline state of carburized case[1, 2].

The goal of this research work was development of catalyst that would allow to lower endogas generation temperature and consequently generate atmosphere with low carbon residue content (not exceeding 1%). One more significant goal was stabilization of catalyst phase composition and minimization of solid-state transformations between catalyst components at high temperatures [3]. Achievement of these goals would allow to reduce carbonization process time and improve its quality, as well as achieve process velocity amounting to 0,2-0,3 mm/h.

2 Experimental/methodology

γ-Al_2O_3 / Pt system was used as catalyst body to be applied on heat resistant high-porosity material with the following composition: Fe-Ni-Cr-Al. It was selected because it is well-characterized and easily accessible. Besides these catalysts are less toxic than their analogues with NiO active component. Other reasons why platinum was selected as catalyst of choice are as follows a) complex platinum compounds can be evenly distributed on the surface of aluminum oxide b) platinum crystallite size can be controlled c) partial oxidation reaction proceeds efficiently and selectively on platinum [4].

Heat resistant Fe-Ni-Cr-Al alloy was selected not only because of its thermal stability, but its structural properties as well. First, open cell high porosity (95-98%) structure gives an opportunity to blend gas-air mixture (hydrocarbon: air) homogeneously and completely. Secondly, catalyst microstructure allows to avoid local overheating that can be caused by high exothermicity of partial hydrocarbons oxidation reaction.

Thirdly, high surface area creates maximum adhesion with γ-Al_2O_3/Pt system. γ-Al_2O_3 stabilization was performed at 85-950^oC by means of doping 0,5% rare-earth oxide (either La or Pr or Nd). X-ray phase and BET-method analysis demonstrated that atoms of rare-earth element embedded into γ-Al_2O_3 crystalline grid stabilize its phase and prevent phase transistions γ-Al_2O_3 / δ- Al_2O_3 / θ- Al_2O_3 / α- Al_2O_3. Surface area of γ-Al_2O_3 doped with rare-earth oxide and heat treated at 950^oC amounted to 90-105m^2/g.

Catalyst was manufactured in 2 stages. In the first stage catalyst substrate Fe-Ni-Cr-Al was impregnated with γ-Al_2O_3 / La_2O_3 suspension and then heat treated at 1000^oC. In the second stage, the catalyst was impregnated with platinum complex compound solution followed up by deliquification and heat treatment under hydrogen at 950^oC. Pulsed chemisorption method of CO was used to establish that platinum content on the surface amounts to 65-77%. Size of 87% of platinum particles falls within 2 to 11 nm range. Catalyst samples 34 mm in diameter and 32 mm in height were manufactured for test purposes.

Endogas was generated by means of passing 35 litres/hour of propane/butane mixture and 400 litres/hour of air through synthetized heterogeneous catalysts at 930^oC. Content of generated gas mixture was as follows: CO 23,84%vol.; CO_2 0,09%vol.; CH 0,88%vol.; H_2 30,63%vol. The catalyst recovered after tests did not change its dimensions and did not have any soot on the surface.

18ХГТ/HGT grade alloy structure steel sample was carbonized at 920^oC under generated endogas for 4 hours after temperature equalization. Then the sample was cooled down to room temperature, after that heating for hardening at 830-840^oC was performed followed by temper hardening in base oil Е120А/И20А at 200^oC for 2 hours. Test results demonstrated that carburized case thickness amounted to 1,2 mm, thickness of efficient layer with thickness exceeding 500HV0,1 amounted to 0,7 mm.

3 Results and discussion

1. High conversion rate in 800 to 940°C temperature range (residual methane content not exceeding 0,91% vol.);

2.Addition of rare-earth elements oxides allows to stabilize aluminum oxide structure and maintain high surface area at high temperatures;

3. Low levels of soot formation on catalyst surface lead to absence of necessity in forced catalyst burning;

4. Endogas generation is maintained in the required gas-air mixture delivery volume range from 0,4 to 1,5 m^3/hour;

5. End result – steel carbonization process is high velocity, easy to control and is characterized by high quality of microstructure.

4 Conclusions

Catalyst samples were successfully tested in ZAO "Nakal – Promyshlenniye Pechi".

Keywords: impregnation, the active ingredient, carrier of active alumina, formation

1 Introduction

Spherical alumina are widely used in chemical and petrochemical industry as an adsorbent, desiccant, media and catalyst for various processes. Spherical catalyst has an optimum range in size, provides the most dense packing of grains has a maximum ratio of volume to external surface of the grain. It has a maximum surface loading. Due to the increased mechanical strength of such a catalyst has a long life[1]. The development of modern and advanced catalytic and adsorption processes with moving and fluidized and fixed layers of particles requires the development of methods of producing mechanically strong ball and the resulting pellet catalysts and sorbents, resistant to abrasion and impact loads[2]. In the manufacture of oxide catalysts widely used method of applying active ingredients to the finished porous base. The technology of producing such catalysts involves two separate processes: getting media and the actual catalyst. In the process of obtaining media includes such stages as the preparation of raw material, its molding, drying and heat treatment. Introduction components may make the active components of the coagulation of pseudosasa; impregnation of the finished spherical granules media. Upon receipt of spherical granules distributed way using hydrocarbon-ammonia or liquid molding processes, including chemical peptization pseudoboehmite hydrogel (PB), and the coagulation of droplets pepsirefresh PB. This technology is versatile and productive, guarantees of phase and structural uniformity of spherical granules, allows to carry out the process continuously, that is rational in heavy industries.

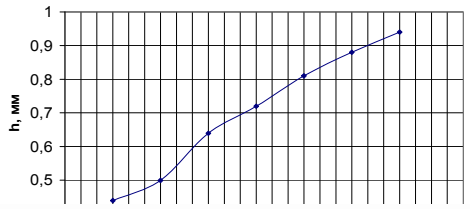

Fig. 1 - The dependence of the depth of diffusion impregnation of salt from time

2 Experimental/methodology

Earlier in the study process of impregnating a porous support γ-Al_2O_3 with a solution containing compounds of the active component, were used cylindrical granules of γ-Al_2O_3 carrier brands AOA-1 and A-64. In this work, using Sol-gel technology samples were obtained spherical granules of γ-Al_2O_3 with a homogeneous texture (d_{gr}=4-5 mm) for subsequent synthesis catalysts. As a source of raw materials used presidency aluminum hydroxide pseudoboehmite structure with a specific surface area of at least 200 m^2/g and a content of impurities of sodium-0,03;iron(III)-0,035; sulfur(VI)-0,02 in terms of oxides, % mass. In the introduction of the active component was carried out by impregnation stage coagulation of the catalyst granules of γ-Al_2O_3 using aqueous solutions: $(NH_4)_2CrO_4$, $(NH_4)_2Cr_2O_7$. Molding paste was produced using a cylinder, with holes at the bottom. Drops fell into the tank with a two-

layer fluid, the upper layer kerosene, lower - solution of chromate (bichromate) ammonium. In the upper layer drops took a spherical shape, and the lower coagulate and saturated with dissolved salt. All stages of preparation and molding were carried out in optimal conditions (in accordance with [3]):

• peptization equivalent of nitric acid, HNO_3: 30 mg acid in 1 g-mol of Al_2O_3;
• pH of sol: pH of 3.2 to 3.8 and its density is: ρ=1,25-1,3 g/cm^3;
• the size of the dosing channel: d =5 mm;
• the height of the layers of kerosene h =30 mm and ammonia solution h=220 mm;
• the concentration of ammonia in neutralizing the solution C=18% mass. and time stay granules t=180 sec;
• temperature and time of drying (110 ^oC - 4 h) and annealing (550 ^oC - 4 h).

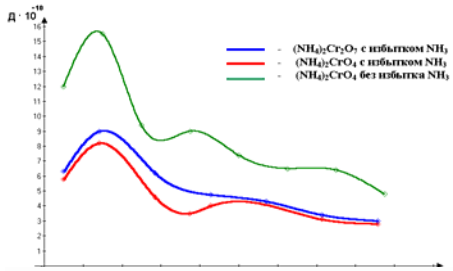

Fig. 2 - Change of the diffusion coefficient depending on time

3 Results and discussion

Investigated the increase of time of impregnation of the granules from 30 to 240 sec. The dependence of the depth of diffusion impregnating salt h, mm time is presented in figure 1. Found that the rate of diffusion of NH_4^+ (as indicator used phenolphthalein) inside the granules exceeds the diffusion rate of chromate ions, probably due to the smaller size of the ions NH_4^+ (1,43 Å) compared with the chromate ions CrO_4^{2-} (5,41 Å). Determined the effect of the concentration of ammonia solution to the diffusion rate of chromate and bichromate ions. The diffusion coefficient defined by the equation calculation time full response interdiffuse in the field[3]. Considering the dependence of diffusion coefficient on the depth of the granules (Fig.2) for the different nature of the solutions of the complexes, it can be noted that the diffusion coefficient with increasing time of impregnation increases to some maximum value and then decreases, with an excess of ammonia causes a considerable decrease of the diffusion coefficient ceteris paribus. The decrease of the diffusion coefficient caused by the formation of the shell of the granule layer of aluminum hydroxide increased density. The obtained structural-mechanical properties of the synthesized samples are shown in table 1.

Table 1 - characteristics of samples of spherical carrier of γ-Al_2O_3 catalyst

	$P_\circ$, MPa	**V_Σ, см^3/г**	**Sуд, m2/g**
The carrier	4,5	0,6	230
The catalyst	4,5	0,4	190

4 Conclusion

Thus, in this work was done a method for producing spherical granules Al_2O_3 by sol-gel transition peptized pseudoboehmite alumina hydroxide, and the introduction of the active catalyst component in the step of coagulation; properties of the synthesized samples correspond to the optimum values for this type of catalysts.

Keywords: *in-situ* XPS, methane oxidation, Pd/Al2O3 catalysts, active component

1 Introduction

It is well known that the charge state of the active component of catalyst may change under the influence of the reaction medium. This can lead to the formation of new catalytically active sites on the surface differing significantly from those in thus prepared samples. Catalytic combustion is widely used for the abatement of methane emissions from methane- or natural gas combustion devices, including natural gas vehicles and the significant effect of active component particle size on the activity was already revealed for many catalytic systems. Palladium supported on alumina is a common catalyst used for the oxidative removal of small amounts of hydrocarbons from gaseous or liquid streams [1]. In the present study we performed *in-situ* XPS study of the reaction of total oxidation of methane over alumina-supported palladium catalysts, depending on the Pd initial state and the particle size of the active component.

2 Experimental/methodology

In-situ experiments were carried out on the photoelectron spectrometer VG ESCALAB "High Pressure" which allows measuring spectra at a pressure of the reaction mixture up to 0.1 mbar [2]. In our case the experiments were performed at 0.02 mbar, with variation of temperature from 30 to 450 ^oC and oxygen to methane ratio – from 4/1 to 1/1. The methane and oxygen flows were regulated separately with Horiba-Z500 mass flow controllers. Total pressure in the high-pressure gas cell was measured with a MKS type 121A baratron.

3 Results and discussion

Samples with close particle size (4-5 nm) but different initial state of Pd (metal or oxidic, Fig.1a) were chosen to reveal the state of active component under the reaction conditions. It was shown that Pd state doesn't change at samples exposing to the reaction mixture at $O_2/CH_4 = 4/1$ and room temperature. Temperature increase up to 430^oC at $O_2 + CH_4$ mixture presence resulted in methane and O_2 consumption accompanied by CO_2 appearance in the gas phase. At that, independently on the initial Pd state in the sample, both oxidic and metallic state of palladium formed on the surface that follows from the position of Pd3d core level spectrum at 335.8 ± 0.1eV. Peak fitting of these spectra was performed supposing presence of both components and showed that the relative content of Pd^{2+} and Pd^0 states in these samples is very close (Fig.1b). Variation of the temperature and reaction mixture composition showed that both these parameters affect Pd^{2+}/Pd^0 ratio.

Study of redox capability of palladium showed that full reduction of PdO to Pd^0 by methane occurs at temperatures 200-300 °C, whereas oxidation of the metallic phase to PdO in the

oxygen atmosphere for 6 hours, even at 400 °C, leads to the formation of the mixed metal-oxide phase with E_b = 335.8 ± 0.1 eV, which indicates its high stability.

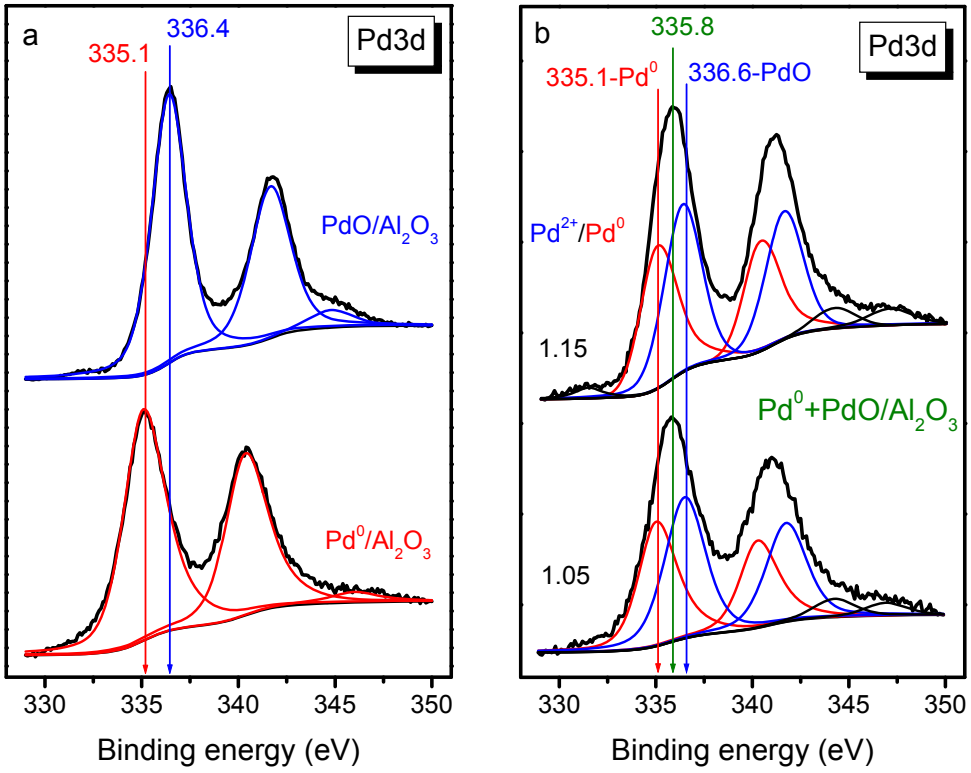

Fig. 1. Pd3d core level spectra of Pd/Al_2O_3 samples characterized by different Pd state (Pd^0 and PdO) recorder under the reaction mixture (O_2 / CH_4 = 4/1, P = 0.02 mbar) at T = 30 °C (a) and 430 °C (b).

4 Conclusions

Mixed metal-oxide state of Pd characterized by E_b = 335.8 eV forms on the surface of $1\%Pd/Al_2O_3$ samples under reaction conditions independently of the initial state of Pd in as prepared samples. Ratio between Pd^0 and PdO therein depends on both temperature and O_2 to CH_4 ratio in the reaction mixture.

Keywords: Ni catalysts, SBA-15, dry reforming of methane, impregnation, deposition-precipitation, carbon deposition

1 Introduction

Dry reforming of methane (DRM) has awake the interest in the last decades due to its double application, in production of synthesis gas (syngas, $CO+H_2$) used for several liquid hydrocarbon production, and in obtaining pure H_2 by purification of syngas, promising to become one of the major sources of energy in the near future. The coke formation during DRM is one of the substantial problems to be solved for catalyst stability, and it is related with the nature of the active phase (metal), its dispersion over the support employed, and other factors as the high temperature reaction and activation of CO_2 [1]. Nickel is one of the promising alternatives to the active and stable noble metals used as Pt, Rh or Ir, due to its good catalytic performances for a low cost material. Some studies for avoiding the coke deposition in Ni based catalysts are related with doping with noble metals (Pt) or by oxidative effect promoted by CeO_2 [2] due to the ability of this oxide to change between Ce^{3+}/Ce^{4+} oxidation states. The aim of this study is to combine both alternatives using mesoporous SBA-15 as a support, since it has a high specific surface area for helping better dispersionand smaller size of the metallic particles. In this context we have used different synthesis methods to evaluate the properties of Ni-M/SBA-15.

2 Experimental

Firstly, the SBA-15 used as support was prepared by the method described elsewhere [3]. After that, the 10%Ni-M/SBA-15 systems were prepared by three methods: [Im] using a conventional incipient wetness impregnation method, and calcining in air at 550 ºC; [ImU] consisting in a modification of the method described in [4], enhanced by ultrasound treatment and heating in Ar at 500 ºC; and [DP] deposition-precipitation, described by *Liu et al*. [5] and modified by us adjusting some parameters as the decomposition temperature of urea. Basically, a solution of the metallic precursor (Ni or Ni-Ce) together with nitric acid is added to the SBA-15 under stirring at 55 ºC. Then the urea was added, and the solution is heated for 2 h.The Pt-doped catalyst was prepared by adding 1% Pt by the ImU method over the previously calcined Ni/SBA-15 DP. Additionally, a Ni/SiO_2 catalyst was prepared as a reference, using a high surface commercial support (Aldrich-CAS: 112926-00-8, $600m^2/g$) by DP-method. The physicochemical state of the powders was characterized by means of BET, TEM, XRD, TPR, XPS, Raman and XAS. The measurements of the catalytic performance for the DRM reactions were accomplished in an atmospheric flow reactor using 20 mg of catalysts pre-reduced *in situ* at 750 ºC in H_2 5% vol. in He for 1h. The feed gas was a CH_4:CO_2 (1:1) mixture with a space velocity of 240000 ml/h·g and the temperature for reaction was 750 ºC.

3 Results and discussion

The BET results for calcined SBA-15 show surface area about $650m^2/g$ which decrease up to 250-300 m^2/g in the catalysts prepared by DP method (calcined and reduced systems).

According to our results, this effect must be related with the formation of $Si(OH)_4$ in SiO_2 during the treatment, acting as the precipitant agent of Ni^{2+} which results in formation of a nickel phyllosilicate phase detected by XRD in the calcined samples.

In the case of Im and ImU systems, the BET values present differences between the calcined and the reduced samples, with values around 450 and 350m^2/g respectively. Temperature programmed reduction (TPR) for Im, ImU and DP Ni/SBA-15 samples shows very different profiles (Fig.1) where the maximum of H_2 consumption varies from temperatures of 350 ºC for Ni-Im to 650 ºC for Ni-DP. It is also clear from these profiles that the modification applied in the Ni-ImU method results in different reducibility properties of the nickel phase. Ce and Pt doped catalysts present similar behavior under TPR than the monometallic Ni-DP, with a slight shift to lower temperatures. The high temperature of reduction for Ni/SBA-15 DP is associated with the formation of a nickel phase strongly interacting with the SBA-15 support, maybe related with the phyllosilicate phase detected in that sample.

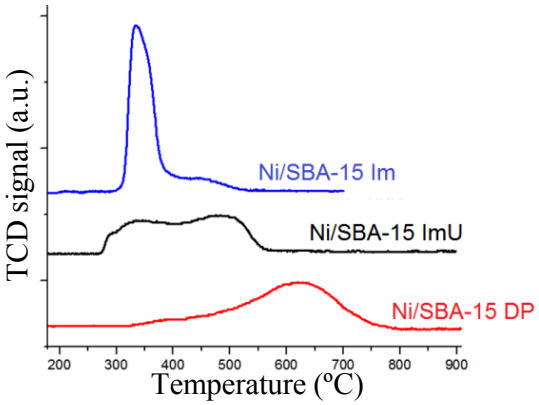

Fig. 1. TPR profile for Ni/SBA-15 monometallic systems.

The wider reduction peak observed for Ni-DP and Ni-ImU compared with Ni-Im, could be ascribed to a high dispersion of the metallic active phase, resulting in smaller particles with a better homogeneous size distribution (3-4 nm), as reflected in Fig. 2. Also, metallic particles inside the mesoporous structure can be easily detected.

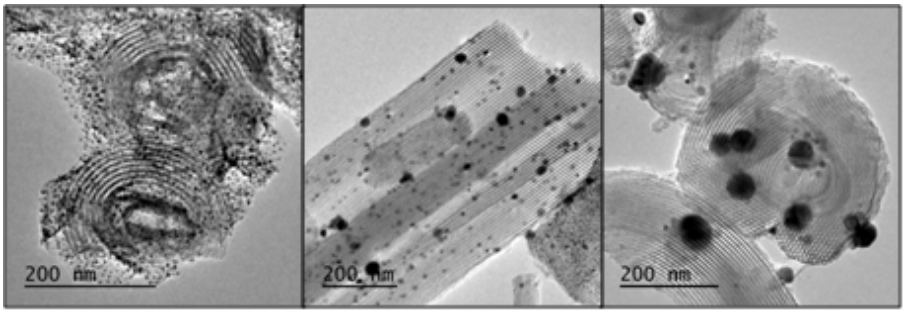

Fig. 2. TEM images for reduced samples: Ni/SBA-15.

Catalytic testduring 40h in DRM at 750 ºC, shown significant differences between the systems studied (Table 1). Thesamples prepared by DP present the most promising results based on a higher stability, together with a lower carbon deposition, as detected by ATD and Raman spectroscopy after DRM. This catalytic performance is promising even for Ni monometallic system, with improved conversions by adding 1%Pt and 10%CeO_2. Unexpectedly, in these doped systems the amount of coke detected after reaction were much higher. These data prove the singularity of our Ni/SBA-15 DP catalyst, where the outstanding performance, specially the high stability in reaction, seems to be related with the metal-support interaction described before

Table 1. CH_4 and CO_2 conversion for DRM at 750 ºC.

Sample	**CH_4 conversion (%) Initial/1000/2500min**	**CO_2 conversion (%) Initial/1000/2500min**
Ni/SiO_2 DP	61 / 36 / 20	73 / 46 / 31
Ni/SBA-15 DP	60 / 60 / 60	73 / 73 / 73
Ni/SBA-15 Im	43 / 23 / -	53 / 33 / -
Ni/SBA-15 ImU	29 / 18 / 15	40 / 29 / 24
Pt/Ni/SBA-15 DP	75 / 71 / 67	81 / 79 / 76
Ni-CeO_2/SBA-15 DP	70 / 59 / 53	81 / 73 / 66

Keywords: alkyne selective hydrogenation, alkene, activated carbon, palladium, supported catalysts

1 Introduction

The carbonaceous materials are widely used as catalyst supports in different industrial reactions. The catalysts supported on activated carbon (AC) have advantages over other material: low cost, stability, mechanical strength, high surface area, ability to modify their surface chemistry, etc. [1]. Olefins obtained by hydrogenation of alkynes, are of great academic and industrial interest, either for the synthesis of biologically active compounds, in the production of margarine industry for lubricants, plastic, etc., also presenting fine chemical applications. The objectives of this work are: a) to prepare low loading palladium catalysts supported on activated carbon, using chloride and nitrate as precursor salts, and b) to evaluate them as catalyst during the liquid phase selective hydrogenation of 1-heptyne to 1-heptene.

2 Experimental

Palladium was supported on activated carbon (Norit CNR-115, S_{BET}: 1503 $m^2\ g^{-1}$, micropore volume: 0.738 g mL^{-1}) by incipient wetness impregnation. Aqueous acidic solutions (pH = 1, HCl or HNO_3 0.1N) of $PdCl_2$ or $Pd(NO_3)_2$ used as precursor salts, were deposited on CNR to prepare the PdCl/CNR or PdN/CNR catalysts, with 0.4 wt% Pd. Samples were dried 24 h at 373 K and reduced in H_2 at 393 K. The metal content was determined by ICP in OPTIMA 21200 Perkin Elmer equipment. The hydrogen chemisorptions were determined at 303 K using a Micromeritics AutoChem II in 2920 instrument. Fourier transform infrared spectroscopy (FTIR) spectra were recorded on a Thermo Nicolet Model IR-200 spectrometer from 400 to 4000 cm^{-1} in transmission mode. To obtain the disk, 0.5 mg AC was mixed with 100 mg of KBr and then pressed. The electronic state of surface species and their atomic ratios were obtained by X-ray Photoelectron Spectroscopy (XPS) on a VG-Microtech Multilab Equipment. Binding energies (BE) of Pd $3d_{5/2}$, N 1s and Cl $2p_{3/2}$ were analyzed. C 1s signal was used as a reference. The catalyst evaluations were carried out in a stirred tank reactor of stainless steel equipped with a magnetic stirrer operated at 800 rpm, 303 K, 150 kPa H_2 pressure and using 0.75 g catalyst. 75 mL of 1-heptyne in toluene (5%) was used as feed solution. Reactants and products were analyzed by Gas Chromatography with Flame Ionization Detector (FID) and a capillary column.

3 Results and discussion

Table1. Metal loading, Dispersion values, XPS results and TOF

Catalysts	Metal loading (%)	D (%)	XPS			TOF (s^{-1})
			Pd $3d_{5/2}$ (eV)	Pd/C ($^{at}/_{at}$)	Cl or N/Pd ($^{at}/_{at}$)	
PdN/CNR	0.39	48	335.2	0.074	2.04	$1.7.10^{-1}$
PdCl/CNR	0.42	62	335.2	0.006	1.56	$6.4.10^{-2}$

Table 1 shows the metal loadings, dispersions (determined by hydrogen chemisorption technique), XPS results and TOF values for PdCl/CNR and PdN/CNR. As shown in Table 1, PdCl presents higher dispersion than PdN. XPS revealed that both catalysts have the same position for the Pd BE at 335.2 eV, indicating the presence of Pd° species on the surface [2]. The Pd/C atomic ratios show a markedly greater amount of palladium on the PdN catalyst surface. Cl/Pd and N/Pd atomic ratios indicate the presence of chloride and nitrogen on the surface due to the low reduction temperature used. Such temperature does not permit the complete elimination of precursor salts that remains on the surface of the carbon support. IR profile of PdN/CNR showed a main peak at 3444 cm^{-1} assigned to O–H stretching due to water absorbed on the surface of the material, and to hydroxylated groups. In this region, for PdN also appears an overlapping signal of N-H stretching due to the treatment with nitric acid. Besides, in PdCl/CNR the broad signals at 3444 cm^{-1} were observed but with less intensity indicating only O-H vibration remains, but the C–H vibrations of methyl and methylene groups are no longer discernible indicating a decrease in the aliphatic character of the material [3]. Both catalysts have a band at 1635 cm^{-1} which is a characteristic peak for carbon materials [4] and is probably ascribable to carbonyl groups which are highly conjugated in the graphene layer such as quinone and/or ion radical structure C=O. This is more intense for PdN/CNR caused by the treatment with HNO_3 during preparation steps.

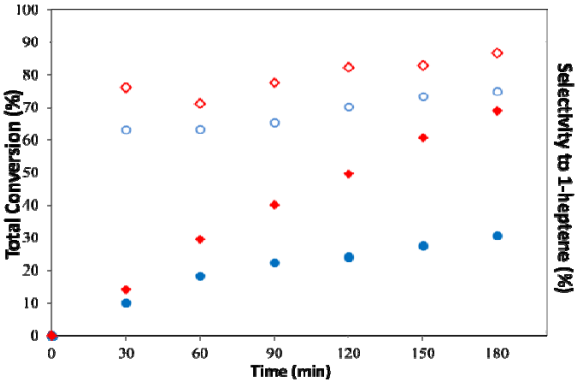

Fig. 1. 1-heptyne Total Conversion (%) (filled symbol) and Selectivity to 1-heptene (%) (open symbol) as a function of time for PdN/CNR (□,□) and PdCl/CNR (□,□)

Fig. 1 shows 1-heptyne total conversion and selectivity to 1-heptene for both catalysts. It can be seen the best performance of PdN/CNR catalyst, presenting at 180 min c.a. 70 % of 1-heptyne total conversion (55% higher than PdCl/CNR) with c.a 80% of selectivity to 1-heptene. In Table 1 the high TOF number indicates that PdN/CNR sample is the most active catalyst. Although PdN/CNR is low dispersed, it has an abundance of active species on the catalyst surface, as shown by XPS. It is possible that in PdCl/CNR, the superficial remaining chlorine interacts as a poison, decreasing the total conversion.

4 Conclusions

Two palladium catalysts were synthesized from different precursor salts (chloride and nitrate) on activated carbon with 0.4 wt% Pd. PdN/CNR showed the best performance in activity and selectivity during the selective hydrogenation of 1-heptyne to 1-heptene. The characterization results show that the treatment with HNO_3 during the preparation step of PdN/CNR modified the support surface. The best performance of PdN/CNR can be attributed to the high concentration of active species Pd° on the surface of the support catalyst. It is possible that the remaining chlorine in PdCl/CNR interacts as a poison, decreasing the total conversion.

Keywords: activity block catalysts, carrier, alkanes, hydrogen

1 Introduction

It was previously determined optimal activation conditions: concentration ≥ 0.2%, the ratio of elements Pt : Ru (2 : 1, 1 : 1) on a carrier in the comparative study of low-percentage disperse Pt, Ru and Pt-Ru/2% Ce/(θ+α)-Al_2O_3 catalysts in the oxidation of the methane of natural gas. The process conditions are τ = 4 msec, T = 1173K, 1.6% CH_4 : 0.8% O_2 = 2 : 1 in argon to produce synthesis gas with a ratio of H_2 / CO = 2.0 without the formation of CO_2, which is the most suitable for use in the synthesis of methanol and hydrocarbons by the Fischer-Tropsch process [1]. The study by physical and chemical methods has shown that oxygen on the surface of Pt-, Ru- and Pt-Ru/2% Ce/(θ+α)-Al_2O_3 catalysts is adsorbed in 2 forms (T_1 = 273 - 573 and T_2 = 573 - 1173 K). Introduction of ruthenium into the platinum catalyst with the ratio Pt : Ru = 2 : 1 and 1 : 1 increases the adsorption of oxygen in the second temperature range. Evolution of the structural oxygen (which is required for the selectivity of process) at temperatures from 973 to 1173 K, i.e. at temperature corresponding to temperature of syngas production with high selectivity was determined. It is assumed that the reaction of selective catalytic oxidation of CH_4 on the Pt : Ru (2 : 1, 1 : 1) catalysts is carried out by the direct mechanism with participation of reduced Pt-Ru clusters having the highest adsorption capacity of atomic hydrogen [2]. It is known that catalyst stability is one of the most important characteristics. The test of catalyst operation was performed on optimal catalysts Pt : Ru = 1 : 1 and 2 : 1 in the selective catalytic oxidation of methane to syngas at the millisecond contact times in prolonged terms. It was found that the synthesized catalyst was active and selective for 410 h [3].

2 Experimental/methodology

The block ceramic catalyst having supported active phase consisting of 1% (Pt+Ru)/2% Ce/(θ+α)-Al_2O_3, was prepared for the research. The active phase of catalyst was prepared by sequentially supporting of elements on the (θ+α)-Al_2O_3 100-200 microns, S_{sp} = 57.7 m^2/g) from the aqueous solutions of metal salts $Ce(NO_3)_3 \times 6H_2O$, $Ru(OH)Cl_3$, and $H_2PtCl_6 \times 6H_2O$ by capillary wetness impregnation followed by heating in air at 873 K for 3 h. Microspherical 1% Pt-Ru/2% Ce/(θ+α)-Al_2O_3 catalyst was supported on the block ceramic honeycomb carrier (fragments of blocks d = 10 mm; h = 20 mm, the channel size 1.0 × 1.0 mm, wall thickness 0.5 mm). Layering of the active phase of catalyst with binder on the blocks in several steps is the essence of process.

Tests of the ceramic block catalysts in oxidation of CH_4 were conducted in flow apparatus at atmospheric pressure in a quartz reactor with internal diameter of 0.025 m. The prepared catalyst block is wrapped in fiberglass and placed in a reactor. Initial reaction mixture was introduced at a rate of 50 ml/min after purging the system with inert gas (Ar) for 30 min at varying the ratio of reaction gases CH_4 and O_2 in a mixture from 1 : 1 to 4 : 1 and gradually

increasing the temperature from 700 to 875°C and volume rate from 1000 to 10000 h^{-1}.

3 Results and discussion

The process of oxidative conversion of hydrocarbon mixtures which are close to real while gradually increasing the reaction temperature from 700 to 875°C was investigated. Increase of methane conversion from 28 to 48% is observed with the growth of temperature. The amount of the produced H_2 increases from 33% to 84% at 850°C and again decreases to 70.2% at 875°C. A small amount of CO is formed at a temperature 700°C which increases with increasing temperature from 0.6 to 40.5%. Formation of C_2H_4 is observed at a reaction temperature 750°C in an amount of 13.0% and with the growth of temperature is lowered to 4%. Thus, the temperature 850°C is optimal for the formation of hydrogen, and 875°C and 750°C - for CO and C_2H_4, respectively. Effect of space velocity on direction of oxidative conversion of hydrocarbon mixture, which is close to the real, at variation of space velocity from 1000 to 10000 h^{-1} was studied. It was found that the hydrogen yield was 40.5% at 1000 h -1. Amount thereof increased to 84.0% at 5000 h^{-1} and then reduced to 45.1% with increasing space velocity up to 10,000 h^{-1}. The same dependence is observed for the formation of CO and ethylene. The amount of CO is increased from 10.5% to 38.0% and ethylene - from 7.8% to 13.0% at 5000 h^{-1}. Product yield gradually decreases with further increase in space velocity to 10000 h^{-1}. Increasing the space velocity from 1000 h^{-1} to 5000 h^{-1} positively affects on the conversion of initial mixture to desired products. 5000 h^{-1} is optimal space velocity for the formation of desired products. Thus, optimum ratios of main gases in the reaction mixture were also determined.

4 Conclusions

Thus, optimization of technological modes of oxidative conversion of hydrocarbon mixture was carried out. Effect of varying the reaction temperature, space velocity and ratio of gases for selective production of desired products was investigated. The temperature ranges of 725-875°C and space velocity 5000 h^{-1} are optimal process parameters to produce hydrogen compositions. It is determined that the oxidative conversion of methane to hydrogen-containing mixture is carried out at the optimum ratio of components $CH_4 : O_2 = 2 : 1$ at a concentration of gases (50% : 25%), respectively.

Keywords: aerogels, sulfated alumina, dehydrochlorination, electron-acceptor, sites, EPR

1 Introduction

Aerogels are materials obtained by a sol-gel process followed by supercritical drying of the latter. The obtained materials have high surface areas and pore volumes [1]. Deposition of sulfates on γ-Al_2O_3 is known to lead to a substantial increase of its acidity and catalytic activity in acid-catalyzed reactions [2, 3]. High surface area, wide availability, and reasonable thermal stability make sulfated alumina an attractive catalyst for variety of acid-catalyzed processes that do not require very high acid strength. However, one-step synthesis of sulfated alumina aerogels has not been reported yet. In the current communication we shall discuss the effect of various organic and acidic modifying agents, including sulfates, on the textural properties of alumina aerogels and their performance in reactions with chlorinated hydrocarbons.

2 Experimental/methodology

For preparation of modified Al_2O_3 aerogels, aluminum isopropoxide (Aldrich) was dissolved in a desired amount of ethanol and/or other solvent. A solution of the modifying agent was quickly poured into the reaction vessel with aluminum isopropoxide solution and the resulting mixture was stirred for 10 min. Then, a stoichiometric amount of hydrolysis water dissolved in same solvent was added. The resulting gel was aged for 2 hours, subjected to supercritical drying in an autoclave at 265°C and by calcination either under vacuum or in air.

Dehydrochlorination of 1-chlorobutane was performed in a flow reactor. 99% 1-chlorobutane used in the experiments was introduced into the reactor by saturation of the argon flow with C_4H_9Cl vapor at room temperature. Experiments on decomposition of (2-chloroethyl)ethyl sulfide (2-CEES) were carried out in a 25 ml three-necked flask under argon with stirring. Ten ml pentane, 15 ml decane used as internal standard, 200 mg of powder sorbent and 15 ml 2-CEES were placed in the flask. Electron-acceptor sites of the synthesized aerogels were studied by EPR using spin probes according to an earlier developed procedure [2].

3 Results and discussion

The highest specific surface areas of alumina aerogels after supercritical drying exceeding 1200 m^2/g that are 4-5 times higher than those of typically used alumina materials were obtained for the samples prepared with an ethanol-toluene mixture used as the solvent. After activation under vacuum at 500°C the surface area of the alumina aerogels without the organic modifying agents was typically between 600 and 700 m^2/g. The surface areas of the carbon-coated aerogels was typically somewhat lower, about 400-500 m^2/g. HRTEM data showed that the carbon-coated alumina nanoparticles were nanocrystalline with typical dimensions of several nanometers and covered with several layer of graphitic carbon. XRD data did not show any clear peaks indicating that the aerogels even after calcination remained amorphous to x-rays.

Sulfated alumina aerogels were synthesized by a similar procedure with sulfuric acid used as a modifiying agent. The sulfuric acid addition results in a substantial decrease of the pore volume, whereas the high surface area of the Al_2O_3 aerogels is preserved. The surface areas of the sulfated alumina aerogels after calcination at 600°C usually required to make active acid catalysts were about 600 m^2/g. This value appears to the highest ever reported for sulfated alumina catalysts and is 2-3 times higher than those reported in the literature.

We found that the activity of high surface area nanocrystalline alumina materials in dehydrochlorination of 1-chlorobutane compared favorably with that of other nanocrystalline metal oxides. The temperature of 1-chlorobutane decomposition decreased by ca. 100°C in comparison with MgO aerogel studied in detail earlier [4] while maintaining 98% selectivity to butenes. Sulfated alumina had even higher activity due to its higher acidity.

2-CEES is a mustard gas mimic commonly used to characterize the performance of materials developed for destruction of poisonous chlorinated compounds. We found that alumina and carbon-coated alumina aerogels chemisorbed 2-CEES at room temperature from pentane solution even more efficiently than MgO aerogels or conventional Al_2O_3. Sulfated alumina aerogels showed even better performance in the destructive sorption. 2-CEES conversion rate in pentane solution at room temperature over sulfated aerogel alumina was 3 times higher than on Al_2O_3 aerogel and 8 times higher than on MgO aerogel. This reaction was exceptionally fast over all sulfated oxides, both aerogel and conventionally prepared, so almost maximum conversion was reached in the first 2 minutes. Furthermore, the high surface area of the developed sulfated alumina aerogels made it possible to achieve the absolute highest conversion.

Earlier the activity of alumina and sulfated alumina in ethanol dehydrogenation was found to correlate with the concentration of weak electron-acceptor sites [3]. Their concentration was much higher on the aerogels than on conventional alumina catalysts due to high surface area. The catalytic activity of the synthesized materials in dehydrochlorination of 1-chlorobutane and 2-CEES seems to correlate with the concentration of weak electron-acceptor sites.

4 Conclusions

We have demonstrated that the textural parameters of alumina aerogels can be effectively controlled by selection of the solvents and modifying agents. Carbon-coated Al_2O_3 with permeable carbon coating can be prepared by adding modifying agents with bulky organic groups during gelation followed calcination under vacuum. Typical dimensions of the alumina nanoparticles synthesized by this method do not exceed few nanometers. The activity of high surface area nanocrystalline alumina materials in dehydrochlorination of (2-chloroethyl)ethyl sulfide (2-CEES) and 1-chlorobutane compared favorably with that of other nanocrystalline metal oxides and correlates with the concentration of weak electron-acceptor sites.

Hydrogen and Oxygen Interaction with Single Supported Gold Nanoparticles

Grishin M.V., Kirsankin A.A.*, Gatin A.K., Shub B.R., Dohlikova N.V.

Semenov Institute of Chemical Physics RAS, Moscow, Russia

* kirsankin@mail.ru

Keywords: nanoparticles, adsorption, scanning, tunnelling, spectroscopy

1 Introduction

In recent years, scanning tunnelling microscopy (STM), which ensures resolution at the atomic level, has been widely used for the study of supported metallic nanoparticles. It was found that surface structures and adsorption properties of supported metallic nanoparticles are determined by their shapes which in turn strongly depend on the nature of the support. At the same time, such low coordinated sites as edges and kinks strongly affect the interaction of a surface with adsorbed species. The use of STM for the analysis of surface structures of metallic nanoparticles seems promising, in that this method allows *in situ* analysis of surface structures, i.e., in the course of a reaction.

Scince demonstrating by Haruto their catalytic activity [1] three decades ago gold nanoparticles retains attention of many scientists. Gold nanoparticles which, in contrast with the bulk metal, manifest catalytic activity in certain reactions. In this study we demonstrated dependence of adsorption properties of single gold nanoparticles on the nature of the substrate. High ordered pyrolytic graphite (HOPG) and silicon covered oxide (SiO_2/Si) were used as substrate.

2 Experimental/methodology

Morphology and electronic structure of gold nanoparticles were determined by scanning tunneling microscopic technique by Omicron. The residual gas pressure in the setup chamber didn't exceed $P = 2 \times 10^{-8}$ mbar. Local changing of the surface state of gold nanoparticles was defined by current-voltage dependence of tunneling contact including single gold nanoparticle (*I(V)*-curves).

Gold nanoparticles were prepared by a deposition method. Chloroauric acid with a gold loading of 5 wt % was first dissolved in distilled water and after deposited on the surface of substrate (HOPG and SiO_2/Si). Substrate with acid was dried and then calcined in ultrahigh vacuum (10^{-10} mbar) at 500 K for 6 h.

3 Results and discussion

Single gold nanoparticles supported on HOPG (Au/HOPG)

The formation of gold nanoparticles occurs near the lattice defects of graphite surface. Both isolated nanoparticles of 4-5 nm and large agglomerates with lateral sizes of 40-100 nm consisting of individual 5 nm particles on the graphite surface were observed. The current-voltage dependence of tunneling contact consisting gold nanoparticles corresponds to the metallic conduction.

To study the interaction of hydrogen with gold nanoparticles at room temperature sample was kept over 500 seconds at room temperature in molecular hydrogen at a pressure of $P = 2 \times 10^{-6}$ mbar (exposure 1000 L). The hydrogen exposure doesn't lead to shape and sizes changing of gold nanoparticles. The band gap with width of 0.8 V on the *I(V)*-curves was observed after hydrogen exposure. Hydrogen-gold binding energy lower limit was measured by thermodesorption method and is equal to 1.7 eV. Based on the results of quantum-chemical calculation made by us the

hydrogen adsorption on Au_{13}-H_{12} clusters is characterized by breaking of H-H bond and formation of Au-H bond with binding energy of 3 eV.

The oxygen adsorption can be determined only after the preliminary exposure of gold nanoparticles in hydrogen. Current-voltage dependence of tunneling contact of Au/HOPG with adsorbed oxygen and hydrogen doesn't differ from these of gold nanoparticles coated by hydrogen only. Perhaps oxygen adsorption occurs without breaking of O-O bond.

Au/HOPG sample, coated firstly by hydrogen and then by oxygen, were exposed into the hydrogen for evaluation of Au/HOPG reactivity. The measured current-voltage dependence exhibit multiple local maxima located almost symmetrically with respect to the coordinate origin. The voltage differences corresponding to the position of peaks on the experimental curves was 0.41 and 0.25 V between adjacent peaks which is accurate within a dimensional factor corresponds to quanta of electron-vibration excitation of the O-H bond and the deformation vibration of the water molecule.

Single gold nanoparticles supported on SiO_2 (Au/ SiO_2)

The lateral diameter of single gold nanoparticles supported on SiO_2 is 4-5 nm. The comparison of gold nanoparticles diameters into SiO_2 and HOPG allows making a conclusion that type of substrate doesn't have a significant influence on the morphology of gold nanoparticles.

Au/HOPG and Au/Sio_2 equally interact with hydrogen. Hydrogen is chemisorbed on gold nanoparticles supported on SiO_2 at room temperature as well as on gold nanoparticles supported on HOPG. However at the following puffing of oxygen the formation of water molecules on the surface of gold nanoparticles was observed. Thus, it was found that water is formed at the gases puffing by H-O-H scheme on Au/HOPG and by H-O scheme on Au/SiO_2.

4 Conclusions

The conditions of hydrogen and oxygen adsorption on Au/HOPG and Au/Sio_2 were determined by methods of scanning tunneling microscopy and spectroscopy. Production of water molecules on gold nanoparticles was observed. It was shown that, application of semiconductor as a substrate dramatically increases the reactivity of gold nanoparticles.

Cu(I) and Rh(I) Complexes of Novel Pyridyl-Containing Phospholanes

Shamsieva A.V.*, Musina E.I., Karasik A.A., Sinyashin O.G.

A.E. Arbuzov Institute of Organic and Physical Chemistry of Kazan Scientific Center of Russian Academy of Sciences, Kazan, Russia

* shamsieva.aliya@mail.ru

Keywords: phospholanes, P,N ligands, Rh(I) complexes

1 Introduction

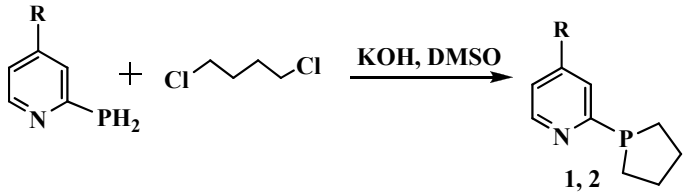
The correlation of stereoelectronic effects in tertiary phosphine ligands with the reactivity of their coordination complexes is key to understanding their efficiency in homogeneous catalysis. Cyclic phosphines are in special interest for coordination chemistry and catalysis due to their relatively rigid structrure. However the chemistry of phosphorus heterocycles is much less developed than the analogous nitrogen chemistry [1]. Cyclic phosphines have been shown to be excellent ligands for catalysis and particularly hydroformylation catalysis [2-5]. There are only two works focused on studying rhodium-catalysed hydroformylation of 1-octene using phenyl or *tert*-butyl substituted cyclic phosphines [6] and bidentate cyclic bisphosphines with ring size from 5 to 7 [7].

It was demonstrated that the catalyst activity decreases with increasing phosphacycle ring size and the most active catalyst system was based on the rhodium complex with ligand with smaller ring (**L_5**).

Herein we describe the synthesis of new phosphalanes containing pyridyl moiety on phosphorus atom and their complexes with transition metals.

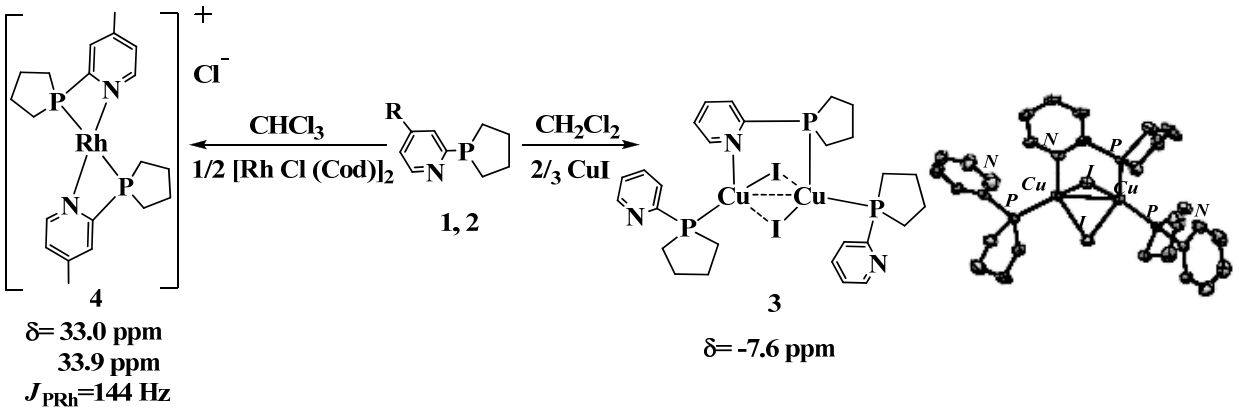
2 Results and discussion

A novel pyridyl containing tertiary cyclic phosphines – 1-(pyridine-2'-yl)phospholane **1** and 1-(4'-methyl-pyridine-2'-yl)phospholane **2** were obtained in good yields in reaction of corresponding primary pyridylphosphines with 1,4-dichlorobutane in superbasic medium according Scheme **1:**



Scheme 1.

Reaction of **1** and CuI led to the formation of complex **3** with "butterfly" shaped Cu_2I_2 halide core and bidentate P,N-bridge coordination of one ligand molecule and P-monodentate coordination mode of two others (Scheme **2**).



Scheme 2.

The abillity of the ligand **1** to form the P,N-coordinated complexes motivated us to test it coordination with rhodium, which is catalytic active metal. Thus, the reaction of **2** with $[RhCl(Cod)]_2$ led to bis-P,N-chelate complex **4**, the spectral parameters of complex **4** are similar to that of described catalyst [8], which makes it perspective to test in hydroformylation reactions.

Development of Stable Catalysts for Debenzylation of Hexaazaisowurtzitane Derivatives

Malykhin V.V.*, Sysolyatin S.V.

Institute for Problems of Chemical and Energetic Technologies SB RAS, Biysk, Russia

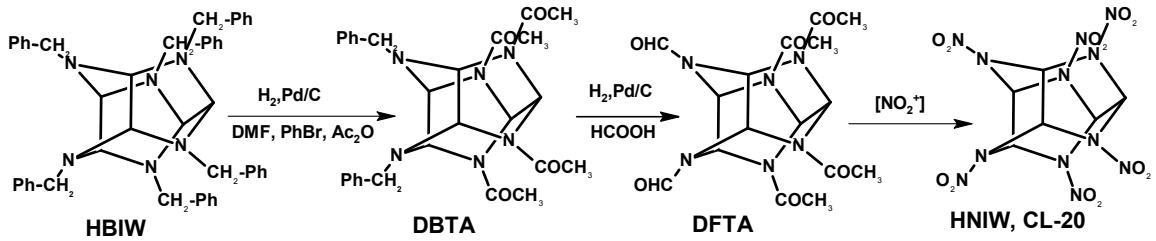
* astro-78@mail.ru

Keywords: catalytic debenzylation, Pd catalyst, hexaazaisowurtzitane, derivatives

1 Introduction

In the field of high-energy materials, great attention has been paid over the last decade to studying the properties and searching for effective synthesis methods of 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12- hexaazaisowurtzitane (HNIW, CL-20, HAW), a powerful explosive [1].

HAW has not received wide application due to its high cost and complexity of the industrial synthetic method. One of the known synthetic routes to HNIW is depicted in the scheme below [2,3]:



At the present time, the synthetic methods of the polycyclic cage are fairly well studied, as are DFTA nitration techniques [3,4], and they can be applied without any difficulty. However, the two catalytic stages of the process (HBIW→DBTA→DFTA), which are more complicated and are price determinative in the entire synthesis method of HAW, have been much less studied. A Pd catalyst is used sequentially at the two stages of debenzylation. The key problem in the practical realization of these stages is that the expansive Pd/C catalyst would be rapidly deactivated, not allowing its multiple reuse. The known techniques to regenerate Pd catalysts do not permit the catalyst activity to be recovered to the initial level—which is necessary for exhaustive reaction of hydrodebenzylation. The catalyst recycling may reduce the HAW production cost.

2 Results and discussion

The effects of the catalyst preparation methods on the catalyst activity were studied. The reducing agent nature was found to considerably influence the catalytic properties while the surface finishing technique and support dispersion had little impacts. The activities of the differently obtained catalysts were evaluated under model and relatively near-real conditions.

The possibility of the multiple separate use of the catalyst at the synthesis stages of DBTA and DFTA was investigated and demonstrated. Optimum catalyst loadings that enable the catalyst recycling up to 10 times at the first stage of debenzylation and up to 14 times at the second were identified.

The catalyst deactivation character at the two process stages was studied by TEM microscopy. The catalyst deactivation at the debenzylation stages is essentially caused by the irreversible enlargement of the palladium particles (Fig. 1).

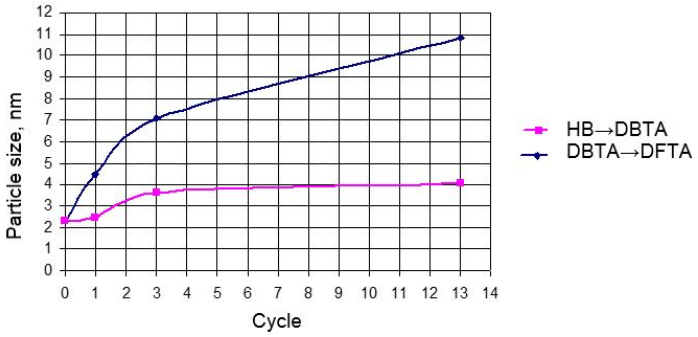


Fig.1. Variation of the mean Pd particle size upon recycling the catalyst at the debenzylation stages

The different characters of deactivation at the debenzylation stages do not enable recycling the catalyst sequentially in the two-stage process (HB→DBTA→DFTA). The key solution to the multiple reuse of the catalyst at the debenzylation stages of HB is separately using the catalyst: the first process (HB→DBTA) employs one sample of the catalyst and the second process (DBTA→DFTA) uses another one (freshly prepared or the spent one from the first stage) [5].
Based on the studies conducted, a technology has been developed for the two-stage catalytic debenzylation of HB with multiple reuse of the catalyst, which allows the catalyst consumption to be appreciably reduced.

4 Conclusions

The technology for the two-stage catalytic debenzylation of HB permits the Pd catalyst consumption to be decreased by a factor of five.

The study results have been corroborated in the course of working out the regimes on a pilot setup at IPCET SB RAS.

Keywords: the catalyst molybdenum, 1,1'- dioxydicyclohexylperoxid, epoxidation, propylene

1 Introduction

Researches on improvement of propylene hydroperoxide epoxidation of are carried on beginning from introduction of joint receiving styrene and propylene oxide at Public Joint-Stock Company «Nizhnekamskneftekhim» (Russia, Tatarstan). However today's actual problems are increasing molybdenum solubility, decreasing ethyl benzene hydroperoxide (EBHP) consumption in the catalyst preparation, increasing catalyst stability, and also development of new catalyst with the best technological and technical-and-economic indicators.

The analysis of both scientific and technical literature and also the patent publications connecting with receiving molybdenic catalysts for olefins epoxidation shows that for the catalyst synthesis the various hydroperoxide compounds can be used (hydrogen peroxide, peracids, ethyl benzene hydroperoxides, cumene hydroperoxides, I tretbutit hydroperoxides, I tretamit hydroperoxides and so on).

We developed the way of receiving peroxide derivative of cyclohexanone based on reaction between the cyclohexanone and hydrogen peroxide that is contained in sewage of ethyl benzene oxidation shop in production of styrene and oxide of propylene [1]. The result of interaction is the 1,1 '-dioxydicyclohexylperoxide.

In literature sources there are no data on using this peroxide in synthesis of the molybdenic catalyst for epoxidation. Therefore it was very interesting to study possibility of the catalyst preparation on the basis of 1,1 '- dioxydicyclohexylperoxide received with using the peroxide-containing sewage.

2 Experimental/methodology

In the researches the ethyl alcohol (State standard specification 18300-72), powdery metal molybdenum (TC 48-19-316-92) and 1,1 '- dioxydicyclohexylperoxide with the content of active oxygen – 6,9%, melting temperature – 69,1 °C and molar weight – 230,1 was used.

The epoxidation catalyst was prepared by dissolution of powdery metal molybdenum in alcohol solution of 1,1 '- dioxydicyclohexylperoxide in the thermostatically controlled reactor with a mixer at the temperature of 50 °C within 2 hours. For preparation of catalysts the peroxide alcohol solutions with concentration of 0,4 - 1,68 mol/l was used. The molybdenum content in catalytic solution was 0,7 - 4,0% mass. Peroxide concentration was determined by method of iodinemetric titration. The content of the dissolved molybdenum in catalytic solution was determined by a vanadatometric method.

3 Results and discussion

The researche was carried on in two directions. At the first stage the composition and also the catalyst preparation conditions was optimized. The analysis of the obtained data showed that the most convenient method of the molybdenum-containing catalyst synthesis is the way based on dissolution of metal molybdenum powder in alcohol solution 1,1 '-

dioxydicyclohexylperoxide. After experimental studying of various factors influencing activity of the received catalyst samples the optimum compounding and also synthesis optimum conditions were developed. At the second stage the pilot production tests of propylene epoxidation by ethyl benzene hydroperoxide on the basis of the received optimum catalyst were carried out. The tests of process of propylene epoxidation showed the high selectivity of reaction of propylene oxide formation and also product yield exceeding similar indicators for the industrial catalyst.

The results received during the pilot production tests were used for development of basic data for design of set for molybdenic catalyst synthesis on the basis of 1,1 '- dioxydicyclohexylperoxide.

4 Conclusions

The catalyst received with using 1,1 '- dioxydicyclohexylperoxide has following advantages in comparison with industrial one: it allows to exclude the ethyl benzene hydroperoxide from catalyst synthesis process, it allows considerably to decrease a consumption of ethyl alcohol. The main ecological advantage is the utilization of peroxide-containing sewage.

Keywords: water oxidation, layered double hydroxide, photosensitizers

1 Introduction

Water oxidation has a key role in the field of hydrogen production. In the recent years, several new concepts appeared to design potential novel catalysts, *e.g.*, LDHs with high activity for water oxidation, improving the appealing of this area[1]. Although the intercalation of LDHs with photosensitive compounds is described in the literature for obtaining sensors with high stability, the effect of the intercalated photosensitizer on the LDH's photocatalytic activity is less known. Moreover, in the literature, there is example for the electron transfer between the lattice sites of the positively charged LDH and adsorbed $[Ru(bpy)_3]^{2+}$ $[Fe(bpy)_3]^{2+}$ and $[Os(bpy)_3]^{2+}$ cations[2]. The unique combination of properties of $[Ru(bpy)_3]^{2+}$ (bpy = 2,2'-bipyridine) and of its modified versions, like chemical stability, redox properties, excited-state reactivity and excited state lifetime made it interesting as photosensitizer. In practice, the bipyridine-type Ru(II) complexes as photosensitizers, can be a part of photocatalytic molecular devices.

2 Experimental/methodology

Synthesis of $[Ru(2\text{-}pyridyl\text{-}2'\text{-}benzothiazole)_2](Cl^-)_2$ - RuPBT - complex provides potential photosensitizer that can be built into a composite system for catalysis. The active substrate, NiFe−LDH was synthesized with 3:1 ratio of the divalent and trivalent metals. RuPBT was characterized using ESI-MS, and FT-IR spectroscopy and its light absorption was measured by UV-VIS spectrophotometry. Since RuPBT is positively charged like the NiFe-LDH layers, terephtalate anion was used as a link, attaching the complex to the surface of the LDH. The successful synthesis of the molecular-photosensitizer-on-functional-LDH composite was proved by using a variety of techniques (XRD, FT-IR, cyclic voltammetry and XPS). Furthermore, catalytic activity of the host material was studied in oxygen evolving reaction (OER).

RuPBT was synthesized by reacting $RuCl_3 \bullet xH_2O$ with the 2-pyridyl-2'-benzothiazol ligand with the ratio of 1:3 at 80 ˚C in dimethyl-formamide. The obtained metal complex has a broad absorbtion band with λ_{max} at 480 nm.

NiFe-LDH was synthesized via co-precipitation method, from nitrate salts. The structure of the obtained material was characterized by XRD. The basal distances of the LDHs (d_{003} = 7.9 Å) were the same even when different surface modification methods were applied. In the gallery space of the NiFe-LDH CO_3^- anions were added to avoid the possible modification of the composition during OER. Na-therephthalate (TT) and the 2:1 mixture of Na-therephtalate and RuPBT (TT-RuPBT, c = 3 M) were disolved in a water:ethanol:NaOH 5:1:1 solution in the presence of NiFe-LDH. After stirring for 24 h at 60 ˚C the residue was filtered and cleaned by washing. No changes in the basal distances of the LDH occured during the modification of the surface.

3 Results and discussion

Surface concentration of Ru on LDH was determined by X-ray photoelectron spectroscopy (XPS). The peaks present at 283.2 eV and 287.4 eV were assinged to Ru 3d, while those at 463.3 eV and 466.8 eV to Ru 2p. The Ru/Ni ratio is 0.0112.

For the electrochemical measurements (cyclic voltammetry and chronoamperometry) a thin film of the LDH or LDH-TT-RuPBT was fabricated on the surface of an ITO (indium doped tin oxide) electrode. 0.1 g of a 10 g/dm^3 suspension was layered on the surface obtaining 1 mg of the dry, thin layer LDHs. The CVs were recorded at pH 9.0 in borate buffer in the presence or absence of 0.1 mM of RuPBT in the bulk solution. Importantly, a new cathodic peak is present when LDH-TT-RuPBT is tested. Note that an electrocatalytic anodic wave is present either way with the onset potential being at ~0.97 V.

Electrocatalytic water oxidation (*e.g.* OER) tests were conducted in pH 9.0 borate buffer setting 1.25 V at the ITO against the AgCl/Ag ref. electrode, either in the dark or under continous irradiation (>360 nm, 300 W Xe-lamp). The NiFe-LDH on ITO showed much higher O_2 production rate when irradiated. Importantly, the charge (Q)/evolved n(O_2) ratio corresponds to ~100% efficiency. Irradiating the samples with light at λ = 480 nm wavelenght only the NiFe-LDH-TT-RuPBT composite system showed oxygen production rate.

4 Conclusions

RuPBT was successfully synthesized. The obtained metal complex was immobilized on the surface of NiFe-LDH with terephtalate anions. Several techniques proved the presence of the RuPBT on the surface of the LDHs. Furthermore CV measurements showed significant difference in the electrochemical properties of the organic-inorganic composite material.

Our experiments demonstrate the potential of NiFe-LDH as light-responsive water oxidation electrocatalyst. RuPBT (as an archetype of robust molecular photosensitizer) was successfully attached to the LDH causing no detectable structural changes. Therefore we think that LDHs can be applied as host-catalyst bifunctional materials to accomodate photosensitizers that in turn may allow their photoactivation in the visible range. Further investigations will aim to explore this field.

Synthesis of Zeolite Membranes of the Type MCM-22 and Y for Use in the Separation Process Oil/Water

Barbosa A.S.*, Rodrigues M.G.F.

Federal University of Campina Grande, Academic Unit of Chemical Engineering, Campina Grande, Brazil

* antoniellybarbosa@yahoo.com.br

Keywords: zeolite MCM-22, zeolite, zeolite membrane, α-Al2O3, oil-in-water

1 Introduction

Oily wastewater from industry and domestic sewage is one of the main pollutants to the environment in the world. With the production of crude oil and natural gas, an aqueous stream named "produced water" is normally accompanied due to the hydraulic fracturing process. The produced water, which contains dispersed oils, suspended particles and dissolved solutes, constitutes the largest waste stream from oil and gas manufacturing industries [1]. Many have been made in the treatment of oily different membranes with effluents. Ceramic membranes have been known for years, and used in many different applications, depending upon their numerous advantages: stability at high temperature and pressure resistance, good chemical stability, high mechanical strength, good durability and antifouling properties. Ceramic MF membrane may be made from alumina, mullite, cordierite, silica, spinel, zirconia and other refractory oxides [2]. The aim of this work is the use of thin zeolite membranes (MCM-22 and Y) (rubbing and mechanics mixture) for the separation of suspensions of oil-in-water.

2 Experimental/methodology

The methodology used in the synthesis of materials: zeolites MCM-22 and Y, α-alumina ceramic membranes and the membranes zeolite Y and MCM-22, followed by methods described [3] e [4].

3 Results and discussion

The results of XRD of samples of MCM-22 zeolite, ceramic membrane, MCM-22 zeolite membrane, Y zeolite, ceramic membrane, Y zeolite membrane are shown in Fig. 1.

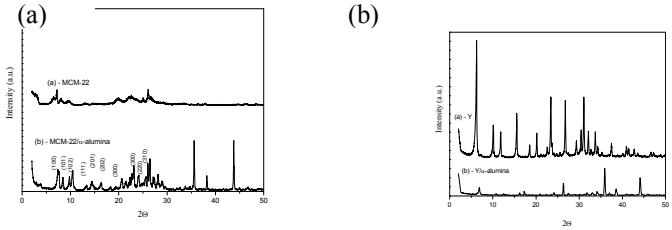

Figure 1. XRD patterns of the samples: (a) MCM-22 zeolite and zeolite Membrane MCM-22 and (b) Y zeolite and zeolite Membrane Y.

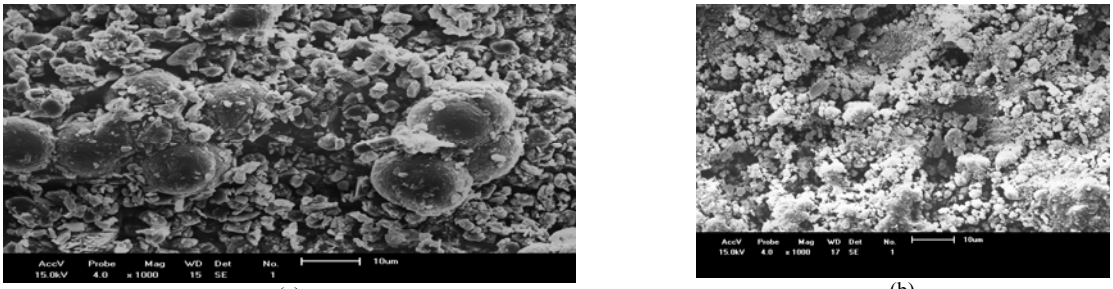
Two distinct phases can be identified as a constituent of the zeolitic membrane structure: MCM-22 zeolite and clay (α-Al_2O_3) membranes are shown in Fig. 1(a). The XRD pattern showed that the MCM-22 zeolite synthesized on the ceramic membrane (α-alumina) showed crystalline structure as described by Yang et al. [5] without evidence of other crystalline phases (impurities). The formation of MCM-22 zeolite on the surface of the porous (α-Al_2O_3) membrane can be confirmed by observation of characteristic peaks in the regions corresponding to 2θ = 12–25˚ and 2θ = 26–29˚; the peaks have good intensity [6]. From the XRD pattern

(Figure 1b), it was found that the material obtained has characteristic peaks of zeolite Y, with the peaks corresponding to 2θ values of 6,2º; 10,3º; 12.5 °; 15,8º; 17,6º; 20,0º; 21,7º; 26,0º; 27,9º; 31,0º and 34,0º, which according to the standard IZA (International Zeolite Association) and a JCPDS card 43-0168, peaks are typical sodium Y zeolite (NaY) and can also observe the presence of the crystalline phase stable α-alumina (standard record JCPDF 10-0173), thus confirming the formation of zeolite membrane Y.

Figure 2 shows the SEM images obtained for MCM-22 zeolite membrane and Y zeolite membrane.



(a) (b)

Figure 2. Micrographs of samples: (a) zeolite membrane MCM-22 (b) zeolite membrane Y

Figure 2a provides an example of a zeolite membrane MCM-22 that was prepared. Two different morphologies on the surface of zeolite membrane MCM-22 was observed. Upon close examination of the cross-section (Figure 2b), the membrane has grown a zeolitic film composed of crystals of MCM-22 and there is the morphology of the ceramic (α-alumina) support, the image displayed by this layer is according to, referring to the ceramic α-alumina support [3].

Through the micrograph (Figure 2b), there is the formation of a heterogeneous surface with no cracks and surface defects. It was found that the support was covered with zeolitic material. It was also possible to observe the presence of grain boundaries similar to those of zeolite Y [4].

Conclusions

The XRD pattern showed that the MCM-22 zeolite membrane and Y zeolite membrane obtained by the method of secondary growth synthesized on the ceramic support crystalline structure showed no evidence of other phases characterized as impurities. A SEM micrograph of the membrane zeolite MCM-22 and Y zeolite membrane showed the formation of a zeolite layer over the ceramic support, which spherical particles grown on the surface of the ceramic support.

Membrane Zeolite MCM-22/γ-Alumina Applied to the Adsorption Capacity of the Gasoline

Barbosa A.S.*, Rodrigues M.G.F.

New Materials Development Laboratory, Federal University of Campina Grande, Campina Grande, Brazil

* antusiasb@hotmail.com

Keywords: membrane zeolite MCM-22/γ-alumina, adsorption

1 Introduction

Industrial processes generate effluents contaminated with organic substances and they have to be treated before disposal without harming the environment. An efficient and sustainable process for purification or for the remediation of groundwater have to meet environmental legislation while operating cost [1]. The zeolite membranes belong to the group of microporous inorganic materials, which are a promising technology. They have advantages over polymeric membranes, especially in respect to chemical resistance, biological stability and resistance to high temperatures and pressures, and over traditional methods of separation (distillation, centrifugation, etc.), such as low power consumption energy, long life, light physical space occupation and ease of cleaning [2]. The preparation and characterization of zeolite membranes is still an innovative subject in Brazil. Within this context, this work is to synthesize zeolite membranes of the MCM-22 type on the γ-alumina ceramic supports, using the secondary growth technique (rubbing), to evaluate the performance in the test adsorption capacity in gasoline.

2 Experimental/methodology

For the synthesis of the ceramic support (γ-alumina) was initially carried out thermal decomposition of aluminum sulfate (Al_2 (SO_4) $_3.16H_2O$) P.A., in a muffle furnace at a temperature of 1000°C using a heating rate of 5°C/min and 2 hours threshold. Then 200ml prepared dispersion having the following composition: 40% of alumina obtained above; 0.2% PABA para-amino benzoic acid (dissolved in ethanol); 0.5% oleic acid (lubricant) and 59.3% ethyl alcohol. The mixture was ground for 1 hour in a ball mill and then placed in an oven for 24 hours at 60°C; umidificou with 7% water, allowed to stand for one day. Was weighed 3 g of the material and placed in the mold. The pressing was performed with 4 tons. The compressed material was subjected to sintering at 700°C for 1 hour.

The zeolite membrane was prepared using the technique of secondary growth (rubbing) [3]. One solution to the synthesis of MCM-22 zeolite membrane was prepared. The methodology used was based on the procedure described in [4]. It is initially hydrolyzed tetraethyl orthosilicate in the aqueous hydrochloric acid solution under heating to obtain the synthesis gel. Later there was prepared an aqueous solution consisting of: sodium aluminate, sodium hydroxide, hexamethyleneimine, to this solution was added the previously hydrolysed gel synthesis, where it was kept under stirring at room temperature for 20 h. The solution was then placed in Teflon crucible and placed in stainless steel autoclaves, where the γ-alumina ceramic substrates with the seeds of zeolite MCM-22 were deposited by rubbing immersed. The hydrothermal synthesis for the growth of the zeolite layer on the support surface occurred at 150°C for 4 days. The synthesis product obtained was washed with distilled water to neutral pH and dried in an oven at 60°C for 24 hours.

3 Results and discussion

Figure 1 shows the XRD pattern of zeolite MCM-22 obtained membrane / γ-alumina in Table 1 and its adsorption capacity for gasoline.

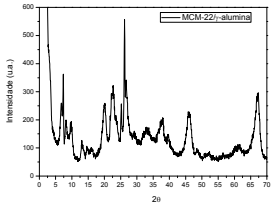

Fig. 1. XRD pattern of zeolite membrane MCM-22/γ-alumina.

Table 1. Adsorption capacity of the samples

Samples	Capacity (g gasoline / g sample)
MCM-22/γ-alumina	22,01

The peaks relating to the XRD patterns of zeolite membrane MCM-22 / γ-alumina synthesized with secondary growth method (rubbing), have similar peaks to those found for the zeolite powder [5, 6] together with the characteristic peaks of ceramic support [7], which indicates that typical zeolite membranes MCM-22 / γ-alumina were successfully obtained. High adsorption capacity values of the gasoline zeolitic membrane (MCM-22 / γ-alumina) were observed in table 1. Studies carried out in the laboratory development of new materials [8, 9] show that organophilic clays to adsorb gasoline values 5.13 and 5.62 respectively. By comparing the results of this study with the literature [8, 9] it can be seen that the adsorption capacity values were much higher than for gasoline, demonstrating that the zeolite membranes are very promising materials for gas adsorption capacity.

4 Conclusions

In conclusion, the formation of zeolite membranes on the γ-alumina ceramic support was investigated. Based on the results of X-ray diffraction, it was verified that the preparation method used to sow the ceramic support, (Rubbing), was effective in obtaining the zeolite membrane MCM-22/γ-alumina as well as the adsorption of gasoline.

Study of Adsorption of Hydrogen and Ethane on Bimetallic Platinum and Iridium Nanoclusters Using Quantum-Chemical Calculations

Garifzianova G.G.*, Shamov A.G.

Kazan National Research Technological University, Department of Catalysis, Kazan, Russia

* garifz@kstu.ru

Keywords: platinum, iridium nanocluster, DFT

1 Introduction

One of the most promising directions in the field of catalysis is the use of catalysts containing several atoms of metal and deposited on an inert support. A large number of works devoted to the study of physical and chemical properties of nanoclusters of platinum group, as well as bimetallic clusters based on them [1-2]. Modern quantum-chemical methods are widely used along with modern experimental techniques for exploration of geometry and electronic structures.

Understanding the mechanism of interaction between hydrogen and platinum-iridium clusters is of fundamental scientific and practical interest, since the adsorption of hydrogen is an essential stage in many industrially important catalytic processes, such as hydrogenation and dehydrogenation of hydrocarbons.

2 Results and Discussion

The Structure of nanoclusters Pt_nIr_m (n,m=1 ÷ 3) were studied using DFT with different basis sets. The calculations were performed using the Gaussian 09 program [3]. The geometry structures of nanoclusters were obtained for states with different spin multiplicities.

We studied adsorption of hydrogen molecule on the bimetallic nanoclusters Pt_nIr_m (n,m =1 ÷3). For this purpose, potential energy surface (PES) scan calculations with geometry optimization at each point were performed. Inspection of the geometry structure of resulting Pt_3IrH_2 cluster (method B3LYP/LanL2DZ) showed that position of hydrogen on top of the platinum is more favorable than bridge position. A similar study of the mechanism of hydrogen adsorption was conducted for rhombic cluster Pt_2Ir_2. Results of the latter study showed that adsorption of hydrogen on the clusters Pt_nIr_m (n,m =1 ÷ 3) is barrierless reaction. Relative stability of Pt-Ir clusters is strongly affected by the presence of hydrogen, thus, Pt_2Ir_2 cluster transformed from the cluster with diamond-shaped flat structure into three-dimensional tetrahedral cluster.

The activation energy of the ethane hydrogenolysis on these bimetallic Pt-Ir clusters is smaller than on monometallic iridium and platinum clusters [1]. Potential energy profiles and activation barriers were calculated for key stages of the ethane conversion on bifunctional $PtIr_m$ (m =2 ÷ 3) catalysts. Geometrical parameters of the transition states TS1 on the clusters $PtIr_3$ is shown in Figure. The activation enthalpy for this process is 42.9 kJ/mol.

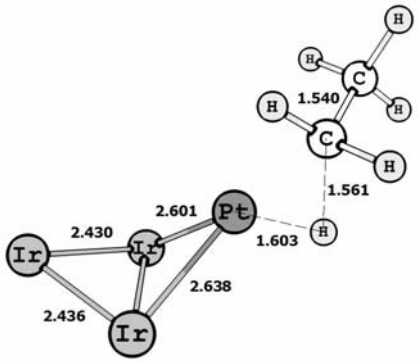

Figure. Optimized geometries of transition state TS1 structure reaction of the ethane hydrogenolysis on these bimetallic $PtIr_3$ cluster. Bond lengths are given in Å.

3 Conclusions

Results of the latter study showed that adsorption of hydrogen on the clusters Pt_nIr_m (n,m =1 ÷ 3) is barrierless reaction. Geometrical parameters of the optimized structures of nanoclusters and transition states of the ethane hydrogenolysis on these bimetallic Pt-Ir clusters were also obtained.

Keywords: zinc containing, layered double hydroxides, platinum, catalysts, alkane, dehydrogenation, EXAFS

1 Introduction

Platinum catalysts supported on aluminum–magnesium oxide materials are widely used in base-catalyzed reactions and in the conversion of hydrocarbons. The formation of the properties of the catalysts may depend considerably on the structure and composition of the precursor of the oxide support, namely, layered double hydroxide (LDH). The general formula of LDHs is $M^{2+}_{1-x}M^{3+}_x(OH)_2[(A^{n-})_{x/n}\bullet mH_2O]$, and they consist of brucite-like layers in which part of the divalent cations (M^{2+}) is isomorphically substituted by trivalent cations (M^{3+}) that have a similar ionic radius. The excess positive charge of the layers is compensated by hydrated A^{n-} anions located in interlayer spaces. A unique feature is that with this type of hydroxide precursor, the M^{2+} and M^{3+} cations undergo uniform distribution during the subsequent formation of the mixed oxide phase. The introduction of special modifiers to adjust the properties of supported platinum to the demands of a particular reaction to obtain target product with high selectivity is an effective approach. The novelty of this work was to introduce the modifier cation (zinc) in the structure of the support during the LDH synthesis. Formation of zinc-containing LDH is poorly described in the literature but it is known that zinc modifies the properties of the supported platinum. In particular, in the presence of ZnO, the dispersion of Pt grows and dehydrogenation activity of supported catalysts increases. Our study examined the effect of zinc in LDH on the formation of active sites of the catalysts Pt/Mg(Zn)AlO$_x$, their composition, adsorption and catalytic performance. Catalytic properties were tested in propane and n-decane dehydrogenation.

2 Experimental/methodology

LDH-Mg(Zn)Al-CO_3 (with CO_3^{2-}-anions in interlayer space) was synthesized by co-precipitation, M^{2+}/Al=2. LDH-Mg(Zn)Al-OH (with OH^--anions in interlayer space) was obtained after calcinations of LDH-Mg(Zn)Al-CO_3 at 550 °C and subsequent hydration of mixed oxides in water. Anchoring of platinum chloride complexes was carried out on LDH-Mg(Zn)Al-OH. Elemental analysis was made by ICP-AES (Varian 710-ES). Structural features of LDH and mixed oxides were studied by XRD (D8 Advance, Bruker). Adsorption–desorption isotherms of nitrogen at 77.4 K were measured using a static volume vacuum system ASAP-2020M (Micromeritics). CO and H_2 pulse chemisorption (AutoChem II 2920, Micromeritics) and transmission electron microscopy (JEM-2100, JEOL) were used to estimate the particle size of platinum. X-ray photoelectron spectroscopy (XPS) was carried out on a spectrometer SPECS, Germany. EXAFS and XANES spectra of the PtL_{III} absorption edge were measured at the ID26-beamline of the European Synchrotron Radiation Facility (ESRF, Grenoble, France). Catalytic properties of Pt/Mg(Zn)AlO$_x$ were investigated under the following conditions: T = 550 °C, atmospheric pressure, WHSV 8 h^{-1} and H_2/C_3H_8 molar ratio of 0.25 (in propane dehydrogenation); T=460°C, pressure 0.2 МПа, WHSV 17 h^{-1}, $H_2/C_{10}H_{22}$ molar ratio of 7 (in decane

dehydrogenation).

3 Results and discussion

Study of the LDH showed that hydrotalcite-like structure was saved when a partial or complete replacement of Mg to Zn took place as well as the introduction of Pt(IV) anionic complexes in the interlayer space of Mg(Zn)Al-OH. Calcination of zinc-containing LDH with adsorbed platinum complexes led to an interaction between zinc and platinum with a significant modification of platinum properties. In zinc-containing samples the particles of platinum had different morphology and smaller sizes in comparison with $Pt/MgAlO_x$. In accordance with the EXAFS data for $Pt/Mg(Zn)AlO_x$ there are no peaks in the spectra corresponding to platinum-platinum bonds (fig. 1a). Therefore it can be assumed that platinum atoms surrounded only by zinc atoms. The results of XPS showed that the Pt/Al atomic ratio for all the samples was close to ~ 0.007. The value of binding energy $Pt3d_{5/2}$ for sample with Zn/(Mg+Zn)=0.1 (2122.7 eV) was significantly higher, than for the samples Zn/(Mg+Zn)=0.5, 0.7. For the latter, the energy was close to that of the metallic state of platinum (and even slightly lower) and was equal 2121.4 eV. From the EXAFS and XPS results it can be concluded that platinum in these samples is in the Pt-Zn alloy particles with a relatively low platinum concentration.

The resulting catalysts are characterized by a higher propane conversion (close to the equilibrium at a Zn/(Mg+Zn)=0.1) with a selectivity in the propylene formation 99% (fig. 1b). When Zn/(Mg+Zn)>0.1, there is some decrease in activity while maintaining high selectivity. This may be result of decreased specific surface area and changes in the pore space of the oxide support due to the formation of additional phase enriched by zinc. Modifying of platinum in the presence of zinc also has been shown in the transformation of higher alkanes. Decrease in the content of dienes in the products of n-decane conversion may be a consequence of the weakening of the C_{10}-olefin adsorption on platinum. Thus their further dehydrogenation to dienes becomes impossible. This behaviour is usually explained by the formation of alloys and the electron transfer to the platinum atoms.

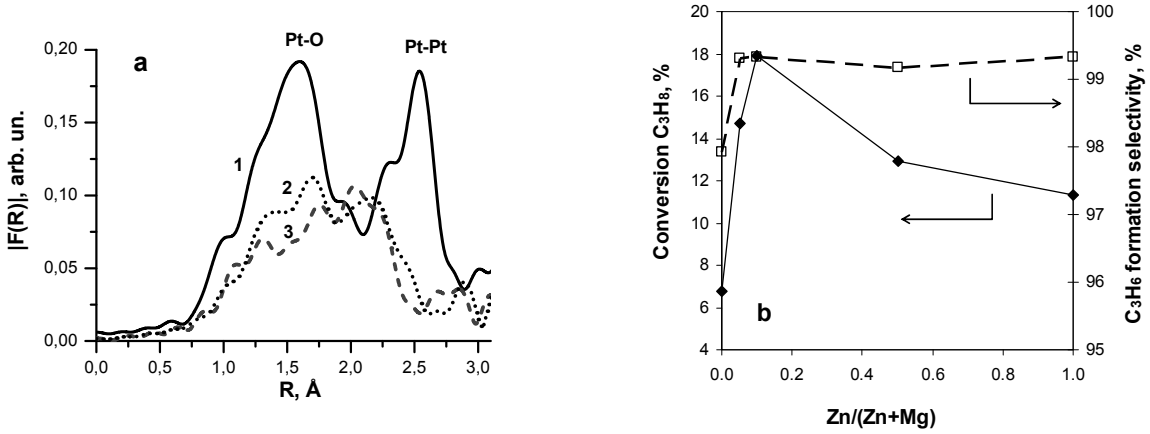

Fig. 1. a) Fourier transform magnitude |F(R)| of kχ(k) function in the 3–18 $Å^{-1}$ region for the PtL_{III} EXAFS spectra of samples 1.0%Pt/Mg(Zn)AlO_x, Zn/(Mg+Zn)=0, 0.5, 0.7 (curves 1, 2, 3, respectively); b) propane conversion and propylene formation selectivity for 0.3%Pt/Mg(Zn)AlO_x, Zn/(Mg+Zn)=0, 0.05, 0.1, 0.5, 0.7, 1.0.

4 Conclusions

The work illustrated the effect of platinum modifying with zinc when it is introduced into the structure of the support during the synthesis of LDH. The changes in the chemical composition, morphology and sizes of supported metal particles were detected. Supported platinum in catalysts $Pt/Mg(Zn)AlO_x$ was characterized by the adsorption and catalytic properties providing selective producing of olefins from light and higher alkanes.

Keywords: catalyst, iron, copper, potassium, Fischer-Tropsch synthesis, rice, husk, ashes

1 Introduction

SBA-15 is a new class of mesoporous silicate that has a high thermal and hydrothermal stability when compared to materials belonging to the M41S family, due to the greater thickness of the walls of the pores [1]. The evaluation and the influence of the support as the surface area and the pore size in the mesoporous structure materials enable higher metal dispersion and the reactants and products access to the pores of the catalyst, providing a higher catalytic activity [2]. The rice husk ash may be used in the synthesis of mesoporous materials because it is amorphous, and only becomes crystalline silica when heated to high temperatures [3]. Among various fields iron oxides are applied highlight the processes involving adsorption and catalysis, which have attracted great interest due to redox and textural properties [4]. Two metals are normally present in the iron catalysts, potassium and copper. Potassium acts on the activity and selectivity. Copper has a significant influence on the speed which iron catalyst achieves maximum activity, although there are questions about the impact on other properties of the catalyst [5]. This work aims to evaluate the textural properties of the catalyst Fe/Cu/K/SBA-15RHA.

2 Experimental/methodology

The catalyst Fe/Cu/K/SBA-15RHA was prepared with the molecular sieve SBA-15RHA synthesized by hydrothermal method [6] using Pluronic P123 as template, hydrochloric acid and rice husk ash as silica source, treated previously by heat and chemical processes [7]. The catalyst Fe/Cu/K/SABA-15 was prepared using nitrates of iron and cupper and potassium bicarbonate as metals precursors. The incorporation of metals was taken by simultaneous wet impregnation with solutions from metals precursors. The catalyst was prepared with molar ratio 100Fe/5Cu/18K/139SiO_2. The catalyst was submitted to heat treatment under nitrogen and synthetic air flow for conversion of nitrates to oxides. The textural properties from SBA-15 and catalyst were obtained by characterization by nitrogen adsorption, evaluated by adsorption N_2 isotherms and desorption isotherms at -196°C using equipment Micromeritics ASAP 2020 a relative pressure range (p/p_0) ranging from 0.02 to 1.0.

3 Results and discussion

Figures 1 (a) and (b) show the N_2 adsorption/desorption isotherms at 77 K of the calcined SBA-15RHA and catalysts Fe/Cu/K/SBA-15RHA.

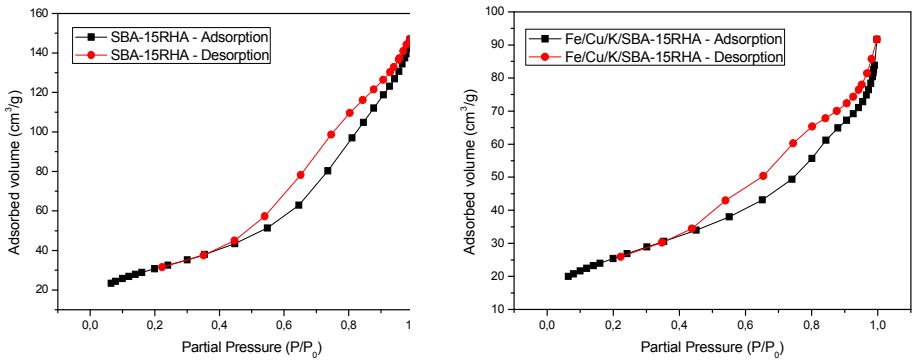

Fig. 1. N_2 adsorption/desorption isotherm at 77 K for calcined SBA-15 (a) and catalyst Fe/Cu/K/SBA-15 (b)

The isotherms for the calcined SBA-15 sample were of type IV and H1 hysteresis type, comprising two vertical branches over a range of 0.5 to 0.8 (P/P0) on the abscissa axis. This behavior is characteristic of mesoporous materials of which the SBA-15 is part [6]. The patterns on adsorption and desorption pressures were maintained in the catalyst Fe/Cu/K/SBA-15RHA, having the three phases of condensation (monolayer, capillary condensation and external multilayer) and H1 hysteresis type associated with the difference between the pressures on the adsorption and desorption. The textural analysis of the calcined SBA-15RHA support and the catalysts is presented in Table 1.

Parameter	S_{BET} (m^2/g)	Specific pore volume (cm^3/g)	Average pore diameter (nm)
SBA-15RHA	112	22.3	7.6
Fe/Cu/K/SBA-15RHA	91.7	12.8	7.8

Table 1. Textural properties of molecular sieve SBA-15RHA and Fe/Cu/K/SBA-15RHA catalyst.

There was a decrease in pore volume of 42.6%, and 18.1% in surface area when compared to the synthesized molecular sieves, used as supports. With the inclusion of metals in used rate, it was expected that reduction of these properties.

4 Conclusions

By the results from specific surface area, total pore volume there were changes in the support (SBA-15), since there was a reduction of its specific surface area, already small, and total volume of pores after impregnation. This would mean that some pores are blocked with iron, copper and potassium species.

Soybean Oil Transesterification Applying Iron-Based Catalysts Supported on Mesoporous Silica SBA-15

Eduardo R.S*, Lima E.G, Rodrigues J.J, Rodrigues M.G.F

Federal University of Campina Grande, Campina Grande, Brazil

* raphael_leahpar17@hotmail.com

Keywords: catalyst, iron, copper, potassium, transesterification soybean oil

1 Introduction

The transesterification has emerged as the best option for obtaining biodiesel, since the process is relatively simple; combined with this technique, researchers seek to lower the biodiesel manufacturing process using reusable catalysts, developing studies on heterogeneous catalysts that are reused in the manufacture of fuel [1]. Studies with heterogeneous acid catalysts have been developed for the transesterification reaction. These catalysts can transesterified the triglycerides esterified the free fatty acids and suffer little influence of water that perhaps may be present in the raw material. Such catalysts use primarily solid with basic or acidic characteristics [2]. Mesoporous materials SBA-15 type silica compounds essentially, have several properties which make them potential acid catalysts, emphasizing their high surface areas. In addition, these materials have thicker walls of the pores, resulting in a higher hydrothermal stability. However, to make them catalytically active by their structures are basically formed of silica, the introduction of metal is required [3]. The factors considered important in the dispersion of the active phase on the support of the metal ions are the oxidation states and the character of the atomic radius, and those related to the selectivity and activity of the catalysts. The wide applicability of VIII group metals as catalysts is partly because of these having variable oxidation state and high activity for breaking C-C links [4].

2 Experimental/methodology

The catalyst Fe/Cu/K/SBA-15 was prepared with the molecular sieve SBA-15 synthesized by hydrothermal method [3] using Pluronic P123 as template, hydrochloric acid and Tetraethylorthosilicate as silica source. The catalyst Fe/Cu/K/SABA-15 was prepared using nitrates of iron and cupper and potassium bicarbonate as metals precursors. The incorporation of metals was taken by simultaneous wet impregnation with solutions from metals precursors. The catalyst was prepared with molar ratio 100Fe/5Cu/18K/139SiO_2. The catalyst was submitted to heat treatment under nitrogen and synthetic air flow for conversion of nitrates to oxides. The materials were characterized by XRD and N_2 adsorption. *Transesterification of reaction:* The prepared catalysts were subjected to the reaction test using a high pressure chemical reactor with a temperature of 200ºC and with 2 hours. The reaction was conducted at a molar ratio of 1:12 oil/methanol with 5% (w/w). After the reaction, mixture was washed and the final product submitted to gas chromatography. *Ester Content:* The analysis of the methyl esters were determined by gas chromatography, using a gas chromatograph Varian450c with flame ionization detector, capillary column stationary phase Varian Ultimetal "Select Biodiesel Glycerides + RG" (0.32 mm x 15m x 0.45 um.).

3 Results and discussion

The Figure 1 shows the isotherms of X-ray diffraction pattern of catalyst Fe/Cu/K/SBA-15 (a) and your N_2 adsorption-desorption at -196°C (b), and The textural analysis of the calcined SBA-15 support and the catalysts is presented in Table 1.

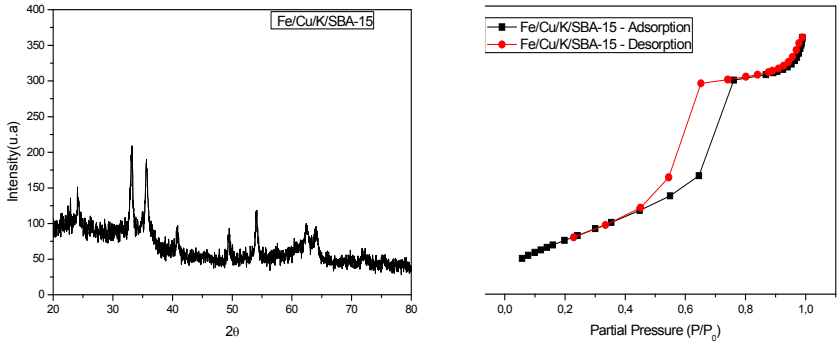

Fig. 1. XRD patterns of the catalysts Fe/Cu/K/SBA-15 (a) and N_2 adsorption/desorption isotherm at 77 K for calcined catalyst Fe/Cu/ K/SBA-15 (b).

Table 1. Textural analysis of catalyst Fe/Cu/K/SBA-15.

Parameter	S_{BET} (m^2/g)	Specific pore volume (cm^3/g)	Average pore diameter (nm)
SBA-15	490	74.7	6.0
Fe/Cu/K/SBA-15	253	37.4	6.3

The iron should be well dispersed throughout the structure of the molecular sieve SBA-15, which favors the thermal stability of the catalyst. The catalyst presented evidence of crystalline formation. It is found through analysis of N_2 adsorption-desorption isotherms of type IV and H_1 hysteresis type, comprising two vertical branches over a range of 0.5 to 0.8 (P/P0) on the abscissa axis. This behavior is characteristic of mesoporous materials of which the SBA-15 is part [3]. There was reduction of the specific surface area and total volume of pores after impregnation. This would mean that some pores are blocked with iron, copper and potassium species.

The analysis by gas chromatography provided satisfactory result of Conversion of the of soybean oil to esters applying the catalyst Fe/Cu/K/SBA-15. The value of conversion to ester of the soybean oil was 65.38%. It can be said that there was median conversion and average yield of esters.

4 Conclusions

The catalyst Fe/Cu/K/SBA-15 showed characteristic peaks phases of the oxides of iron and copper by XRD and characteristic patterns of mesoporous materials by nitrogen adsorption analysis.The transesterification reaction of soybean oil with ethanol carried out in this study had a median conversion of 65.38% with the catalyst Fe/Cu/K/SBA-15.

Ni-XMo(W,V)/Al_2O_3 Catalysts Comparative Investigation in Hydrotreating of Light Coker Gasoil

Tomina N.N.*, Maximov N.M., Bajanova A.S., Moiseev A.V., Pimerzin A.A.

Samara State Technical University, Samara, Russia

* tominann@yandex.ru

Keywords: hydrotreating, diesel fuel, light coker gasoil, phosphorus

1 Introduction

In the recent years hydrotreating tungsten-containing catalysts attracted a lot of interest. These catalysts are active in hydrogenation processes and have stability at high temperatures. The sulfidation of WO_3 into WS_2 has a problem like more high temperature, than MoO_3 one. In the same time it's well known, that mixed system WO_3+ MoO_3 is more easily sulfide. In this way, we chose Mo and (W+Mo) mixed systems for active phase design, and promoted catalysts with Ni [**1**].

2 Experimental/methodology

A line of catalysts Ni-XMo(W,V)/Al_2O_3 (X = Si, P, V) was synthesized. Amounts of Ni and (Mo+W) were constant. Ni was introduced from organic salt, Mo and W were introduced from heteropolyacids (HPA) ($SiMo_{12}$-, PMo_{12}-, $PVMo_{11}$-, VMo_{12}-, SiW_{12}- and PW_{12}-HPA) by means of wetness impregnation method. Ni-AHM/Al_2O_3 and Ni-AHW/Al_2O_3 (AHM – ammonium heptamolybdate, AHT – ammonium heptotungstate) samples were applied as comparative patterns. The impregnation was carried out in two steps: a part of Mo was introduced in the first and a part of Mo or W was introduced in the second one. After each impregnation catalysts were dried at temperatures of 60, 80, 110ºC for 2 hours. Before catalytic tests catalysts were sulfided.

The catalytic activity of the samples was determined in a bench-scale flow reactor unit in the hydrotreating process of light catalytically cracked gas oil (LCGO). Contents of sulfur and polycyclic aromatic hyrocarbones (PAH) in mixture were 2,06 and 14,32 wt. % respectively.

The hydrodesulfurization (HDS) activity and hydrogenation (HYD) activity were estimated like HDS and HYD degree, respectively.

3 Results and discussion

The results of catalytic tests are showed in **Table 1** and **Fig. 1**.

Table 1. Relative HDS activities and contents of spent Ni-XMo(W,V)/Al_2O_3 catalysts

Catalyst	Coke content on spent catalyst, wt. %	Relative HDS degree: HDS/(Ni-AHM/Al_2O_3 HDS) at temperature, °C			
		340	360	390	410
Ni-AHM/Al_2O_3	3.00	1.00	1.00	1.00	1.00
Ni-SiMo/Al_2O_3	-	1.26	1.02	0.99	0.90
Ni-PMo/Al_2O_3	1.95	1.22	1.11	1.17	1.09
Ni-PVMo/Al_2O_3	1.70	1.35	1.27	1.28	1.06
Ni-VMo/Al_2O_3	-	1.41	1.28	1.19	1.09
Ni-AHT/Al_2O_3	-	1.36	1.13	1.20	1.06
Ni-SiMoW/Al_2O_3	-	1.40	1.15	1.25	1.08
Ni-PMoW/Al_2O_3	-	1.57	1.38	1.21	1.09

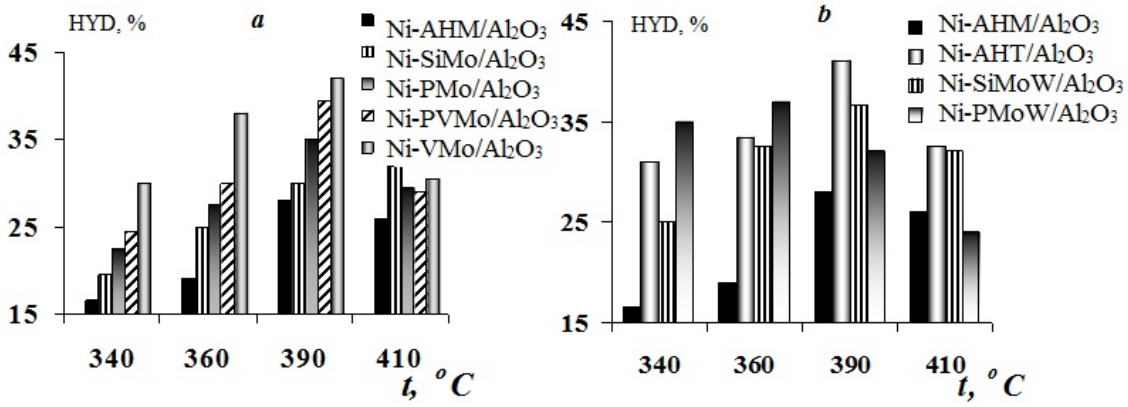

Fig. 1 Relationsips between HYD and temperature of process:
a - Ni-***X***Mo/Al_2O_3 catalysts, ***X* = *Si, P, V;* *b*** - Ni-***X***MoW catalysts, ***X* = *Si, P***
Process conditions: hydrogen pressure – 3.5 MPa, LHSV – 2.5 h^{-1},
hydrogen/feed ratio – 450 nm^3/m

The maximums of PAH HYD and HDS of sulfur compounds were found for catalysts on the bases of $PVMo_{11}$ - and VMo_{12} – HPA. Ni-VMo/Al_2O_3 catatalyst HYD degrees at temperatures of 340-390°C are higher twice than Ni-AHM/Al_2O_3 ones. Ni-AHT/Al_2O_3 catatalyst HDS degrees are higher than Ni-AHM/Al_2O_3 ones. Catalysts with higher hydrogenation activities Ni-PVMo/Al_2O_3 and Ni-VMo/Al_2O_3 have a low content of coke than others.

4 Conclusions

In this way, the best precursors for synthesis of high active hydrogenation Ni-XMo(W,V)/Al_2O_3 catalysts are $PVMo_{11}$ - and VMo_{12} – HPA. The catalysts, which contained W, showed a better HDS and HYD activities than without W ones.

Keywords: self-sustained oscillations, propane oxidation, nickel

1 Introduction

Self-sustained rate oscillations in the oxidation of light hydrocarbons over transition metals are a well known phenomenon. Recently, we have shown that the regular kinetic oscillations arise during the oxidation of propane over Ni foils and wires [1-3]. The oscillations were observed in a temperature range 650-750□C under oxygen-lean conditions when the propane/oxygen molar ratio ranges from 3/1 to 15/1. The oscillations were of the relaxation type, which can be described as a fast change between "low-active" and "high-active" states. The driving force for the self-sustained kinetic oscillations was shown to be the periodic reoxidation of nickel. According to an *in situ* XPS study [3], the high-active state of the catalyst surface is metallic nickel, whereas during the inactive state, the surface is covered with a thick layer of NiO. Here, we present the results of our further study. We focus on studying the influence of morphology of the catalyst surface on the emergence of self-sustained oscillations.

2 Experimental

Three types of samples were used in our study: rectangular pieces of a Ni foil (0.125 mm thick, purity 99.99%, Advent Research Materials Ltd.), thin Ni films (1 μm thick) deposited on a Si substrate by magnetron sputtering, and thick Ni films (20 μm thick). In the last case, the thick Ni films were electrochemically deposited on the thin Ni/Si films.

The kinetic measurements were performed in a vacuum apparatus equipped with a fused silica flow reactor and a quadrupole mass spectrometer [1,3]. The surface morphology was studied using a scanning electron microscope LEO 1430 (Carl Zeiss) and a focused ion beam (FIB) system LEO 1540XB Crossbeam (Carl Zeiss).

3 Results and discussion

First, we studied the propane oxidation over the thick Ni foil and found that the appearance of regular oscillations is preceded by a long induction period. The duration of the induction period depends on pressure and temperature of the reaction mixture and varies in a range from a few tens of minutes to several hours. During the induction period, a rough and porous structure of the catalyst surface developed because of its strong reconstructing. The thickness of the reconstructed layer was approximately 10-20 μm. This process was accompanied with at least an 80-fold increase in the effective surface area compared with a clean, not-treated nickel foil, which undoubtedly led to a drastically increase in the number of active sites. We believe that it is the main reason for the induction period, which is always observed before the appearance of self-sustained oscillations in the catalytic oxidation of light hydrocarbons over catalysts with a low specific surface area (single crystals, foils, or wires). Moreover, without such reconstructing, the oscillations cannot arise due to low activity of these catalysts.

Indeed, over thin Ni/Si films, oscillations in the oxidation of propane under the same conditions

do not appear. In contrast, over the thick Ni/Si films, the regular kinetic oscillations arise after an induction period similar to that obtained for the Ni foil. According to SEM, over the thick Ni/Si film, a rough and porous structure developed under reaction conditions. Typical SEM images are presented in Fig. 1. The thin Ni/Si film transforms to separated agglomerates over the surface of silicon substrate. We believe that in this case the effective surface area is not enough for the emergence of self-sustained oscillations.

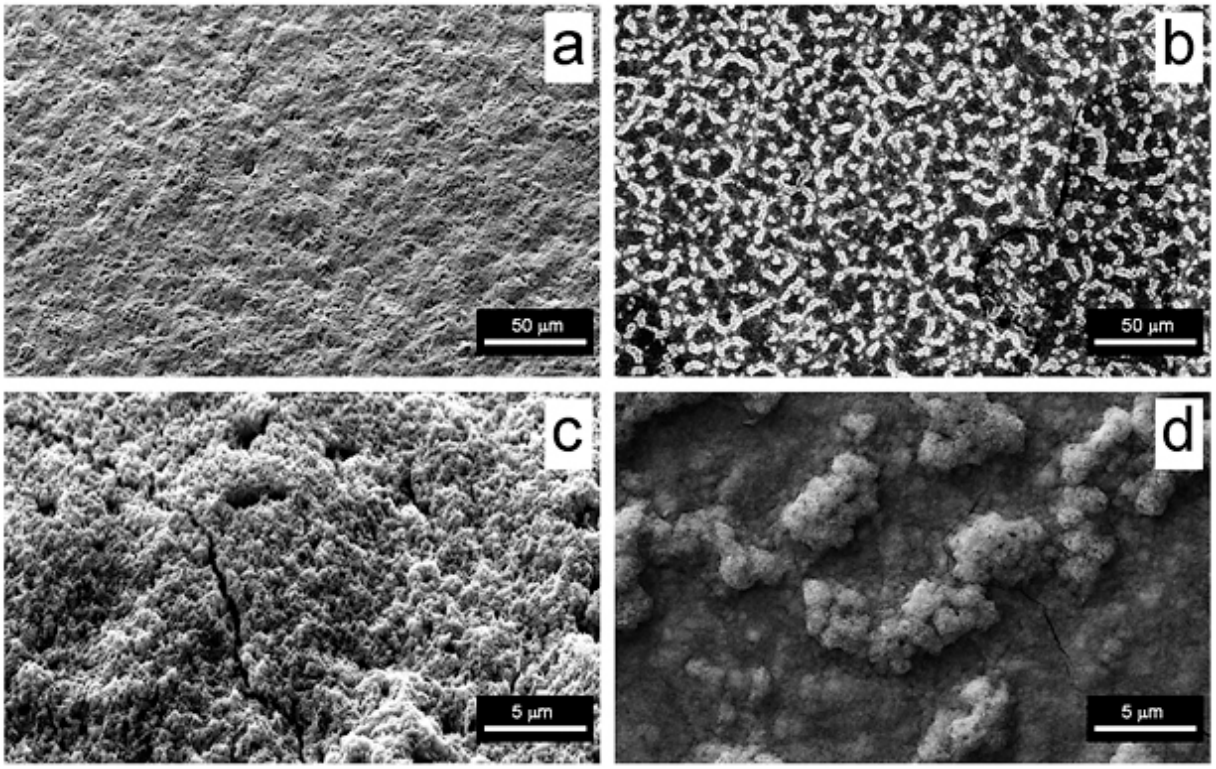

Fig. 1. Typical SEM images of the thick Ni/Si film (a, c) and thin Ni/Si film (b, d) used as catalysts of the oxidation of propane.

4 Conclusions

The main reason for the induction period observed before the appearance of self-sustained oscillations in the catalytic oxidation of light hydrocarbons over catalysts with a low specific surface area (single crystals, foils, or wires) is the formation of porous structure on the catalyst surface. Without such reconstructing, the oscillations cannot arise due to low activity of these catalysts.

Study of the Catalytic Effect of Nanosilica and Polycarboxylate on Cement Hydration and Mechanical Properties of Cement Mortars

Benmounah A.*, Samar M., Saidi M., Safi B., Kheribet R.

Research Unit: Materials, Processes and Environment (UR/MPE), Boumerdes University, Boumerdes, Algeria

* benmounah2000@yahoo.fr

Keywords: cement paste, nanosilica, superplasticizer, hydration, fluidity, mechanical strengths

1 Introduction

Given that the nanosilica particles (NS) and the polycarboxylate superplasticizer (PCE) have shown respectively a great pozzolanic activity and a best fluidity for cement pastes as have been demonstrated in previous studies [1-3]. Based on these results, the catalytic effect of mixture nanosilica (silica nanoparticles) and PCE-superplasticizer on hydration of different cements has been investigation in this study. The PCE addition to a cement paste can increase the flowability thus reducing the water demand and accelerated the setting time process of the different cements studied. The obtained results show that the PCE has played as a deflocculating agent of the cement particles reducing the particle size of the agglomerates through a steric hindrance mechanism. Also, Mechanical strengths of studied cements were improved by the mixture presence of NS and PCE. Indeed, it was found that the nanosilica particles have played a catalyst role of cements hydration reactions and thus causing the formation of new calcium hydrosilicates that contribute to the improvement of mechanical resistances. The optimum attained in the combined effect of the mixture (NS and PCE) that involved relevant microstructural modifications as proved by pore size distributions and SEM observations. These phenomenon are highlighted by measuring the mechanical strengths of the cements studied and also, by the DTA, TGA, and XRD.

2 Experimental study

Four cement types (C1: CEM II 42.5 based on pozzolan, C2: CEM II 42.5 based on blast furnace slag, C3: CEM II 42.5 based on limestone and C4: CEMI 52.5 ES) were used in this work. The superplasticizer used is based on polycarboxylate (PCE) containing the nanoparticles of silica Fume with a high content of silica approximately 83% with an estimated loss on ignition of 13.7%. To conduct the experimental work a prismatic 40x40x160 mm3 samples were manufactured for each mixture. All the specimen of mortars were mixed and prepared using a mortar mixer with a vertical axis and a capacity of 5L Also, the setting times were determined of all cement pastes with a superplasticizer presence Three-point bending test and uniaxial compression are carried out at 2, 7 and 28 days on water stored samples (under 21±1°C).

3 Results and discussion

The obtained results show that the PCE and NS have played a catalyst agent of the cement particles reducing the setting times of cement hydration (fig.1). Also, Mechanical strengths of studied cements were improved by the mixture presence of NS and PCE. Indeed, it was found that the nanosilica particles have played a catalyst role of cements hydration reactions and thus causing the formation of new calcium hydrosilicates that contribute to the improvement of mechanical strengh (fig. 2). The optimum attained in the combined effect of the mixture (NS

and PCE). The results indicate also the effectiveness of NS and PCE-superplasticizer in producing high bulk density and in accelerating the pozzolanic activity to produce more C-S-H gel by consuming calcium hydroxide Ca (OH) 2 according the reaction (1), in order to improve the mechanical properties of cement pastes [4-6].

$$Ca(OH)_2 + H_4SiO_4 \rightarrow Ca^{2+} + H_2SiO_4^{2-} + 2\,H_2O \rightarrow CaH_2SiO_4 \cdot 2\,H_2O \text{ (C-S-H)} \qquad (1)$$

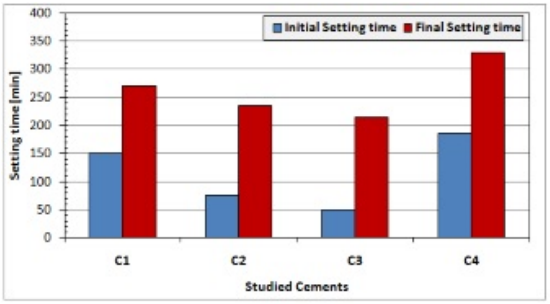

Fig. 1. Setting times of studied cements in a presence of NS and PCE

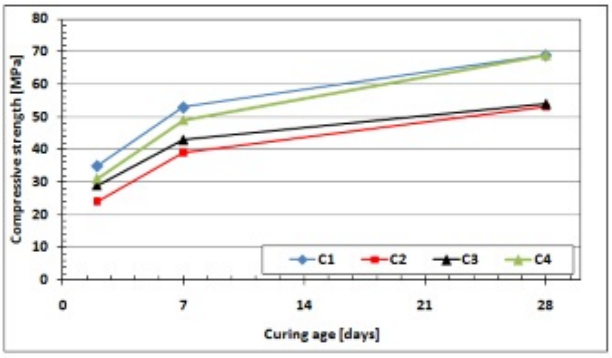

Fig. 2. Compressive strength evolution of the mortars based on C1, C2, C3 and C4

4 Conclusions

Catalytic effect of NS and PCE on the cement hydration has been investigated in this work. It can be concluded that the nanosilica particles in PCE presence, have played a catalyst role of cements hydration reactions and thus causing the formation of new calcium hydrosilicates which have contributed to the improvement of mechanical strength of the studied cements [6-7]. The results indicate also the effectiveness of NS and PCE-superplasticizer in producing high bulk density and in accelerating the pozzolanic activity to produce more C-S-H gel by consuming calcium hydroxide Ca (OH)2 in order to improve the mechanical properties of cement pastes.

Keywords: grapheme, functionalized graphene oxide, mesoporous, silica, SBA-15, catalysis

1 Introduction

Graphene-based hybrid materials have shown many applications in the fields of nanoelectronic and energy storage devices, advanced optical materials and catalysis due to their outstanding thermal and mechanical stabilities, superior electrical conductivity, rich chemical functionality of the surface [1]. The hexagonal SBA-15 silicas functionalized via framework incorporation different heteroatoms as well as via chemical bonding of organosilanes exhibits interesting catalytic performance [2]. The development of graphene-containing mesoporous materials (GCMM) in a form of 3D-graphene aerogels and ordered mesoporous carbons as well as and their application in electrochemical capacitors has been reported [3]. Probable combination of the unique properties of carbon nanomaterials with graphene structure and mesoporous silicates in the same material looks highly promising for its application in catalysis.

2 Experimental/methodology

Graphene oxide (GO) was synthesized via modified Hummers method [4] from pristine graphite (UPV-1-TMO) and followed by graphite oxide ultrasonication in DW for 1 h to produce a suspension of GO sheets. Functionalized graphene sheets (FGS) was obtained via GO facile covalent functionalization with (3-aminopropyl) triethoxysilane from hydroxyl groups by a coupling reaction. Graphene-containing mesoporous materials (GCMM) was prepared in sol-gel process using tetraethylorthosilicate (TEOS) as the silica source, the triblock copolymer (Pluronic P123), as the surfactant and GO or FGS, as the graphene source, in acidic condition. Following experimental GCMM- samples were prepared: SBA-15-GO (Al-SBA-15-GO), SBA-15-FGS (Al-SBA-15-FGS). Chemical surface modification of GCMM-samples was carried out by treatment in the presence of sulfuric acid and aluminum chloride at selected conditions.

3 Results and discussion

Experimental samples were characterized by XRD, TEM, N_2 adsorption-desorption methods. Elemental C, H, S, N-analysis showed that the weight content of elements in the graphene oxide, (wt.%): C (67,34 ± 0,2), H (1,47 ± 0,5), O (31,04 ± 1,0), S (0.15); the molar content of C/O~2,9/1. Based on the results obtained by x-ray diffraction studies (Fig. 1b), the appearance of graphene oxide peak centered at $2\Theta = 11.6^{o}$, corresponding to the (001) inter-planar spacing of 7.59 Å. Calculated thickness of GO layer was about 2.5 nm, what indicated that we had graphene oxide with multilayer structure. The peak in 43^{o} (Fig. 1b,c) corresponded to the disordered carbon materials. The disappearance of the (001) diffraction peak (Fig. 1c) was due to fact that the GO can be reduced in direct esterification reaction during the synthesis of silica mesoporous structure. XRD of reduced graphene showed a broad peak in the region of $20–30^{o}$ The XRD pattern of SBA-15-GO-sample indicated the hexagonal mesoporous structure

was obtained as supported by low angle XRD peak at 1,76°. The formation of this type of structure was confirmed by the results of the TEM-analysis (Fig. 2a,b).

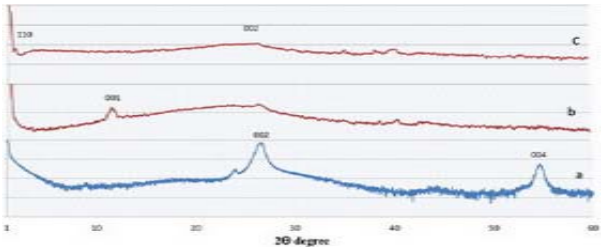

Fig. 1. XRD patterns of graphite (UPV-1-TMO) (a), GO(b) and SBA-15-GO(FGS) (c)

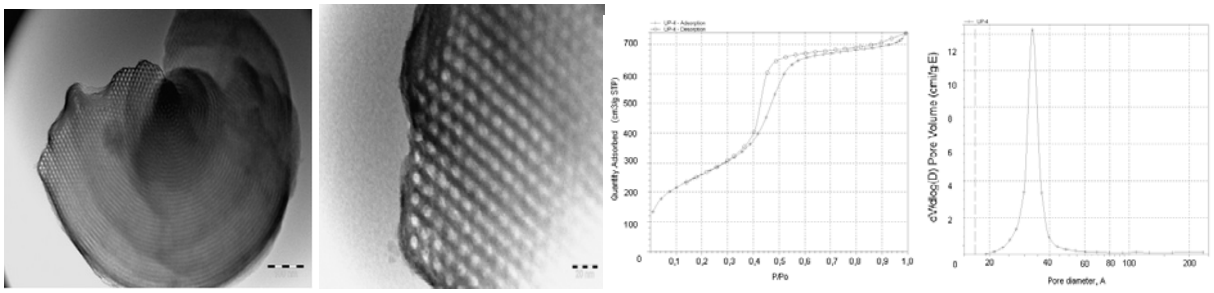
After modifications of the samples the XRD patterns indicated that all the samples retained the characteristic patterns of the hexagonal mesostructure. Figure 2 (c,d) shows the N2 adsorption–desorption isotherms and the BJH pore size distribution curves of SBA-15-GO-sample.



a) b) c) d)

Fig.2. TEM micrograph of SBA-15-GO (a,b), N2 adsorption–desorption isotherms (c) and the pore distribution of SBA-15-GO (d)

The sample has a BET surface area of 956 $m^2g^{-1}$and pore volume of 1.1 cm^3 g^{-1}. Textural properties of the synthesized graphene-containing mesoporous materials were similar and fit into a narrow range. The reactions of dehydration of butanol-1 and oligomerization of n-decene-1 were performed as the test reaction for investigating the catalytic activity of the functionalized GCMM. The samples obtained with FGS, as the graphene source, showed greater activity in the reaction of oligomerization of n-decene-1.

4 Conclusions

In this work, we demonstrate a hydrothermal synthesis of graphene-containing mesoporous materials with well-ordered SBA-15 structure, high surface areas (~956 m^2 g^{-1}) and large pore volumes (~1.1 cm^3 g^{-1}). The functionalized graphene-containing mesoporous material showed good catalytic efficiency in test reactions of dehydration of butanol-1 and oligomerization of n-decene-1.

Keywords: mordenite, Mo-MOR, Ni-MOR, transesterification, biodiesel

1 Introduction

The current energy production in the world comes mostly from non-renewable sources which consequently increases the environmental impact. These facts have stimulated the alternative sources for fossil fuel development. One of the most promising sources is biodiesel, an alternative diesel fuel derivate from renewable sources with high quality, which allows the substitution of fossil diesel oil without engine modifications [1]. Heterogeneous catalysis is widely applied in industry due to important advantages it offers to chemical processes such as improved selectivity and easy catalyst separation from reaction mixture, reducing process stages and wastes. This is the reason why nowadays heterogeneous catalysts are being developed to produce biodiesel [2]. This work aims at the synthesis of heterogeneous catalysts MOR, Mo-MOR and Ni-MOR, for application in the transesterification reaction of soybean oil, aiming at the preparation of biodiesel.

2 Experimental

Synthesis of zeolite MOR: The mordenite zeolite was synthesized hydrothermally according to the methodology proposed by Kim and Ahn [3]. The composition of the reaction mixture was: $6Na_2O:Al_2O_3:30SiO_2:780H_2O$. In a typical synthesis, the sodium hydroxide was dissolved in deionized water, and then added to the sodium aluminate dissolved in water to the starting solution at room temperature. To this mixture was added Aerosil 380 silica slowly. Then the gel was transferred to a stainless steel autoclave and brought to the oven, where it remained for 72 hours at a temperature of 170°C (hydrothermal treatment). After this time, the solid was recovered by filtration, washed and dried at 80°C for a period of 24 hours. *Synthesis of Catalysts:* The catalysts were prepared by wet: Mo-MOR (2.5% MoO_3) being used as precursor ammonium heptamolybdate ($(NH_4)\ 6Mo_7O_{24}.4H_2O$) and Ni-MOR (2.5% NiO) and the precursor nitrate nickel ($Ni\ (NO_3)_2.6H_2O$, supported on MOR. the impregnated catalysts after calcined were subjected to a dispersion of oxides sore support in a muffle furnace at 500°C for 6 hours with a heating rate of 5 °C/min. *Biodiesel Synthesis:* The prepared catalysts were subjected to the reaction test using a high pressure chemical reactor with a temperature of 200 ºC and 2 hours. The reaction was conducted at a molar ratio of 1:12 oil/methanol with 5% (w/w) of catalysts. After the reaction mixture was washed and the final product submitted to gas chromatography.

2 Results and discussion

The XRD patterns of the MOR zeolite and their respective catalysts Mo-MOR and Ni-MOR synthesized are shown in Fig. 1. XRD patterns of MoO_3-MOR (Mo-MOR) and NiO-MOR (Ni-MOR) catalysts are shown in Fig. 1, all catalysts exhibit the characteristic peaks (2θ = 9.8, 22.4, 25.8, 26.4, 27.7 and 27.9◦) of mordenite, indicating preservation of the zeolite framework after

impregnation of metals. The diffraction peaks of bulk MoO_3 (2θ = 12.7, 23.3, 25.6, 27.3 and 38.9◦) and NiO (2θ= 40º, 46.58º, 44.58º and 43.38º) are not clearly observed in the patterns. This suggests that Mo and Ni species exist as highly dispersed surface species, as is observed in the literature [4]. Faherazzi et al. [5] have reported peaks Ni (cubic) and NiO (hexagonal) at the 2θ values of 40º, 46.58º, 44.58º and 43.38º, respectively. In this case, there is the presence of the 46.5 peak, some peaks are missing, and hence the size of the particles might be below the detection limit of XRD [6].

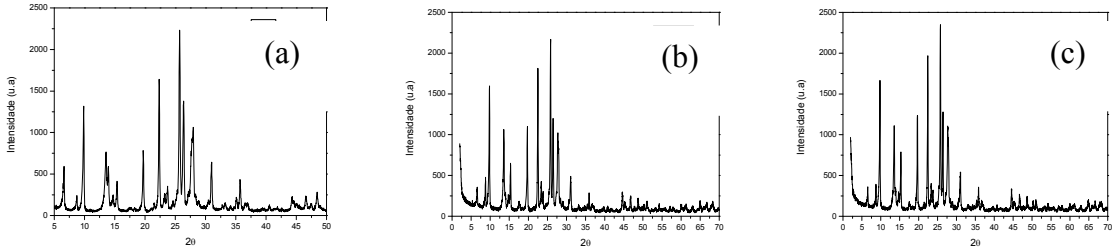

Fig. 1. Diffractograms of the samples: (a) zeolite MOR, (b) catalyst Mo-zeolite MOR and (c) Ni- zeolite MOR.

The amount of ester is a parameter considered very important for the quantification of product formed in the reaction. After the catalytic tests, biodiesel was subjected to characterization to check the conversion reaction. This parameter was evaluated by determining the ester content by gas chromatography as described in Table 1.

Table 1. Conversion results in the reaction of transesterification.

Catalysts	Conversion (%)
Zeolite MOR	22.57
Ni-Zeolite MOR	69.70
Mo-Zeolite MOR	75.35

Zeolite MOR is a natural zeolite with the content silicon [3]. The result of chromatography was satisfactory for the test with zeolite MOR, the conversion to esters obtained was 22.57%, this is can explained due acidic sites. However, deposition of metal (Ni or Mo) on the surface of the zeolite MOR renders acidity to it, and therefore this would be an efficient alternative to increase the acidity of solid catalysts (Ni-Zeolite MOR and Mo-Zeolite MOR). This can be confirmed by chromatography in the analysis of catalysts Ni-Zeolite MOR and Mo-Zeolite MOR, which provided satisfactory results as the percentage of total esters.

3 Conclusions

The transesterification reaction of soyebean oil with ethanol showed in this work presented efficient conversion of 69.70% with Ni-Zeolite MOR catalyst and 75.35% Mo-Zeolite MOR.

Keywords: catalyst, soybean oil, transesterification, hard green clay

1 Introduction

Biodiesel is an attractive alternative to fossil based fuels on the basis of its biodegradability, non-toxicity and low C emission characteristics [1-2]. Biodiesel is generally produced using four different methods involving base-catalyzed transesterification, acid-catalyzed transesterification, enzyme-based transesterification and non-catalytic transesterification under supercritical alcohol conditions and transesterification of refined oils via homogeneous alkaline catalysts [3]. Use of heterogeneous catalysts provides many advantages in comparison to employing homogeneous catalysts including the recoverability and reusability of the catalyst particles and easier separation and purification of the glycerol (above 99%) and methyl esters. Clays such as dolomite, kaolin, and bentonite are abundant, inexpensive and have relatively high surface to volume ratios to allow them to serve as catalyst supports for the transesterification of oils with methanol to biodiesel [4]. The present work focuses on application of Mo catalysts supported of production biodiesel by transesterification of soybean oil.

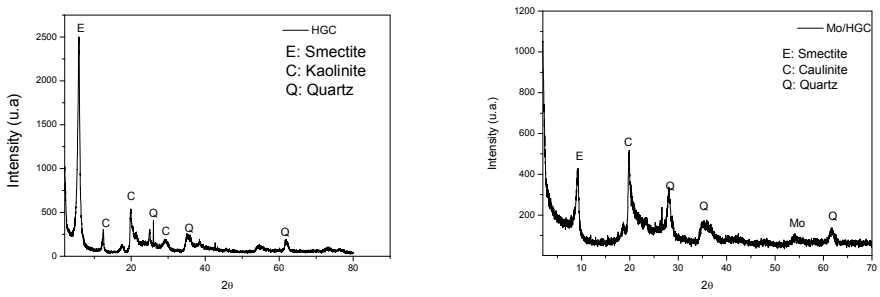
2 Experimental/methodology

A hard green clay, provided by Boa Vista City (Brazil), was used. *Preparation of Catalysts*: The Mo/HGC catalyst was impregnated with molybdenum oxide generated from ammonium molybdate [(NH4)6Mo7O24 . 4 H2O] (Merck) as the source of molybdenum. The deposition on the substrates is held with a percentage of 5 % for the catalyst by wet impregnation each employing the aqueous solution of Mo. The solution remained under stirring at room temperature for 30 minutes. Subsequently, the mixture intended to drying in an oven at 100 ° C for a period of 24 hours [5]. catalyst Mo-HGC. *Transesterification of reaction:* The prepared catalysts were subjected to the reaction test using a high pressure chemical reactor with a temperature of 200 ºC and with variation of 2 and 4 hours. The reaction was conducted at a molar ratio of 1:12 oil/methanol with 5% (w/w). After the reaction, mixture was washed and the final product submitted to gas chromatography. *Ester Content:* The analysis of the methyl esters were determined by gas chromatography, using a gas chromatograph Varian450c with flame ionization detector, capillary column stationary phase Varian Ultimetal "Select Biodiesel Glycerides + RG" (0,32 mm x 15m x 0.45 um.).

3 Results and discussion

The XRD patterns of the hard green clay pure and catalyst Mo-HGC prepared are shown Figure 1. XRD patterns of hard green clay pure Fig. 1a makes a reference bentonite clay from type with crystallographic phases of the smectite group (5.79º), kaolinite (12.17º, 20.15º and 26.14º), indicating (24,94º, 34,87º e 61,84º) a crystallographic phase quartz. In a Fig. 1b shown the XRD of Mo-HGC catalyst, it was still observed the peaks characteristic of clay, with a reduction in intensity due to the thermal treatment subjected to the impregnation and appearance

in 54,21º related to the peak of the molybdenum oxide present in the catalyst (Mo-HGC).



(a) (b)

Fig. 1. Diffractograms of the samples: (a) hard green Clay (HGC), (b) Mo-HGC.

The activities of the catalyst were studied the investing effects of metal (Mo) present in the support hard green clay (Table 1). The metal (Mo) present in the surface of the catalyst (Mo-HGC) showed great importance, improving the catalytic activity of the hard green clay support, providing a significant increase in conversion due to the formation of active sites generated by the presence of the metal support. The most important factor in transesterification is the reaction time. The conversion will increase the amount of reaction time, due to increased contact time with the active sites of the catalyst [6]. This effect caused by the reaction time, and the presence of the active sites with high temperature can be checked on the results.

Table 1. Results of catalytic test

Catalysts	**Conversion (%) (2h)**	**Conversion (%) (4h)**
Hard Green clay (HGC)	5.50	9.50
Mo-HGC	62.07	85.68

4 Conclusions

The XRD showed the crystal composition of the clay, that is a bentonite clay and observed the insertion of the molybdenum oxide phase after the impregnation process. In the catalytic test, the more activity was observed in the impregnated catalyst with a longer reaction, the reaction time and the presence of active sites generated by the presence of the metal (Mo) on the support (HGC) surface.

Keywords: catalysis, pillared, clays, montmorillonite, Al_{13}-macrocation, acid activation, basal, distance

1 Introduction

Considerable attention has been paid to the study of pillared clays in the context of the development of new materials, and that has attracted great interest for many years [1]. Currently, the Al_{13}-macrocation is a common treatment accorded to layer-silicates, in industrial operations as well as in research laboratories, this involved processes have been widely studied, especially for smectites like the montmorillonite and bedellite type clays. The montmorillonite (labeled MMT or B: bentonite) is a natural lamellar silicate utilized in the preparation of nanocomposites because of its high aspect ratio, high expandable capacity between lamellas, natural availability and low cost. On the other hand, the platinum catalysts are used for the oxidative catalytic reactions because they play an effective and crucial role in the hydrogen production, but platinum is nevertheless an expensive, for this reason, a recent research has shown how to get the same kind of reactivity using nickel [2] and cobalt that are a thousand times less expensive than platinum. In our work, new materials based on montmorillonite intercalated by Al_{13} and activated by acid treatment were successfully prepared. These obtained materials are modified by impregnation (doping) of nickel, cobalt and platinum which are introduced with weight percentages between 1 and 10%, but only nickel catalysts will be studied in the present work.

2 Experimental/methodology

Natural clays MMT-type are provides from Maghnia region (west of Algeria). Firstly, natural clay (BN) was mixed with an appropriate amount of water for minerals-sedimentation separation. In the second step, through Stokes-method (aggregates fraction<2micrometer), a sodic purification was realized (to remove substantial amounts of impurities) with 1N concentration of sodium chloride solution, to obtain the sodic-montmorillonite (sodic-MMT). The resulting suspension was centrifuged and precipitate was repeatedly washed to remove chloride ions. Finally, three different principal materials were prepared: (1) the exchanging of sodic-MMT by aluminum oxo-polycomplex macrocation "Al_{13}-macrocation", followed by calcination at 400°C (noted BAl_{13}), (2) the treating of sodic-MMT with sulfuric acid (noted BAc) [3], (3) the treating of sodic-MMT with sulfuric acid followed by Al_{13}-macrocation (noted $BAcAl_{13}$). These three materials were modified by impregnation with 1-10%W/W of nickel. Synthesized nanoparticles have been characterized by various physicochemical techniques such as: X-ray diffraction, SAXS (2theta<8°), TGA/DTA analysis, X-ray fluorescence, SEM, determination of specific surface area by BET method; porosity analysis and FT-IR.

3 Results and discussion

The structural and textural properties of supports and catalysts (1%w/w) are presented in

Fig.1. It can been seen that properties are highly dependent on treatments and changes undergone by different modification of samples (acid treatment, macrocation and nickel impregnation) in agreement with literature [3]. The nitrogen adsorption/desorption isotherms (Fig.1-Left) showed type-IV characteristic of mesoporous systems and the quantities of adsorbed N_2 vary in the order: Ni/BAl_{13}>BAl_{13}>$Ni/BAcAl_{13}$; this result indicates important adsorptive properties that depending on different supports. The Al_{13}-macrocation was confirmed by XRD patterns (Fig.1-Right), by observing the increase of basal line.The nanostructure of different systems were analyzed by Small Angle X-ray Scattering (SAXS). The interlayer distance d_{001} (2theta), observed for BAc, Ni/BAc, BAl_{13}, Ni/BAl_{13}, $BAcAl_{13}$ and $Ni/BAcAl_{13}$ samples, were respectively 14.62Å (6.03°), 11.5Å (7.6°), 17.52Å (5.04°), 15.7Å (5.60°), 17.8Å (4.95°) and 15.7Å (5.62°). The SAXS-calculations showed, for each solid, a decreasing of d_{001} after impregnation of support by nickel element. This result could be attributed to a decreasing of crystallinity degree which is probably related to the consequence of nickel particles dispersion as shown with the results of Table.1. The catalytic activity of these materials is evaluated in degradation of organic pollutants. Work is in progress.

Fig. 1. (Left) N_2 adsorption-desorption isotherms of supports and nickel samples (Right) XRD patterns at room temperature of nickel catalysts and supports.

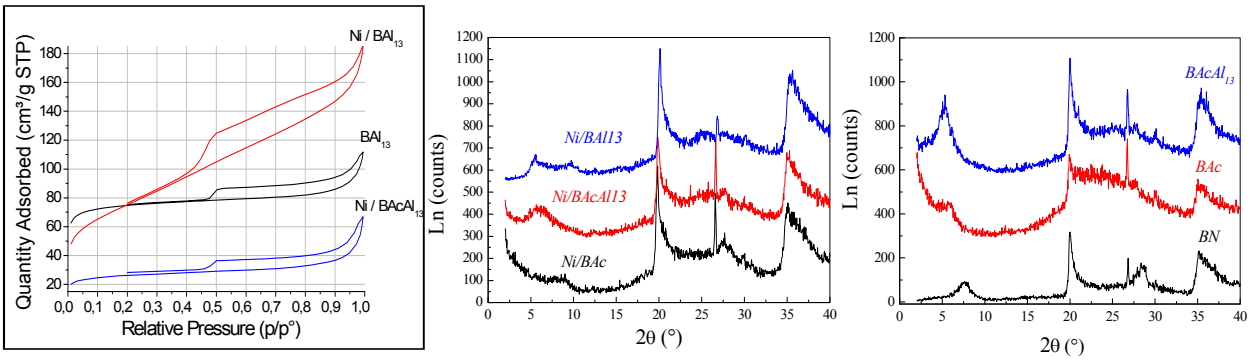

Table 1. SAXS-calculations parameters of sheets.

Catalysts/Supports	Degree of crystallinity	Number of sheet/particle
BAc	3.83	4.2
Ni/BAc	2.08	2.0
BAl_{13}	20.0	4.3
Ni/BAl_{13}	6.75	1.4
$BAcAl_{13}$	11.25	1.5
$Ni/BAcAl_{13}$	2.92	1.2

4 Conclusions

This report studies the effect of different modifications in nanoscopic structure of MMT, corresponding to macrocation by Al_{13} nanocomposites, by nickel impregnation and by acid treatment of sheets. SAXS experiments were able to provide a better idea regarding the size of the interlamellar spacing (mesopores localizations) and average lamellar distance. Nickel containing clay modified with Al_{13}-macrocation displayed higher increase of the interlayer spacing indicating higher modification, which could be interesting for our study.

Keywords: Ni catalysts, Co catalysts, Cu catalysts, methods of prepartion catalysts, dry reforming of methane, microemulsion method

1 Introduction

A number of techniques have been used for the production of the nanoparticles, such as coprecipitation, sol-gel, hydrothermal and microemulsion [1].

In this paper, Alumina-supported Ni, Co and Cu (25 wt.%) were prepared by two different preparation techniques and have been tested in the reaction of reforming of methane by carbon dioxide at the temperature of 923 K. The two different catalyst preparation methods are the sol-gel (SG) and the microemulsion (ME). The physicochemical characteristics of the prepared catalysts were investigated by means of X-ray powder diffraction (XRD), temperature programmed reduction (TPR), transmission electronic microscopy (TEM-EDS) and BET surface area techniques.

2 Catalyst preparation

The M/Al_2O_3 (M = Ni, Co and Cu [25wt %]) catalysts were prepared by sol-gel (SG) and water-in-oil microemulsion (WO) methods. WO and SG catalysts was prepared using $M(NO_3)_2.xH_2O$ as source of metal (M) and aluminum nitrates as source of Al_2O_3.

The WO catalyst was prepared by the following procedure. Two different emulsions (WO1 and WO2) were prepared WO1 and WO2 have the same components and ratio of cyclohexane, CTAB, 1-butanol with the exception of the Water phase was put in WO1 precursors of the metal and the support and in WO2 was put the precipitating agent (NH_4OH). Then the WO2 was added dropwise into the WO1. The system was kept under stirring for 24 h. he precipitate is filtered and washed with methanol. The obtained powders were dried at 110 ° C and calcined at 900 ° C for 2 h with 3°C/ min.

The Sol-gel catalysts were prepared using the following procedure. Suitable amounts of metal and support precursors were dissolved in the appropriate amount of citric acid solution. Then the solvent was evaporated under continuous stirring at 80 ° C until a gel was obtained. After the resulting gel was dried at 110°C for 24 h, and then calcined at 900°C for 2h with 3°C/min.

3 Results and discussion

The Comparison of BET areas (Table 1) shows whatever the metal studied, that specific areas are significantly higher for the samples prepared by WO compared to those prepared by SG. The results are in agreement with literature the BET surface areas followed the order ME >

SG [2].

The diffraction X-ray analysis of all the catalysts showed the presence of characteristic lines of the MAl_2O_4 spinel phase (M: Ni, Co, Cu) crystallized in a cubic structure. In addition the comparison of MAl_2O_4 crystallite size (Table 1), according to the technique of preparation, shows that the size is smaller on the catalysts prepared by WO. On the other hand the TEM-EDX observations of Ni/Al_2O_3 catalyst prepared by WO show a uniform MAl_2O_4 particle distribution (Figure 1). In contrast, this same catalyst prepared by SG revealed that most of the particles are in the form of two-dimensional cluster.

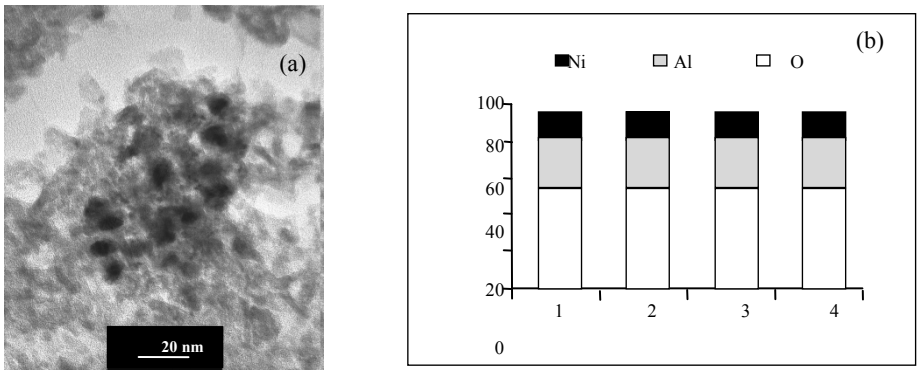

Figure 1. (a) TEM image and (b) EDX elementary distribution of NiAl-ME catalyst calcined at 923 K

ME-prepared samples reveal a positive effect on the catalytic activity and stability of catalysts. It should be noted that the better performances were recorded on the NiAl-ME catalyst (Table 1). This behavior may be related to the presence of a strong metal-support interaction and good dispersion of the particles on the support.

Table 1. Physicochemical properties and catalytic performances in the reforming methane by carbon dioxide (after 10 hours) of all catalysts prepared by microemulsion and sol-gel method.

Catalyst	BET area ($m^2.g^{-1}$)	D_{XRD} (nm)	Activity ($\mu mol.g^{-1}.s^{-1}$)		Selectivity (%)		Carbon resistance (%)
			CH_4	CO_2	H_2	CO	
NiAl-ME	123.8	8.5	175.7	260.4	87.0	93.4	93.4
CoAl-ME	144.0	11.3	128.2	154.4	82.2	86.3	91.8
CuAl-ME	126.3	13.8	99.6	112.8	65.5	71.1	95.5
NiAl-SG	42.8	15.6	149.5	195.8	86.7	91.3	95.2
CoAl-SG	19.4	23.9	114.4	136.0	81.5	86.4	95.4
CuAl-SG	18.3	23.7	91.9	101.2	52.7	74.3	85.6

4 Conclusion

The alumina supported nickel prepared by ME technique appears as the best catalysts compared than the other metal catalysts. The higher activity and stability of this catalyst in CDR is mainly related to the metal-support strong interaction, the small metallic Ni particles and dispersion of nickel that should be ascribed to the high BET surface area.

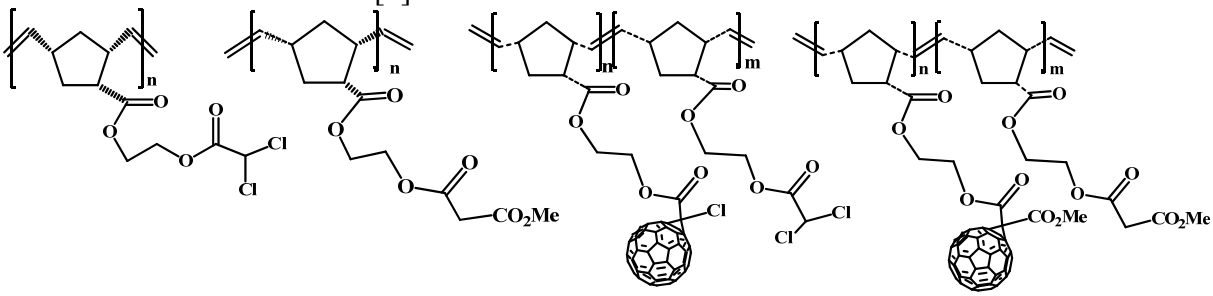
Keywords: Grubbs, 1'st generation, catalyst, fullerene-containing, norbornenes, thermal degradation

1 Experimental/methodology

New norbornenes with the covalently bonded fullerene C_{60} have been prepared as monomers for ring-opening metathesis polymerization. Under the Grubbs catalyst these monomers smoothly enter homopolymerization as well as copolymerization reactions with the parent 'non-fullerene' monomers [1].



I II III IV

The thermal degradation of synthetic homo- (**I**, **II**) and copolymers (**III**, **IV**) of the norbornene series was studied. The temperature of intensive thermal degradation start (T_i), the final temperature of the mass loss (T_f) (calculated by the method of tangents), the temperature corresponding to the reduction of the weight of the polymer thermal destruction at 1% ($T_{1\%}$) and temperature of maximum rate of thermal degradation (T_{max}) are given in Table 1.

Table 1. Parameters of the thermal degradation of polymers of norbornene series

Polymer	$T_{1\%}$, °C	T_i, °C	T_{max}, °C	T_f, °C	*ΔH, kJ/g*
I	118.7	236.9	368.7	437.9	3.65
III	275.9	376.4	395.6	413.8	7.48
II	99.7	262.9	366.0	511.2	8.42
IV	270.0	415.8	449.4	487.1	13.63

2 Results and discussion

Presented in Table 1 parameters of thermal degradation of homo- and co-polymers of norbornene series demonstrate the following. In comparing the data for the homo- (**I**, **II**) and fullerene copolymers (**III**, **IV**), in the case of the latter has been a shift values ($T_{1\%}$, T_{max}, T_i) in the high temperature region. Thus the presence into macromolecule covalently bound fullerene increases the thermal stability of the polymer. Values of parameters of thermal degradation of chlorinated macromolecular compounds **I**, **III** are lower than that of the corresponding

compounds **II**, **IV**. Presumably, this is due to the presence in the macromolecule in addition to bonds C-Cl, the dissociation energy, which is lower than that for C=O, and other C-C bonds and, ultimately, reduces the chemical thermal stability of the structural member.

Keywords: heterogeneous catalysis, silica, nanoparticles, nickel, complex, perfluoroalkylation

1 Introduction

The present study unites the advantages of two different approaches — nanoheterogeneous catalysis (easy catalyst recycling) and electrocatalysis (generation and regeneration of the catalyst active form on the electrode surface without any additional molecular reductant) — to develop a new effective catalytic technique that is both green and atom economical.

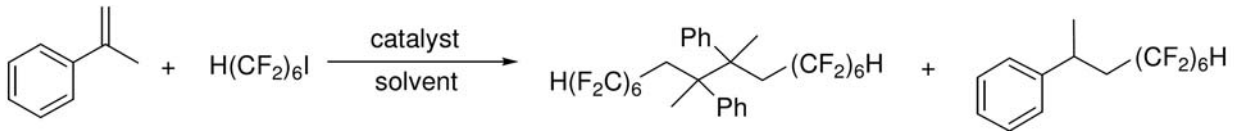
2 Experimental/methodology

Preparative electrolyses were carried out using a B5-49 dc source at a current strength of 100 mA h^{-1} in 30-mL three-electrode cell. Synthesis of the silica nanoparticles (SNs) and their decoration by 3-[2-(2-aminoethylamino)ethylamino]propyltrimethoxysilan (AEPTS) were performed as described in [1-5]. The quantitative analysis of amino-groups at the surface of silica nanoparticles was carried out due to the fluorescent procedure with the use of fluorescamine [6]. The quantity of [(bpy)$NiBr_2$] bound with the AEPTS-SNs was calculated from the difference between the Ni(II) concentration before and after the mixing with aqueous colloids of the nanoparticles and the phase separation by atomic absorption spectroscopy.

3 Results and discussion

The overall goal of this work is to develop a nanoheterogeneous catalyst for olefin fluoroalkylations and to find ways to control the product ratio (monomer/dimer) in the reactions. α-Methylstyrene was used as the organic substrates, $H(CF_2)_6I$ was used as the perfluoroalkyl source, [(bpy)$NiBr_2$] complex was used as the catalyst as it was previously found to be very effective for similar electrocatalytic reactions [7,8].

Table 1. Perfluoroalkylation of α –methylstyrene.



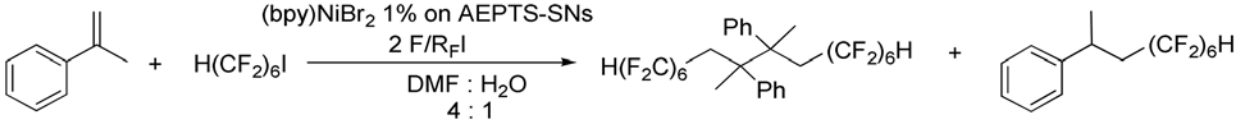
Solvent	Catalyst	Dimer/Monomer ratio	Total yield %
DMF:H_2O (8:1)	(bpy)$NiBr_2$ (1%) on AEPTS-SNs	1.0 : 1.7	48
DMF:H_2O (4:1)	(bpy)$NiBr_2$ (1%) on AEPTS-SNs	1.0 : 1.4	45
DMF:H_2O (4:1)	(bpy)$NiBr_2$ (1%) + added AEPTS-SNs	1.0 : 2.7	46
DMF:H_2O (2:1)	(bpy)$NiBr_2$ (1%) + added AEPTS-SNs	1.0 : 4.1	29
DMF	(bpy)$NiBr_2$ (1%) on AEPTS-SNs	1.0 : 0.8	53
DMF:H_2O (4:1)	(bpy)$NiBr_2$ (1%)	1.0 : 3.8	44

The data presented in Table 1 reveal the immobilization of [(bpy)$NiBr_2$] on the AEPTS-SNs is

one more factor affecting the monomer-dimer ratio in electrocatalytic perfluoroalkylation reactions. This tendency suggests an impact of coordination bonds versus physical and/or electrostatic adsorption in the immobilization of [(bpy)$NiBr_2$] complex on the AEPTS-SNs. Immobilization of the [(bpy)$NiBr_2$] complex through outer-sphere coordination with amino groups at the SNs surface is suggested to hinder access of water to coordination site that can be the reason of the aforementioned different monomer:dimer ratio.

The immobilized catalyst was tested in several reaction cycles. The results in Table 2 demonstrate that the yields of product from reactions run with recycled catalyst do not vary, supporting a heterogeneous reaction process. After each of the rounds in Table 3, the reaction mixture was centrifuged to separate the immobilized catalyst that was washed with DMF-water mixture (4:1), dispersed in water and used directly for the next synthesis. Triple use of such catalyst led only to negligible decrease in the products yield and no loss of the catalytic activity of the immobilized catalyst was observed.

Table 2. Use of recycled [(bpy)$NiBr_2$] catalyst (1 %) immobilized on AEPTS-SNs.



Number of repeats	Dimer/Monomer ratio	Total yield %
1	1.0 : 1.4	45
2	1.0 : 1.1	42
3	1.0 : 0.8	42

4 Conclusions

The present work employs inner-sphere coordination of [(bpy)$NiBr_2$] through amino-groups fixed on the surface of the amino-decorated silica nanoparticles as an efficient tool to switch from homogeneous to heterogeneous perfluoroalkylation catalysis. The introduced heterogeneous catalyst preparation provides sustained immobilization of the complex on AEPTS-SNs. After easy and quantitative separation from the reaction mixture the catalyst retains its high catalytic activity and can be reused. The results indicate that the addition of water to the reaction mixture increases the monomer/dimer ratio significantly.

ZrO_2-Based Oxide Supports for Pd-Containing Catalysts for Hydrodechlorination of Chlorinated Organics

Golubina E.V.*, Lokteva E.S., Kavalerskaya N.E., Turakulova A.O.

Lomonosov Moscow State University, Moscow, Russia

* golubina@kge.msu.ru

Keywords: oxide support, metal-support, interaction, hydrodechlorination, chlorbenzenes

1 Introduction

Hydrodechlorination (HDC) is a remarkable environment friendly and cost saving alternative to the traditional methods for utilization of chlorinated pollutants. At present the structure of active site for many reactions is known but the problem of its synthesis still exists. Some reactions, for example, HDC reaction, are known to be sensitive to electronic state of supported metal. An active site of Pd-containing HDC catalysts should contain both metallic and partially oxidized Pd [1]. Since the reduction is a necessary step during catalysts preparation, is it difficult to control an oxidation state of active metal. Metal-support interaction provides useful instrument for tuning of oxidation state of active metal in the catalysts on oxide supports and could result in enhanced catalytic activity. Another important fact is an accessibility of active sites for large chlororganic molecules due to steric factor and diffusion limitations. At this point of view supplying of optimal pore size is important as well.

In this work the comparison of different types of binary oxide supports for Pd -containing catalysts was made using (1) mixed or egg-shell Al_2O_3@ZrO_2, and (2) yttria or gallia stabilized ZrO_2. In order to obtain various pore size template synthesis was used. The catalysts were tested in gas and liquid phase hydrodechlorination of chlorinated benzenes.

2 Experimental/methodology

Catalysts from 0.5 up to 5 wt.% Pd loading were prepared by impregnation or deposition-precipitation from corresponding chlorides or nitrates solutions. Individual and mixed oxides supports (ZrO_2, Y_2O_3, Ga_2O_3 and ZrO_2-M_2O_3 (M = Al, Y, Ga)) were prepared by precipitation with ammonia at pH 10. Egg-shell support Al_2O_3@ZrO_2 was prepared by deposition of ZrO_2 on Al_2O_3. In modified zirconia the content of second oxide was 1; 5 and 10 %. In some cases the synthesis was performed using templates, namely cetyltrimethylammonium bromide (CTAB), gelatin, polyethylene glycol (PEG).

Catalysts were investigated by SEM (JSM 6490 LV, JEOL, Japan), TEM (JEM 2100F, JEOL, Japan), low-temperature N_2 adsorption-desorption (Micometrics ASAP 2000), TPR (5%H_2/Ar), DSC-TG (449PC Jupiter Netzsch, Netzsch GmbH, Germany), IR spectroscopy of adsorbed CO (Bruker Equinox 55/s), AAS (Thermo Fisher Scientific iCE 3000). Catalytic HDC tests were performed under multi-phase conditions (50°C, batch reactor, hexachlorobenzene (HCB) or 1,3,5-trichlorobenzene (TCB), isooctane as a solvent, Aliquat 336, KOH aq., H_2).

3 Results and discussion

Since HDC is sensitive to electronic state of supported metal, an active site should contain both metallic and partially oxidized Pd. For Pd- containing catalyst the presence of partially oxidized metal was provided due to chemical interaction with zirconia. It was found that only Pd/ZrO_2 prepared by deposition-precipitation (DP) was active in HDC. Pd/ZrO_2 prepared by wet impregnation shows no catalytic activity. The reason is that DP technique, in contrast to

traditional impregnation, provides the formation of bifunctional active sites comprising both Pd^0 and $Pd^{\delta+}$. The presence of $Pd_xZr_yO_z$ in DP Pd/ZrO_2 was observed by TPR. Oxidized Pd was also observed by IR-spectroscopy of adsorbed CO. But activity of Pd/ZrO_2 was still insufficient: 80 % conversion of 1,3,5-trichlorobenzene was achieved within 150 min at 2% Pd loading.

To increase the efficiency of catalyst on zirconia support two ways of support structure improvement were tested: (1) precipitation of ZrO_2 on alumina to increase surface area of final oxide support; (2) modification by yttria, alumina or gallia to stabilize ZrO_2 tetragonal phase.

Modification that involves covering of Al_2O_3 surface with zirconia both to increase the surface area of ZrO_2 and to modify its properties due to interaction with alumina was found to be not successive. The samples with different degree of surface coverage of Al_2O_3 granules with zirconia (theta = 0.1; 0.5 and 1) were prepared. Nonlinear dependence of catalytic activity on coverage degree was observed for Pd-containing catalysts in liquid phase TCB hydrodechlorination. The best catalytic performance in multiphase HDC of TCB was obtained for 2% $Pd/Al_2O_3@ZrO_2$ (theta = 0.1). SEM-EDX analysis shows that Pd and ZrO_2 are separated from each other on alumina surface. Therefore the aggregation of zirconia prevents the uniform coverage of Al_2O_3 surface.

Much more successive was modification of zirconia by small amounts of Al_2O_3, Ga_2O_3 or Y_2O_3 (up to 10%), that results in the increase of catalysts stability. In the presence of most active catalyst (2% $Pd/(1\%Al_2O_3+ZrO_2)$) complete TCB hydrodechlorination in liquid phase was achieved within 60 min. The processing of 500 Mol TCB/1 Mol Pd was performed on this catalyst. TPR analysis reveals the dependence of PdH formation on the nature and amount of modifying oxide. Stable hydrogen consumption/evolution peaks corresponding to PdH formation/decomposition were observed for $Pd/(Y_2O_3+ZrO_2)$ during several cycles of cooling/heating in TPR cell. TPR analysis shows that Ga_2O_3 addition leads to the decrease of PdO reduction temperature from 80°C to RT. The addition of Al_2O_3 to ZrO_2 did not significantly influence on PdO reduction.

Template synthesis was used in order to improve catalytic activity of 2% Pd/ZrO_2 in HDC of large organic molecules e.g. hexachlorobenzene. ZrO_2 with pore size 3.5; 6 and 9 nm were prepared using various templates. Strong correspondence of activity on pore size was established: hexachlorobenzene HDC reaction rate increases with the increase of pore size. Mesoporous mixed oxide supports were studied as well. The best result was observed for the catalyst on mesoporous $Y_2O_3+ZrO_2$ support. Catalytic activity of 2% $Pd/Y_2O_3+ZrO_2$ in HDC of TCB increases: 100% TCB conversion was reached within 40 min, whereas the catalyst on microporous support provides the same TCB conversion only after 80 min.

4 Conclusions

The addition of yttrium or gallium oxide to ZrO_2 used as a support for Pd catalysts leads to the improvement of catalytic efficiency (activity and stability) in liquid and gas phase hydrodechlorination of chlorobenzenes, because of the presence of both metallic and oxidized Pd. Improvement of catalytic performance in HDC of polychlorinated benzenes was achieved also by optimization of pore size both for individual and modified zirconia supports.

Quantum and Chemical Research of Nickel(II) Formazanates - Catalysts for Ethylene Oligomerization

Maslakov P.A.*, Pervova I.G.

Urals State Forestry Engineering University, Physico-Chemical Technology of Environmental Protection, Yekaterinburg, Russia

* pashalx@gmail.com

Keywords: benzothiazolylformazanates, catalysts, ethylene oligomerization

1 Introduction

Mononuclear nickel(II) benzothiazolylformazanates as catalysts have been tested while ethylene oligomerizating. The complexes are different in both nature of a substituent R1 in inter-position and a number of chlorine atoms in aryl substituent in original formazane ligand. General formula for complexes 1-3 (figure 1) and their characteristics are presented in the table 1. As it was shown earlier [1] the complex 1 is the most effective to produce highest olefines while ethylene oligomerizating.

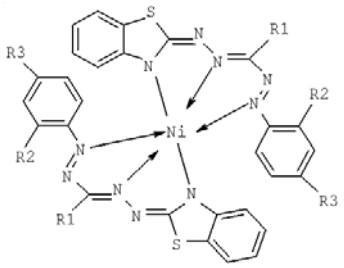

Fig. 1. Complexes, general formula

Table 1. Complexes 1-3 and their characteristics

Complexes, composition	E_0 (kJ/mol)	HOMO energy value (kJ/ mol)	LUMO energy value (kJ/ mol)	E_Σ, energy gap value (kJ/ mol)
Complex 1: R1=C_4H_9, R2=Cl, R3=H	-36668,3	-697,762	10,61081	708,3726
Complex 2: R1=C_4H_9, R2= H, R3= Cl	-45558	-664,949	-0,37399	664,5753
Complex 3: R1=C_7H_{15}, R2=Cl, R3=Cl	-35966,7	-685,628	-3,49771	682,1299

2 Experimental/methodology

PM3 method incorporated into HyperChem has been used for quantum and chemical calculation because it is the method that both shows formazanates molecule geometry and supply us with data comparable to X-ray analysis data [2].

3 Results and discussion

All of above mentioned Ni(II) complexes based on tridentate chlorine-containing

benzothiazolylformazanes are characterized by similar composition NiL_2 and pseudo-octahedral structure of MN_6 coordination unit in according to the quantum and chemical calculation. The calculation also showed a formazane is situated in both imino-form and EZE-configuration.

To establish the correlation between catalytic activity and structure in the nickel complexes as it was shown [3], energy characteristics (Highest Occupied molecular orbital energy value (HOMO), Lowest Unoccupied molecular orbital energy value (LUMO), and Energy gap value $E_{\sum}$) have been defined. According to the data presented in the table both the energy gap and HOMO energy values for complexes 1-3 are almost equal to each other and estimated as > 5 eV (482 kJ/ mol). It is evidence of geometric configuration sustainability in these complexes [4].

At the same time abnormal catalytic activity of formazanate 1 while ethylene oligomerizating resulting to butene yield can be explained by the difference in LUMO energy values. It was calculated it is the complex 1 is so-called «nucleophile» though complexes 2, 3 are «electrophiles».

4 Conclusions

The research showed such approach can be offered to predict catalytic activity for different heterocyclic nickel formazanates.

Keywords: VOx/TiO2 catalyst, oxidative dehydrogenation, oxygen radicals, propane mechanism, DFT

1 Introduction

Oxidative dehydrogenation (ODH) of light alkanes over transition metal oxides is of great interest for synthesis of light olefins as a practicable alternative to non-oxidative dehydrogenation. Supported vanadia catalysts are among the most promising materials for this reaction. However, despite many experimental studies and theoretical simulations the nature of the active and selective surface sites in supported vanadia catalysts is still poorly understood.

Propene ODH over VO_x/TiO_2 catalysts is characterized by low activation energies about 60 kJ/mol [1]. Despite so low activation energy, the propane ODH on VO_x/TiO_2 catalysts typically takes place at 450°C or higher temperatures. The occurrence of a reaction with low activation energy at so high temperatures means that the pre-exponential factor in the reaction rate equation must be quite low. In our opinion, this fact clearly indicates that the reaction is initiated on few very active sites rather than on abundant vanadium species present in high concentration.

We have recently shown by DFT calculations that oxygen isotopic exchange on titania-supported vanadia might be initiated on surface oxygen radicals [2]. Recently such species were experimentally observed by STM and shown to be catalytically active in methanol ODH [3]. These results suggest that oxygen radicals may be present on the surface of oxidation catalysts under catalytic conditions and account for the catalytic activity of VO_x/TiO_2 catalysts. The main objective of this study is to analyze the possible role of the oxygen radicals in oxidative dehydrogenation of propane to propene on VO_x/TiO_2 catalysts using periodic DFT calculations.

2 Experimental/methodology

The structure of VO_3 species on the surface of VO_x/TiO_2 catalyst with distinct oxygen-radical character on experimentally observed (1x4)-reconstructed anatase-TiO_2(001) surface was built by isomorphic replacement of the top Ti atoms by V ones followed by reoxidation of the reduced surface V^{4+} site by an oxygen atom. The calculations were performed using the QUANTUM ESPRESSO code based on the spin-polarized DFT using Vanderbilt Ultrasoft pseudopotentials with exchange-correlation PBE functionals. The reaction pathways of the propane ODH were studied by the Climbing Image Nudged Elastic Band method (CI-NEB). Eleven to seventeen images (including 10÷16 movable ones) were specified to locate the saddle points along the minimum energy path.

3 Results and discussion

The complete pathway for propane ODH over oxygen radicals VO_3/TiO_2 in a uniform energy scale is presented in Figure 1. The first hydrogen abstraction reaction appears to be the rate-determining step of the overall ODH process. Our computations prove that the surface oxygen radical species forming on the supported vanadium oxide catalyst VO_x/TiO_2 are very reactive and can abstract hydrogen atoms from propane with low activation energy E* = 0.56 eV (54 kJ/mol). In our calculation the energetic barrier of the second stage was slightly lower. Still

both values are very close. So, their relative importance may depend on the used model and DFT functional.

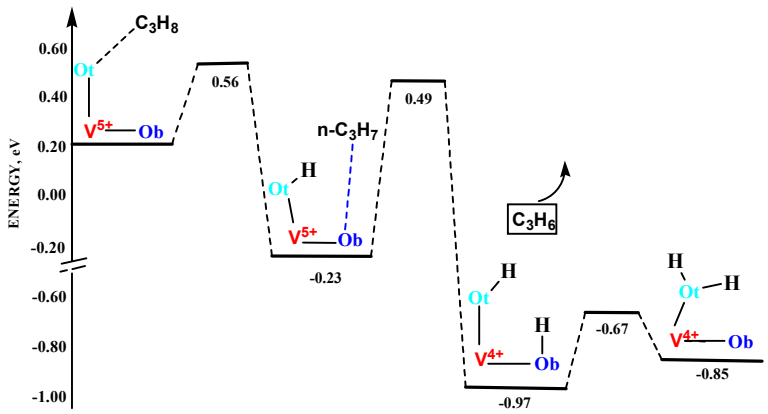

Fig. 1. Energy diagram of propane conversion to propene on the VO_3/TiO_2 active site.

We believe that high temperatures are required for generation of the active radical species in sufficient concentrations. For the reaction to take place above 450°C with relatively low experimental activation energy, the concentration of the active sites should be low. Therefore, oxygen radicals generated in low concentrations at elevated temperatures are quite capable of acting as such active sites.

It is exceptionally important, that the concentration of oxygen radical sites on the surface is low. So, the released propene, which is more susceptible to oxidation than propane, should not be immediately involved in further oxidation, unless it reaches another radical site after migrating on the surface. All these factors combined suggest that propene oxidative dehydrogenation on the oxygen radical species on the surface of VOx/TiO_2 catalyst simulated in this study should be a selective process. On the contrary, if conventional vanadyl groups commonly believed to be the active sites were the places where this reaction takes place, the released propene molecule would be involved in further oxidation processes immediately upon migrating to any adjacent V^{5+} site present in high concentration on the surface. This would make the desired high selectivity practically unachievable.

4 Conclusions

The results presented in this paper demonstrate that oxidative dehydrogenation of propane can proceed over oxygen radicals stabilized on the surface of VO_x/TiO_2 catalysts with low activation energies (~54 kJ/mol) matching the experimentally observed values. The obtained data suggest that oxygen radical species can be the active sites in this and other heterogeneous selective oxidation reactions. Further studies of reaction mechanisms with the emphasis on possible participation of such radicals in various catalytic reactions seem to be very important.

Fickian Spillover Models: Validation and Parameter Estimation

Uner N.B.*, Uner D., Singh D.

Middle East Technical University, Chemical Engineering Department, Ankara, Turkey

* nuner@metu.edu.tr

Keywords: spillover, chemisorption, diffusion, parameter estimation

1 Introduction

The phenomenon and mechanism of spillover process is being discussed for many years and accepted as an important step in understanding the dynamics of catalysts and improving their performance [1]. Although the characterization and the theory of surface diffusion on perfect crystals has been treated to a good extent [2], the effect of spillover and surface diffusion on the performance of regularly synthesized supported catalysts is still vague.

In our previous studies on hydrogen chemisorption on Ru/Vulcan catalysts [3,4], the spillover process could be described sufficiently well by a Fickian surface diffusion mechanism following the formalism of the model presented by Kramer and Andre (KA) [5]. The model is used to predict the contribution of the support to both adsorption and desorption. Careful experiments on sequential adsorption and desorption were done to elucidate characteristics of the diffusion on the support. Such understanding would then be expected to shed light on the surface diffusion-influenced catalysis as new generation of nanostructured catalysts are being synthesized [6].

2 Experimental methodology

Spillover experiments were performed in a handmade glass manifold described in Uner et al [7]. 1 wt% Pt/Al_2O_3 was prepared by incipient wetness method, dried and calcined. The catalyst was placed into glass manifold and evacuated at 150°C for 30 min, this will removed the moisture present in the sample. Catalyst was further heated up to 350°C under 100 Torr H_2 pressure. At 350°C, system was evacuated for 10 min, then 100 Torr pressure was added every half an hour followed by 10 min evacuation for 4-5 times. After reduction process, system was kept under evacuation for 1 hr and then cool down to room temperature. At room temperature it was filled with desire H_2 Pressure, after that, sample valve was opened, to record pressure change and time. The adsorption isotherms were also measured on the same catalyst by dosing hydrogen at a desired pressure and allowing 10 min for equilibration. At sufficiently high pressures a considerable amount of spilled over hydrogen will have accumulated despite short equilibration periods. The system is evacuated for different durations and after which isotherms were measured.

3 Results and discussion

The time dependent uptake curve for the first adsorption is given in Figure 1a. For long times, the data can be converted into rates of diffusion on the support, and the KA model can be fitted. The result of the fit is given in Figure 1b. The KA model can be modified for desorption and it also captures a good trend for desorption, but slightly over predicts. The isotherms collected as described in the experimental methodology section were used to determine the desorbed hydrogen amounts. The experimental data of the desorbed hydrogen amounts and the model fit of the desorption process shown in Figure 1c are in good agreement.

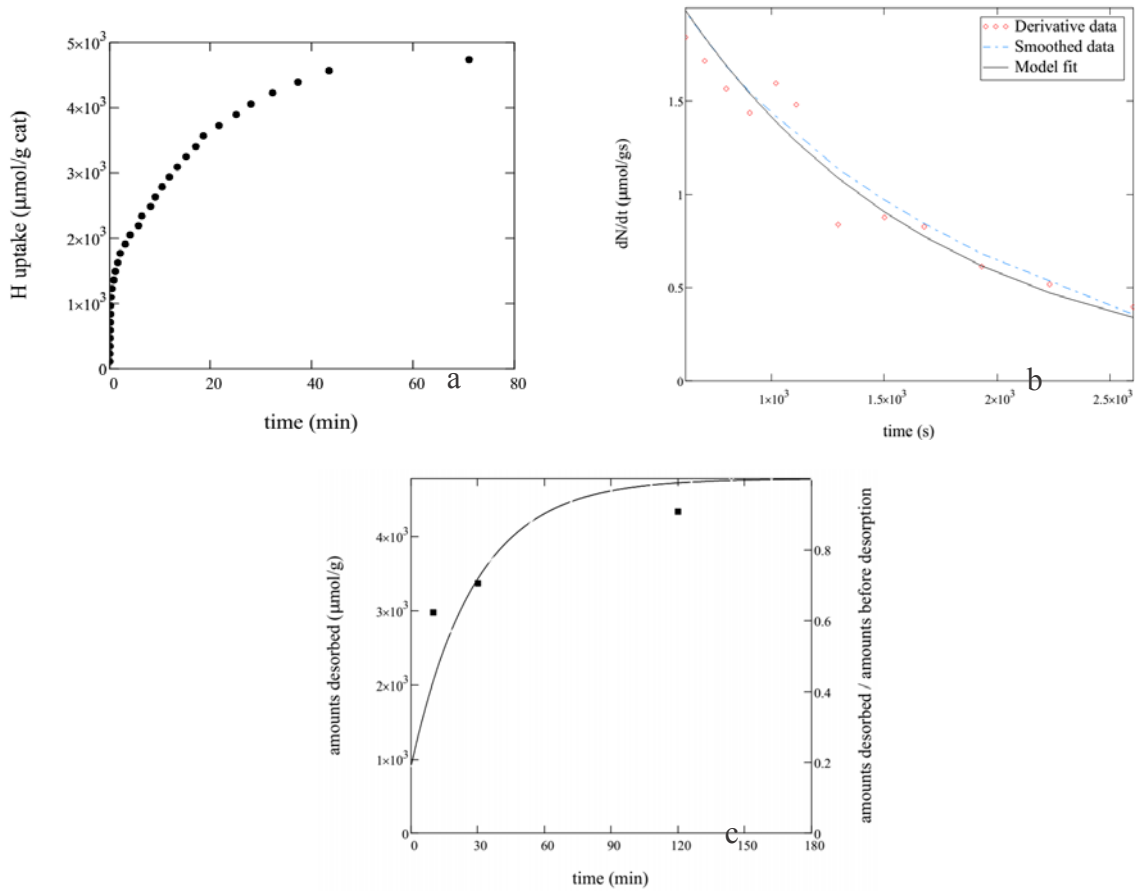

Fig. 1. a) Sample time dependent chemisorption data on Pt/Al_2O_3. b) The quality of fit of the KA model. c) Desorption rate: model versus experiment.

4 Conclusions & Outlook

In this paper, we present a methodology for determining the surface diffusion coefficient of spilled over hydrogen by volumetric chemisorption technique. Experiments are in progress to make these measurements at different temperatures and by changing the metal loading while keeping the particle size constant. The available data will be used to explore the use of spilled over hydrogen in hydrogenation reactions where simple microkinetic reaction models are available.

Keywords: spinel, ethanol steam reforming, oxygen isotope exchange

1 Introduction

The ethanol steam reforming reaction is still in great interest as a way of hydrogen production. Different type of catalysts were used for ESR reaction: noble metals (Rh, Ru, Pt, Pd, Ir), non-noble metals (Co, Ni), simple oxides (ZnO, CuO), perovskites ($LaNiO_3$) and many others. Spinels are also among this catalysts: monometallic Co_3O_4 , two-component systems (NiM_2O_4, where M=Al, Fe, Mn ; MAl_2O_4, where M=Zn, Ni, Cu ; ZnM_2O_4, where M=Al, Co, Fe) and some other systems. One of reasons of such interest is the attempt to replace currently used noble metal and rare-earth containing catalysts for something cheaper and assessable. All works note that spinels show 100 % conversion of C_2H_5OH at the temperatures over 600 °C.

2 Experimental

We have studied ESR reaction catalyzed by mixed spinel-type oxides $Co_{1.8}Mn_{1.2}O_4$, $Ni_{0.33}Co_{1.33}Mn_{1.33}O_4$ and $Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$. Spinels were prepared by thermal decomposition of the mixture of corresponding metal nitrates hydrates followed by annealing at 700 °C.

The samples were characterized by X-ray diffraction, X-ray absorption $L_{2,3}$-edges, BET and oxygen isotope exchange.

For ESR reaction 110 ml/min flow (GSHV = 51000 h^{-1}) with 10 vol % of ethanol was passed through reactor.

3 Results and discussion

According XRD results all initial catalysts have spinel structure with no admixtures found. Surface areas measured by BET were about 5 m^2/g for all samples. To determine the cation distribution in the samples X-ray absorption spectroscopy was used. To interpretate XAS spectra obtained some samples with known structure were studied. We chose Co_3O_4 ($Co^{2+}[Co^{3+}_2]O_4$), $CoCr_2O_4$ ($Co^{2+}[Cr^{3+}_2]O_4$), NiO, Mn_2O_3, MnO_2 as standards. Square brackets represent cations which occupy octahedral site. The latter two samples have Mn only in octahedral site as the Ni in NiO. The results obtained by analysis of spectra are presented in Table 1. According to these data, the $Co_{1.8}Mn_{1.2}O_4$ modification mechanism by replacement Co to Ni is the following: Ni^{2+} replaces Co^{3+} in octahedral sites thus making the part of Mn^{3+} to become Mn^{4+} to keep electroneutrality.

Table 1. Revealed cation distribution in Ni-Co-Mn-O spinel-type oxides from XAS experiments.

Oxide	Cation distribution
$Co_{1.8}Mn_{1.2}O_4$	$Co^{2+}[Co^{3+}_{0.8}Mn^{3+}_{1.2}]O_4$
$Ni_{0.33}Co_{1.33}Mn_{1.33}O_4$	$Co^{2+}[Co^{3+}_{0.33}Ni^{2+}_{0.33}Mn^{3+}_{1.2}Mn^{4+}_{0.33}]O_4$
$Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$	$Co^{2+}[Co^{3+}_{0.2}Ni^{2+}_{0.6}Mn^{3+}_{0.6}Mn^{4+}_{0.6}]O_4$

Heterogeneous oxygen isotope exchange was discovered on all samples under

investigation. Exchangeable oxygen fraction is found to be 100 % of total lattice oxygen for all samples.

By use of numeric modeling surface exchange (R) and diffusion (D) rates were estimated (Table 2). As the exchange was limited by diffusion only the lower bound for R could be determined. It was revealed that diffusion rate correlates with Mn^{4+} content.

Table 2. Isotope exchange parameters estimated from numeric modeling.

Sample	R*10², mol/g*min	D_{eff}*10³,1/s	Mn^{4+} (see Table 1)
$Co_{1.8}Mn_{1.2}O_4$	>7	5	0
$Ni_{0.33}Co_{1.33}Mn_{1.33}O_4$	>7	9	0.33
$Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$	>20	20	0.6

Study of ESR reaction revealed the same trend. The most effective catalyst was $Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$. Ethanol conversion reached 100% at 700 °C (conversion rate $6 \cdot 10^{-5}$ mol·g^{-1}·s^{-1}). Experimental results for this catalyst are presented at Fig. 1.

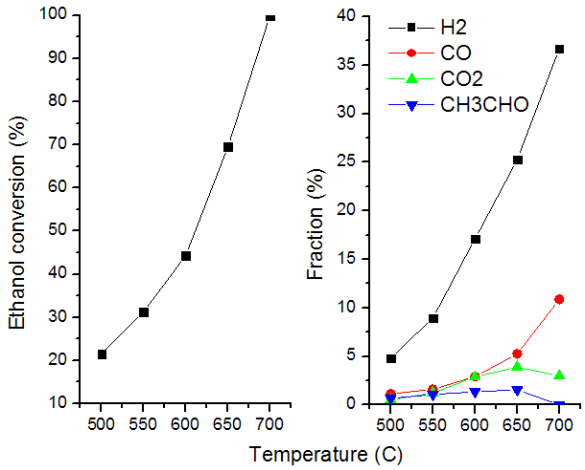

Fig. 1. Catalytic performance for the ESR reaction over the $Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$ catalyst.

4 Conclusions

Ethanol steam reforming (ESR) reaction catalyzed by spinel-type mixed oxides $Co_{1.8}Mn_{1.2}O_4$, $Ni_{0.33}Co_{1.33}Mn_{1.33}O_4$ and $Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$ was studied. Catalytic activity both in ESR and isotope exchange reaction rises up with Mn^{4+} content in the row $Co_{1.8}Mn_{1.2}O_4$ > $Ni_{0.33}Co_{1.33}Mn_{1.33}O_4$ > $Ni_{0.6}Co_{1.2}Mn_{1.2}O_4$.

Keywords: tridentate ligands, sulfur donors, palladium complexes, Suzuki cross-coupling

1 Introduction

Among a plethora of palladium-catalyzed cross-coupling reactions, the Suzuki cross-coupling is one of the most powerful methods for the C–C bond construction. Functionalized carboxamides have been the objects of intense research in coordination chemistry for many years, since the introduction of ancillary donor centers both into acid and amine parts enables the realization of different coordination modes, allowing fine-tuning of physicochemical properties of the resulting complexes. As a rule, such multidentate ligands contain nitrogen and phosphorus donor groups, while their analogs based on thioether-substituted acids are scarcely studied. The known examples represent mercaptoacetic acid derivatives with additional coordination-active groups [1]. To the best of our knowledge, there are no literature data on catalytic activity of the complexes based on these multidentate ligands. At the same time, recently we have shown that S,N,O-palladium(II) complexes of functionalized amides with (thio)phosphoryl pendant arms provide moderate activity in the Suzuki cross-coupling of aryl bromides with phenylboronic acid [2]. Therefore, it seemed interesting to obtain novel amide ligands with ancillary sulfur donor groups and investigate catalytic activity of their palladium complexes in the Suzuki cross-coupling.

2 Experimental

Novel multidentate ligands with the central amide moiety and ancillary sulfur donor groups were readily obtained by the condensation of *o*-thiophosphorylaniline and amino-substituted nitrogen-containing heterocycles with mercaptobenzoic, mercaptoacetic, and mercaptopropionic acid chlorides (Fig. 2).

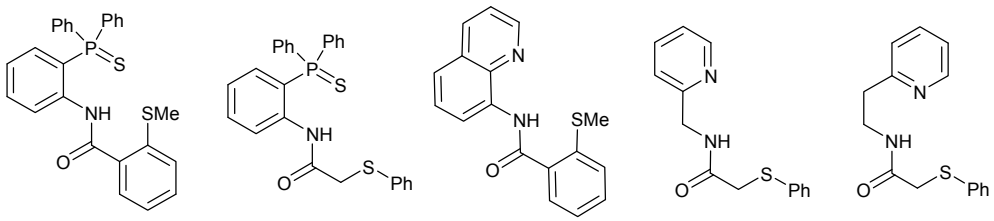

Fig. 2. Selected ligands obtained in the present study

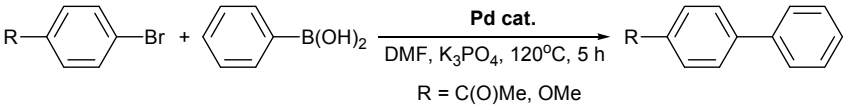
Taking into account an important role of week sulfoxide donor ligands in transition metal chemistry, some of the resulting sulfide ligands were oxidized with H_2O_2 to the corresponding sulfoxide derivatives.

Upon complexation with the Pd(II) ions, the ligands derived readily formed S,N,X-palladium complexes, in all cases adopting a tridenate monoanionic coordination mode.

3 Results and discussion

Catalytic activity of the novel palladium(II) complexes was tested in the Suzuki cross-coupling of several aryl bromides with phenylboronic acid (Scheme 1). For correct comparison of the results, all the experiments were carried out under the same conditions. Fig. 3 demonstrates the results of catalytic experiments on the coupling of 4-bromoacetophenone with $PhB(OH)_2$ for some of the palladium complexes based on functionalized carboxamides.



Scheme 1. Suzuki cross-coupling catalyzed by the novel palladocycles

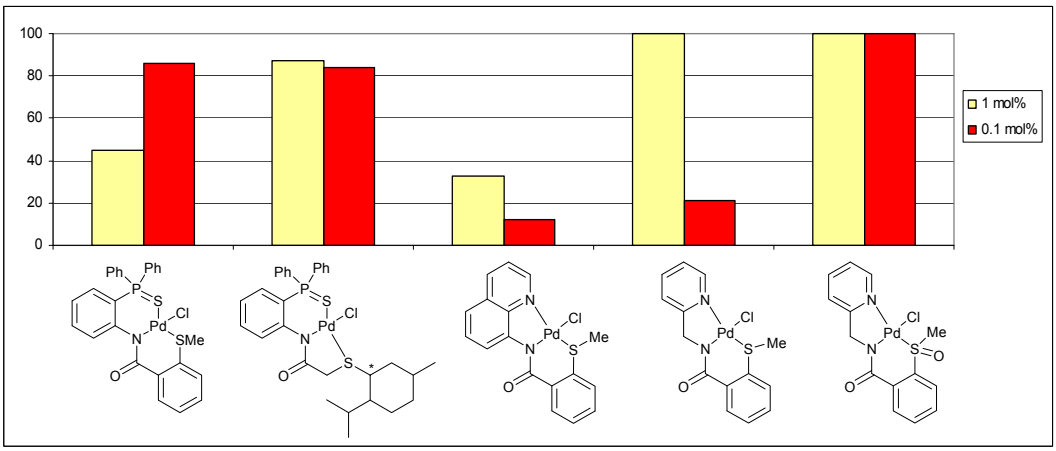


Fig. 3. Catalytic activity of selected palladocycles under study in the coupling of 4-bromoacetophenone with $PhB(OH)_2$

Taking into account the results obtained, the following regularities in the catalytic activity of the complexes under study can be outlined. N,N,S-Palladocycles are generally more active than their S,N,S-analogs based organothiophosphorus ligands, which can be associated with their hemilabile nature. Alkyl sulfides provide higher level of activity than their phenyl sulfide counterparts. The catalytic performance strongly depends on the flexibility of the ligand framework. And, finally, the sulfoxide derivatives are much more active (pre)catalysts than the corresponding sulfide-based palladium complexes.

4 Conclusions

Palladium complexes of functionalized carboxamides based on thioether-substituted acids were tested for the first time as (pre)catalysts for the Suzuki cross-coupling. The main regularities in the structure–activity relationships were established.

Keywords: sol-gel, nickel, manganese, spinal, perovskite

1 Introduction

Spinal and perovskite structures are oxides with chemical formula AB_2O_4 and ABO_3 respectively. They are of great interest because of the variety of properties exhibited by these materials depending on the choice of the elements A and B. In the spinal structure oxides, cationic sites tetrahedral and octahedral form with the oxygen a face centered cubic lattice. The perovskite structure is conveniently described by a cubic lattice, as the cation A is often alkaline earth occupant dodecahedral position, the cation B is generally a transition element 3d, 4d or 5d [1] and is the center of an octahedral site formed by six oxygen atoms. There are several spinals which are used in heterogeneous catalysis, by citing examples: $ZnCo_2O_4$ spinal that can acts as catalyst in various reactions: CO oxidation [2], combustion of hydrocarbons [3] or the selective oxidation and reduction of several organic molecules [4]. The $ZnAl_2O_4$ spinal is very active in methanol synthesis and selective reduction of NO_x with the addition of copper [5]. There is also the spinal $MgAl_2O_4$ which has very interesting properties such as very high melting point (about 2135°C), good mechanical strength and a low dielectric constant. Therefore, it is used in many industrial applications, for example, the preparation of ceramics [6]. In catalysis, the spinal $MgAl_2O_4$ is used because of its low acidity, high heat resistance and good interaction with the metal phase. This material is used as a carrier in catalytic dehydrogenation [7] and in applications for petroleum methods [8]. Similarly, it is widely used as a support or a catalyst for reforming methane reactions [9]. Perovskites also form a large class of catalytic systems for reforming and oxidation of hydrocarbons [10]. For example, the catalysts $LaMO_3$ (M: Ni, Co, Cr) were used in the partial oxidation reaction of methane [11] as well as in the hydrogenation reactions of alkenes [12]. In our work, we have prepared spinal and perovskite materials based on magnesium, nickel, aluminum, lanthanum and manganese.

2 Experimental/methodology

Nitrates of various components were dissolved with citric acid (CA / (metal ions)) = 0.5. The pH of the solution is adjusted to 6 using aqueous ammonia (25%). The mixture is heated to 120°C until a gel. The obtained gel was dried at 180°C and calcined at 800°C for 4heurs (5°C/min).

3 Results and discussion

For both $Ni_{0.1}Mg_{0.9}Al_2O_4$ and $Mn_{0.1}Mg_{0.9}Al_2O_4$ solids, we are observed the formation of spinal phase $MgAl_2O_4$, Ni or Mn is probably introduced in the spinal structure. While for the $Ni_{0.1}Mg_{0.9}Al_{0.5}La_{0.5}O_3$ material, we are noted the presence of a mixture of oxides: MgO and/or NiO and La_2O_3. Finally, the diffractogram of $Mn_{0.1}Mg_{0.9}Al_{0.5}La_{0.5}O_3$ solid revealed the presence of MgO and perovskite phase $LaAlO_3$.

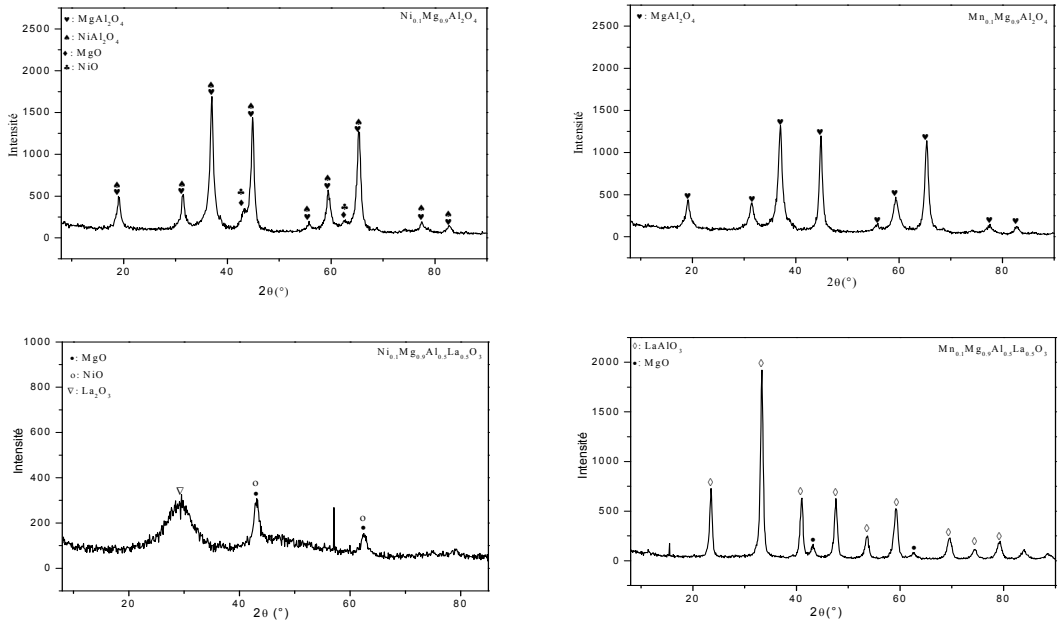

Fig. 1. XRD patterns of the elaborated solids.

Additional, themogravimetric analysis of the precursors of our catalysts are showed three main thermal events due to the elimination of free water at 100-150°C, the decomposition of ammonium nitrate between 260-290°C and the decomposition of citrate complex at 410°C. Furthermore, comparison of FT-IR spectra of various solid before and after calcination is showed a decrease of the intensity of the characteristic bands of H_2O and nitrates after heat treatment (800 °C). Likewise, characteristic bands of the metal oxides (M-O), between 450-700cm^{-1} are observed in the case of calcined solids. Otherwise, scanning electron microscopy is revealed spinal grain size of about 150 µm for the catalyst containing manganese, against about 60µm for the nickel based solids. For the perovskite structure, the grain size is estimated at about 20 µm for catalysts with manganese, and about 40 to 60µm for the solid containing nickel.

4 Conclusions

XRD analysis of the catalysts calcined at 800°C is showed the formation of different phases. The thermal analysis of the various precursors studied is revealed a similar decomposition as a function of temperature. However, relative stability is observed from 500°C for both spinal and perovskite structures. SEM analysis is showed an acceptable homogeneity of the surface of these catalysts.

Photocatalysis of Hydrogen Evolution from Water by Used Thioxanthene Dyes

Ponyaev A.I.*, Glukhova Y.S.

Saint Petersburg State Institute of Technology (Technical University), Saint-Petersburg, Russia

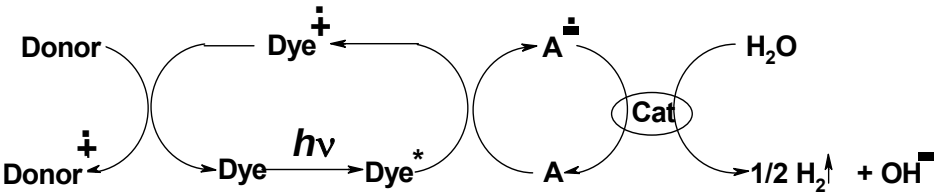
* ponyaev2002@mail.ru

Keywords: photocatalysys, thioxanthene, hydrogen, water, radical, triplet

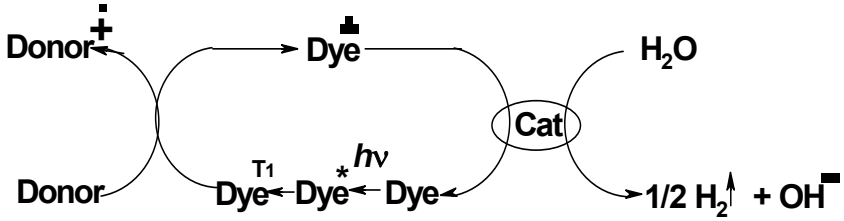
1 Introduction

Photocleavage of water into hydrogen and oxygen is one of the most attractive ways of accumulation of solar energy and the simplest model of natural photosynthesis. A.E. Shilov et al. proposed catalytic cycle decomposition of water to hydrogen consisting of a dye-sensitizer (plays the role of chlorophyll in green plants), an electron carrier and a metal catalyst [1].

2 Experimental/methodology



In the photocatalytic systems by decomposition of water to hydrogen was investigated a number of important xanthene dyes [2]. Xanthene dyes decomposition of water without intermediate electron acceptor in two-component scheme:

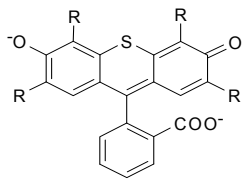


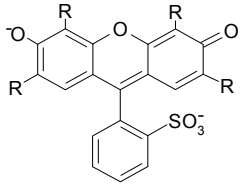
The efficiency of sensitization by xanthene dyes of reaction photocleavage of water is determined mainly by the efficiency of yield triplets and radicals.

Spectral-kinetics parameters of the radicals and triplet state xanthenes dyes has been studied with use setup of flash photolysis with time resolution 10 μs.

3 Results and discussion

The results of spectral and kinetic studies of new thioxanthene anionic dyes and kinetics of photocleavage of water into hydrogen in a homogeneous two-component photocatalytic system has been performed. It is shown that replacing the oxygen atom in xanthene moiety by a sulfur atom (***1-3***) increases the quantum yield of triplet and photohydrogen. Replacement of the carboxyl group of the phthalic fragment on sulfonic group (***4.5***) does not affect the photophysical and photocatalytic properties of the dye, and appears only in the nature of the interaction with the surfactant.





1	***2***	***3***	***4***	***5***
R=H	**Br**	**J**	**R=H**	**Br**

It is shown that replacing the oxygen atom in xanthene moiety by a sulfur atom (***1-3***) leads to a bathochromic shift of the absorption spectrum dianionic form of the dye. With the introduction of four bromine atoms in the molecule thiofluoresceine (***2***) there is a small bathochromic shift in the absorption spectrum and dramatically increases strength of the oscillator of long-wavelength band, which corresponds to the large dipole moment of the transition (table 1).

The quantum yield of triplet φ_T of the tetraiodinethiofluorescein (***3***) had 2-fold less than that of the dye (***1***). Dye (***3***) practically no luminescent unlike compounds (***1,2***) and the main channel that energy dissipation of the dye (***3***) is thermal deactivation. Obviously, this effect is due to the joint presence of heavy atoms of sulfur and iodine. Because of the low quantum yield of triplet formation, tetraiodinethiofluorescein (***3***) has low photocatalytic activity in the reaction of photoreduce water into molecular hydrogen in the system consisting of a dye, catalyst and electron donor.

The influence of the components of the photocatalytic system on the spectral, fluorescent, kinetic characteristics of intermediate products and photocatalytic activity has been studied (table 2). The data obtained allowed to construct a two-component photocatalytic system based on the tetrabromthiofluorescein that effectively worked hundreds of hours to the initial quantum efficiency of 15%.

Keywords: hydrotreating, diesel fuel, light coker gasoil, phosphorus

1 Introduction

Carrier surface modification of hydrotreating catalysts is one of the methods of catalysts activity increasing **[1,2]**. Investigations, which described combined modification of carrier surface and applying of heteropolyacids, are not numerous. This made investigation in that field an actual one. Phosphorus compounds introduction in alumina changes a number of OH-groups on surface, which affect on strengths of carrier and active phase precursors bonds and, respectively, on their activity.

2 Experimental/methodology

A line of catalysts with different amounts of phosphorus was synthesized. Modifier was introduced on the first stage of two stages synthesis by wetness impregnation method from phosphoric acid water solution. After impregnation modified carrier was calcined at temperature of 550ºC. Modified carrier was impregnated with water solution of active phase precursors (Mo, Ni(Co)) on the second stage of synthesis. Properties of synthesized catalysts are listed below in **Table 1.**

Table 1. Characteristics of Co(Ni)Mo/P-Al_2O_3 catalysts

Catalyst	Content, wt. %			Catalyst	Content, wt. %		
	MoO_3	CoO	P_2O_5		MoO_3	NiO	P_2O_5
CoMo/P(0)	18,5	4,6	-	NiMo/P(0)	18,2	4,7	-
CoMo/P(0,5)	18,3	4,7	0,5	NiMo/P(0,5)	18,6	4,9	0,5
CoMo/P(1)	18,2	4,7	1,0	NiMo/P(1)	18,7	4,9	1,0
CoMo/P(2)	18,5	4,5	2,0	NiMo/P(2)	18,4	4,8	2,0
CoMo/P(5)	18,6	4,6	5,0	NiMo/P(5)	18,4	4,8	5,0

The catalytic activity of the samples was determined in a bench-scale flow reactor unit in the hydrotreating process of light catalytically cracked gas oil (LCGO) and straight-run gas oil (SRGO) mixture (1:9 by volume). Contents of sulfur and polycyclic aromatic compounds in mixture were 0,80 and 5,14 wt. % respectively.

3 Results and discussion

The relationships between hydrodesulfurization (HDS) constant (1,5 order kinetic model) and content of P_2O_5 are presented in **Fig. 1** and **3**. The relationships between hydrogenation degrees (HYD) and content of P_2O_5 are presented in **Fig. 2** and **4**. In all cases relationship curves have a complicated character. Samples with P_2O_5 content of 5,0 wt. % were the most active.

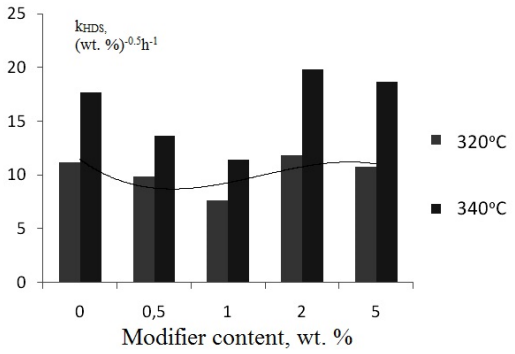

Fig. 1. Relationship between k_{HDS} and P_2O_5 content for CoMo/P catalysts

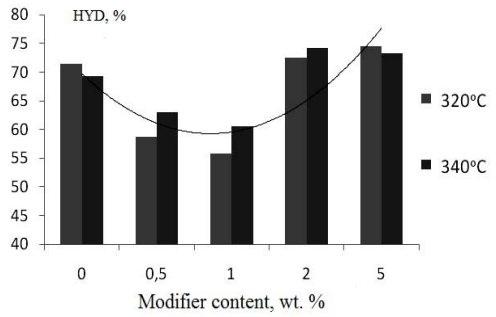

Fig. 2. Relationship between HYD and P_2O_5 content for CoMo/P catalysts

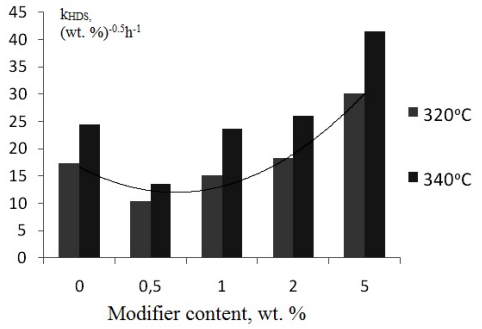

Fig. 3. Relationship between k_{HDS} and P_2O_5 content for NiMo/P catalysts

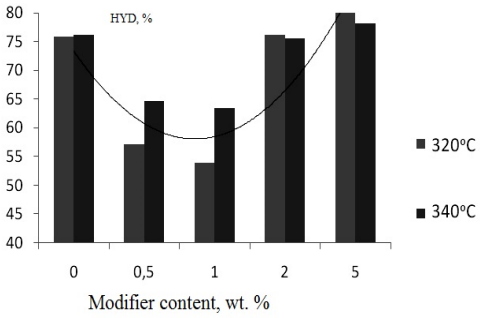

Fig. 4. Relationship between HYD and P_2O_5 content for NiMo/P catalysts

It should be mentioned, that HDS and HYD activities minimum were found for P_2O_5 content of 0,5-1,0 wt. %. The similar relationships were found in **[3]**. Authors explained this phenomenon took into account structure characteristics of modified carrier surface.

4 Conclusions

In this way, modification of carrier with P_2O_5 amounts of 2-5 wt. % get a positive effect on catalytic activities in HDS and HYD reactions. In CoMo catalysts line the maximum of activity was found for CoMo/P(2) sample and in NiMo one – NiMo/P(5).

Keywords: hydrogenolysis, oil fractions, catalyst, hydrotreating

1 Introduction

Intensity of Mo-W systems investigations increased in the last years [**1-4**]. The main works decided to catalytic tests in dibenzthiophene and 4,6 – dimethyldibenzthiophene hydrogenolysis reactions [**1, 4**]. A larger part of investigations carried out with model compounds. So, the catalytic tests of Ni-MoW/γ-Al_2O_3 catalysts with real feed are an actual ones. In this work the results of Ni_6-$PMo_nW_{(12-n)}(S)/Al_2O_3$ catalysts (mole ratio Mo:W) investigations in hydrotreating of diesel and vacuum gasoil fractions are presented.

2 Experimental/methodology

γ-Al_2O_3 carrier was synthesized from AlOOH (TH-100, «Sasol»). Pore structure was determined by adsorption of nitrogen at 77K (S_{BET} = 175 m^2/g, V = 0.901 cm^3/g, $R_{eff.}$ = 87 Å). A line of Ni-MoW/Al_2O_3 catalysts was synthesized by means of wetness impregnation method from aqua solution of Ni, Mo and W compounds ($(Ni(OH)_2)_2$*$NiCO_3$, $H_3PMo_{12}O_{40}\cdot 17H_2O$, $H_3PW_{12}O_{40}\cdot 29H_2O$). Impregnation solution also contained a citric acid as chelating agent. Catalysts were dried at 60, 80 and 110°C for 2 hours. The mole ratios of Mo:W were 1:0, 2:1, 1:1, 1:2 and 0:1 (catalysts denoted as Ni-Mo_nW_{12-n}). Catalysts were sulfided before catalytic tests in flow of H_2/H_2S = 30/70 vol. (5 l/h) at 500ºC for 2 hours. Catalytic activity was determined in a bench-scale flow reactor under hydrogen pressure in the hydrotreating of straight run diesel fraction and light coker gasoil mixture (sulfur content – 0.798 wt. %, polycyclic aromatic hydrocarbons (PAH) content – 5.14 wt. %, Iodine number – 2.4 g/100 ml) and vacuum gasoil (sulfur content – 2.07 wt. %, PAH content – 9.61 wt. %). Hydotreating of straight run diesel fraction and light coker gasoil mixture was carried out under the next conditions: hydrogen pressure of 4.00 ± 0.04 MPa, LHSV = 2.0 h^{-1}, H_2/feed = 600 nm^3/m^3, temperatures of 320 and 340 ± 1 ^{0}C. Hydotreating of vacuum gasoil was performed in the next conditions: hydrogen pressure of 5.00 ± 0.04 MPa, LHSV = 1.0 h^{-1}, H_2/feed = 1000 nm^3/m^3, temperatures of 360 and 390 ± 1 ^{0}C. HR TEM images were recorded for catalysts in sulfide form.

3 Results and discussion

Geometric characteristics of active phase were determinate on the base of HR TEM images [**5**]. The active phase morphology (length of slab – L and number of layers in slab – N) of sample with Mo:W=1:1 was notable different from others. As it assumed in [**6**], active centers (coordinatively unsaturated atoms of Mo and S) are located on the edges of slabs. Hydrogen is able to react with sulfur atoms and form anion vacancies (HDS reaction catalytic centers).

Results of straight run diesel fraction and light coker gasoil mixture hydrotreating are shown in **Fig. 1**. Catalyst with Mo/W = 1/1 demonstrated the highest hydrodesulphurization (HDS) activity.

Results of vacuum gasoil hydrotreating are shown in **Fig. 2**. Catalyst with Mo/W = 1/1

demonstrated the highest hydrodesulphurization (HDS) and hydrogenation (HYD) activities.

Table 1. Active phase characteristics of Ni-Mo_nW_{12-n}(S) catalysts

Parameter of active phase	Ni-Mo_{12}(S)	Ni-Mo_6W_6(S)	Ni-W_{12}(S)	Ni-Mo_6W_6(S) after catalytic test
Average slab length, L, nm	4,0	5,0	3,9	4,1
Average number of layers in slab, N	2,1	2,5	1,6	1,7
% atoms of Mo(W) at edge positions, f_e	24,4	20,8	24,9	23,8
% atoms of Mo(W) at corner positions, f_c	5,2	3,3	5,5	4,8

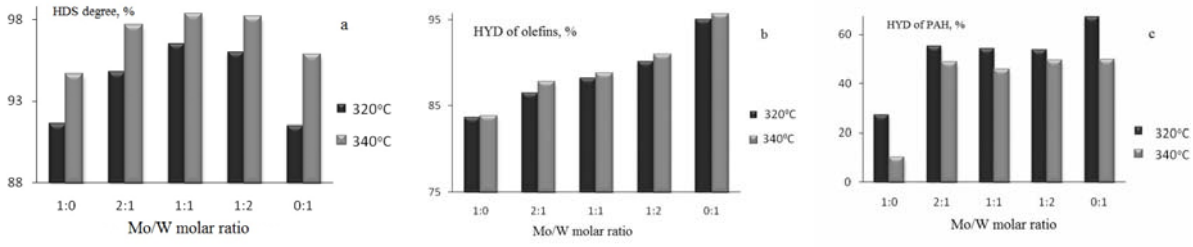

Fig. 1. Relationships between HDS degree **(a)**, HYD degrees of olefins **(b)** and PAH **(c)** of straight run diesel fraction and light coker gasoil mixture and molar ratio Mo/W

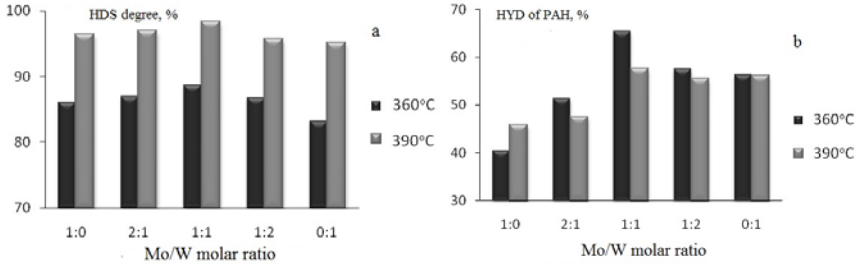

Fig. 2. Relationships between HDS degree **(a)**, HYD degree of PAH **(b)** of vacuum gasoil and molar ratio Mo/W

4 Conclusions

A line of trimetallic Ni-Mo_nW_{12-n} catalysts was synthesized and tested in hydrotreating of oil fractions. Catalyst with Mo/W = 1/1 demonstrated the highest hydrodesulphurization (HDS) activities in hydrotreating of straight run diesel fraction and light coker gasoil mixture and vacuum gasoil. Catalyst with Mo/W = 1/1 also demonstrated the highest hydrogenation (HYD) activity in hydrotreating of vacuum gasoil. Morphologies of active phases were investigated by means of HR TEM. Sulfide phase of Ni-Mo_6W_6(S) had the highest number of edge and corner Mo(W) atoms. It should be mentioned, that catalytic behavior of Ni-Mo_nW_{12-n} catalysts can't be explained in the view of active phase morphology. The Ni-Mo_nW_{12-n} catalysts are very perspective, like it was concluded from catalytic tests.

Keywords: carbon, nanotubes, quantum-chemical, calculations, metal/carbon catalysts

1 Introduction

Usually carbon support in M/C catalysts is considered as an inert material, which is not involved in chemical transformations. However, recently we have found that interaction between metal particles and carbon support significantly changes the morphology of M/C catalysts [1].

2 Experimental/methodology

A variety of processes have been observed, where of particular interest are pitting/etching and nanotube growth under microwave irradiation (Fig. 1).

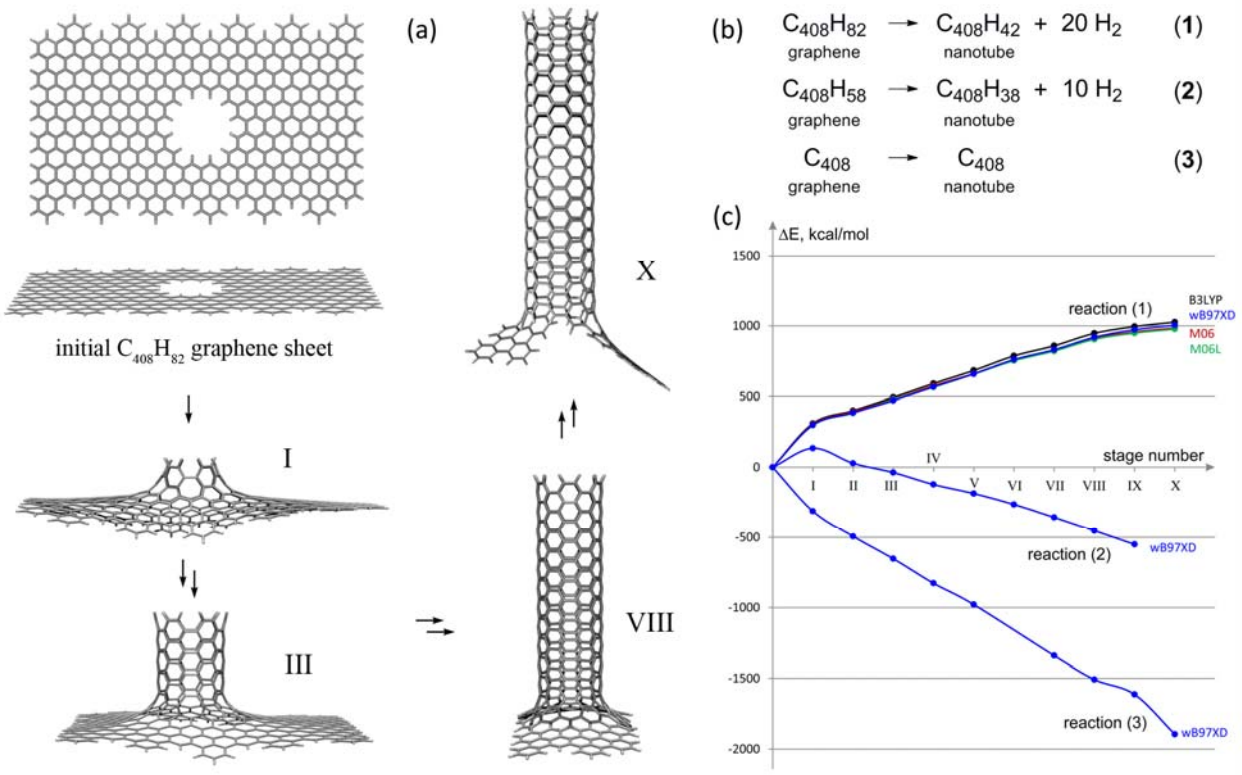

Fig. 1. (a) – Stepwise transformation of a $C_{408}H_{82}$ graphene sheet to a (6,6) nanotube; (b) – summary of nanotube formation reactions for the $C_{408}H_{82}$, $C_{408}H_{58}$, and C_{408} graphene sheets; (c) – relative energies of reactions (1−3) calculated at DFT level.

3 Results and discussion

A detailed computational study has been carried out to study the mechanism of possible modification of the carbon surface.

The nanotube formation process is strongly dependent on the state of the graphene edges: calculated energy change of +2.5; -1.5; -4.6 kcal/mol per one carbon atom was found for $C_{408}H_{82}$, $C_{408}H_{58}$ and C_{408} model graphene sheets, correspondingly. This result suggests a possibility to control CNT formation during the preparation of Metal/Carbon catalysts by changing the reaction conditions.

Keywords: manganese dioxide, microwave-assisted method, environmental catalysis

1 Introduction

Present-day electrochemistry trends and advances belong to processes of energy storage and conversion; they also include the related materials exploring. The exploiting alternative catalytic materials for oxygen reduction reaction (ORR) have triggered dynamic research interests. The main efforts focused on compounds providing considerable catalytic activity, nontoxicity, low cost and abundance. Manganese dioxide is a juicy system and dominant competitor in ORR field. However, the electrochemical activity of MnO_2 is correlated with its crystallographic structure and specific surface area. Manganese dioxide exists in a number of structural forms, where the basic structural element consists of MnO_6 octahedra forming layers and channels [1]. The pyrolusite (β) and ramsdellite (γ) are relatively pure forms of MnO_2. Other ones, such α, δ, contain ions like Na^+or K^+ within the lattice. A number of synthetic methods are known for the preparation of MnO_2 with desired crystal structure and morphology including sol-gel method, electrochemical deposition, precipitation, and hydrothermal synthesis, also a few papers on the synthesis of MnO_2 nanostructures with microwave irradiation [1, 2]. The last approach doesn't need high pressure, temperature, vacuum, catalysts or templates. The microwave-hydrothermal (MWHT) method was used to produce various multifunctional nanomaterials such as zeolites, metal oxides, with intriguing morphologies such as nanopheres, nanowires, and nanoporous networks. Ming et al. demonstrated a methodological approach for utilizing microwave heating during the hydrothermal process to obtain birnessite-type MnO_2. However, the employed process whether the morphology of as-prepared MnO_2 powders can be controlled by simply adjusting the process conditions was not illustrated. These work actually duplicated Xiao et al research who did α- and δ-MnO_2 with hydrothermal synthesis. It still remains debated containing K^+ ions aspect, which are inevitably inside channels from MnO_6 octahedra in α-MnO_2 and between layers in δ-MnO_2 in default, and its influence to electrochemical activity [3]. We report a strategy in microwave-hydrothermal processes that permits exquisite control over the crystal structure and morphology of MnO_2 nanostructures by temperature, time, acidity.

2 Experimental/methodology

Manganese dioxide nanostructures were synthesized by high-yield MWHT technique under mild conditions through redox reaction between permanganate and nitrite ions. In a typical synthesis, $KMnO_4$ and $NaNO_2$ with molar ratio 2:3 were added to 40 ml deionized water to form a homogeneous solution. Different amount of 0.5M H_2SO_4 were then added dropwise into the stirred solution. After stirring for 20 min, the 20 ml obtained suspension was transferred to a 30 ml Teflon vessel. The autoclave was sealed and heated to different reaction temperatures (90, 110, 150, and 170˚C) with holding time of 8, 12 or 25 min in an Berghof MWS-3* microwave digestion system. After the autoclave was cooled down to room temperature, the products were collected by centrifugation and washed with deionized water and absolute ethanol several times to remove the impurities, and dried in air at 70˚C for 12 h. All reactions under the microwave irradiation get a quantitative yield (around 99% and more) while shortening the reaction time.

Different amount of H_2SO_4 was added to initial solution, while keeping other conditions constant. The obtained products were tested by XRD, SEM, BET, EDX.

3 Results and discussion

In the absence of H_2SO_4 in initial solution the sample is only MnO_2 nanoflowers (Figure). As the amount of acid is up to 2 ml, the morphologies of particles are mixture of nanograins attached onto the nanorods. Using 3.5 ml, the sample is almost pure nanorods (Figure). A further increasing H_2SO_4 amount doesn't influence on morphology of MnO_2.

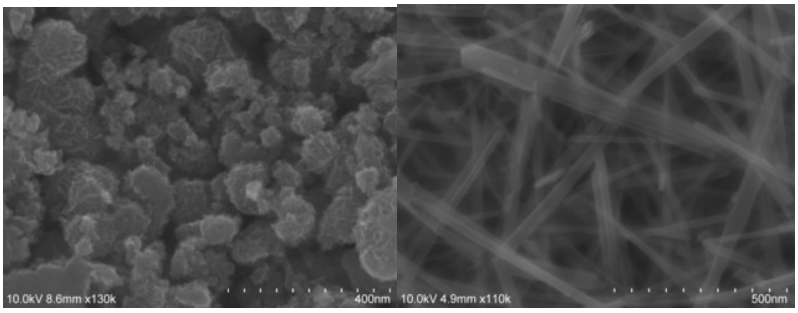

Fig. 1. SEM Images of δ-MnO_2 Nanoflowers (left), MnO_2-Pyrolusite Nanorods (right).

The coherent scattering domain sized (D csd) were calculated by the Shelyakov-Scherrer formula $Dcsd = \lambda/\beta\cos\theta$, were $\lambda Cu = 1.54178Å$ and β is the intrinsic broadening of diffraction maximum, θ - the angle of the reflection. Under acidic conditions, as the H_2SO_4 amount is increased, crystal size (domain size) is essentially constant for the samples with layered structure produced (40-50 nm). In a critical point, where H^+ dominate on K^+ion (in the present case), pyrolusite β-MnO_2 is established as the preferred phase and a structural transition is observed on XRD patterns, crystal size increases dramatically (around 100-200 nm), perhaps reflecting the thermodynamic stability of this phase.

Pyrolusite is obtained as large rod, with octahedral cross-section, a diameter of 100-200 nm and length of 1-2μm (Figure). MnO_2 nanorods grow in the (001) direction, the axis [110] is perpendicular to the side walls. These conclusions were confirmed by TEM and SAED measurements. The shape of β-MnO_2 and the favored growth along a defined direction are generated mainly under thermodynamically preferential crystal growth process.

4 Conclusions

In this work we proved that crystal structure and morphology of MnO_2 can be controlled by varying reaction time and temperature under microwave assistance as well as the amount of acid. Future work will be focused on electrochemical activity.

Keywords: adsorption, CO oxidation, DRIFTS, Cu-CeO_2, doped with Zr, Hf, Th

1 Introduction

In recent years, CeO_2 and TiO_2 based noble metal ionic catalysts have been found to show significant enhancement of CO oxidation and NO reduction at a lower temperature [1,2]. It has been demonstrated that substituted noble metal ions on CeO_2 matrix are catalytically more active than dispersed fine metal particles on Al_2O_3. Pd^{2+}, Pt^{2+}, Rh^{3+}, Cu^{2+}, Ag^{+} and Au^{3+} are the active sites for several important catalytic reactions. Structural studies show that metal ions are incorporated into CeO_2 substrate to a certain limit in the solid solution form of $Ce_{1-x}M_xO_{2-\delta}$ ($x \leq 0.05$). Among the transition metals, Cu based catalysts have been found to be very active for CO oxidation, NO reduction and CO-PROX reaction [3,4]. In our previous study, it has been found that Pd^{2+} ion substituted in different CeO_2 based supports show different activities [5]. It has been observed that activation energy for CO oxidation decreases with increasing ionic character of Pd^{2+} in CeO_2 based catalysts. Therefore, it would be worthwhile to study other metal substitution in different CeO_2 supports and investigate the variation of their catalytic activities. This could give a more general outlook into how active metal ion can be activated by choosing suitable support. In this sense, it would be interesting to study the variation of catalytic activities of Cu^{2+} ion in different Cu doped CeO_2 catalysts.

Diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) is a versatile tool to get information about the nature of adsorbed species on the surface of catalyst during reaction [6]. It can also provide the trends of reaction with respect to the temperature. The present work focus on DRIFTS study to understand CO adsorption at room temperature as well as CO oxidation by O_2 at different temperatures over different Cu substituted $Ce_{1-x}M_xO_2$ (M = Zr, Hf, Th) catalysts. The effect of supports on the substituted Cu^{2+} ions toward CO adsorption/oxidation behavior has been studied.

2 Experimental/methodology

Cu^{2+} substituted $Ce_{1-x}M_xO_2$ (M = Zr, Hf, Th) were prepared by solution combustion method. BET surface areas, XRD patterns and XPS of these catalysts were carried out using Quantachrome Autosorb Automated Gas Sorption System (Quantachrome Instruments), PANalytical X'Pert PRO diffractometer and Thermo Fisher Scientific Multilab 2000 spectrometer, respectively.

CO adsorption at room temperature and in-situ DRIFT spectra of the CO + O_2 reaction as a function of temperature over Cu substituted $Ce_{1-x}M_xO_2$ (M = Zr, Hf, Th) catalysts were recorded with an accumulation of 20 scans at a resolution of 4 cm^{-1} using a FTIR spectrometer from Thermo Scientific Nicolet 380 FTIR with a liquid N_2 cooled high sensitivity MCT detector and a DRIFTS cell.

3 Results and discussion

XRD patterns of the Cu substituted $Ce_{0.75}M_{0.25}O_2$ (M = Zr, Hf, Th) catalysts are indexed to fluorite structure. XPS studies show that Cu, Ce, Zr, Hf and Th are present in +2, +4, +4, +4 and +4 oxidation states, respectively. CO derived products such as carbonates, bicarbonates and formates are formed when CO is interacted with these catalysts at room temperature. When CO is introduced over the catalyst, surface Cu species in +2 oxidation state gets partially reduced by CO and consequently, CO derived species such as carbonates are formed over the CeO_2 based supports. Therefore, frequencies related to Cu and CO interaction in these catalysts are ascribed for Cu^+–CO species whose positions are shifted to higher frequencies in Zr, Hf and Th doped catalysts. The effect of support can be observed when CO adsorption shows variation in the intensity of Cu^+–CO in different supports in similar conditions. Variation of Cu^+–CO peak intensities during CO oxidation have been accepted as probe to find the differences in supports and it is shown in Figure 1. The observed intensities of Cu^+–CO peaks increase with the following substitutions: CeZr < Ce < CeTh ~ CeHf. As all the substituents are non-reducible, only electron withdrawing power as determined by effective nuclear charge (Zeff) can influence the activity. Zeff of Hf4+ and Th4+ is more due to f electron indicating lattice oxygen is more polarized towards Hf4+ and Th4+. Therefore, Hf/Th doped catalysts are more reducing in nature. Therefore, transformation of more Cu2+ to Cu+ occurs significantly in case of Hf and Th. This also affects CO oxidation activities of these catalysts, because because localized charge on Cu2+ induces more +ve charge on 'C' atom end of the adsorbed CO molecule while reacting with lattice oxygen. This explains lowest activity of Zr substituted Cu/CeO2 among all these in Ce0.93Cu0.07O2 and catalysts.

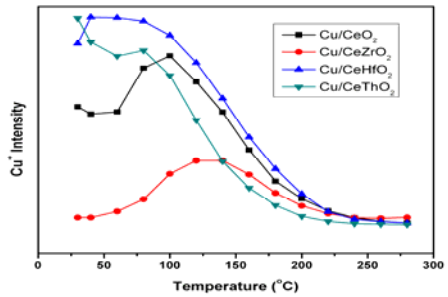

Figure 1. Cu+□CO intensity vs Temperature (°C) $Ce_{0.68}M_{0.25}Cu_{0.07}O_{2-\delta}$ (M = Zr, Hf and Th) catalysts.

4 Conclusions

Effect of electron withdrawing property of supports on CO adsorption and oxidation activities in $Ce_{0.93}Cu_{0.07}O_{2-\delta}$ and $Ce_{0.68}M_{0.25}Cu_{0.07}O_{2-\delta}$ (M = Zr, Hf, Th) catalysts.

Keywords: ZSM-5 zeolite, fly ash, zeolite synthesis, hydrothermal method

1 Introduction

The synthesis of high silica zeolite ZSM-5 was reported in 1972 by Mobil [1]. ZSM-5 is a medium pore zeolite formed by 10-membered rings, which possesses a pore dimension of 0.54-0.56 nm. Its unique pore structure has excellent shape selectivity and tunable acidity, which makes an interesting material for catalyzing organic reactions. Since its discovery, extensive work has been carried out on the synthesis and applications of ZSM-5. High crystalline ZSM-5 can be synthesized within a period of about 168 h in autoclave at 120–180°C under autogenous pressures. The crystallization time can be reduced to 4–6 h under high pressures and temperatures (about 40–60 atm and 230–250°C) [2]. The possibility of synthesizing ZSM-5 at temperatures between 90–100°C and atmospheric pressure has also been reported [3-4]. These methods make available the study of the crystallization mechanism since it require a long induction period. Among the several templates used for the synthesis of ZSM-5, the most common is tetrapropylammonium bromide (TPABr). Previously, almost all the fly ash was disposed by landfill, which became expensive and caused an environmental problem. Mostly fly ash can be used as building materials according to its pozzolanic properties [5–6]. However, due to the fluctuation demand, the alternative uses of fly ash were focused as raw material for zeolite synthesis. The synthesis of zeolites from fly ash can be classified into direct and non-direct synthesis [7-8]. This work is concerned with the synthesis and characterization of ZSM-5 from different fly ashes of the Colombian Industry by the hydrothermal method.

2 Experimental/methodology

Several fly ashes from Colombian Industry were used as raw materials for ZSM-5 zeolite synthesis, by hydrothermal method. The fly ash was subjected to calcination at 700°C for 3 hours as a pretreatment, to weaken the crystallinity of the quartz phase, which is silicon oxide. To adjust the high ratio SiO_2/Al_2O_3 of the zeolite, a suspension of silicon oxide (30% LUDOX) was used and TPABr was added as the structure-directing ofZSM-5 zeolite synthesis. The synthesis through of the hydrothermal method was carried out at crystallization temperature of 190°C for 24 hours in stainless steel reactor with Teflon lining, after which the gel was left to stir for 5 hours. Finally, the material was calcined at 550°C for 5 hours to remove excess humidity and organic compounds into the structure.

3 Results and discussion

Characterization by X-ray fluorescence (F-XRD) in the fly ash identified a high content of silicon oxide (SiO_2) and aluminum oxide (Al_2O_3) in a molar ratio SiO_2/Al_2O_3 close to 1 and low content of otherwise oxides. An analysis by X-ray diffraction (XRD) determined the phases present in the feedstock and thermogravimetric analysis (TGA) allowed to determine the thermodynamic behavior of the material under consideration and defined optimal conditions to calcination.

The zeolite was characterized by several techniques, including an analysis of X-ray diffraction, where the presence of ZSM-5 stage was confirmed; chemical analysis by atomic absorption determined the Si/Al relation and the Na^+ cations percentage. Trough of analysis by scanning electron microscope (SEM) was determined the structural properties of the material and the particle size of the grains formed. Thermogravimetric analysis (TGA) succeeded for identifying the thermodynamic behavior of the zeolite and the thermal stability at high temperatures. Finally, analysis of BET surface area was use for determining the textural characteristics of the catalyst.

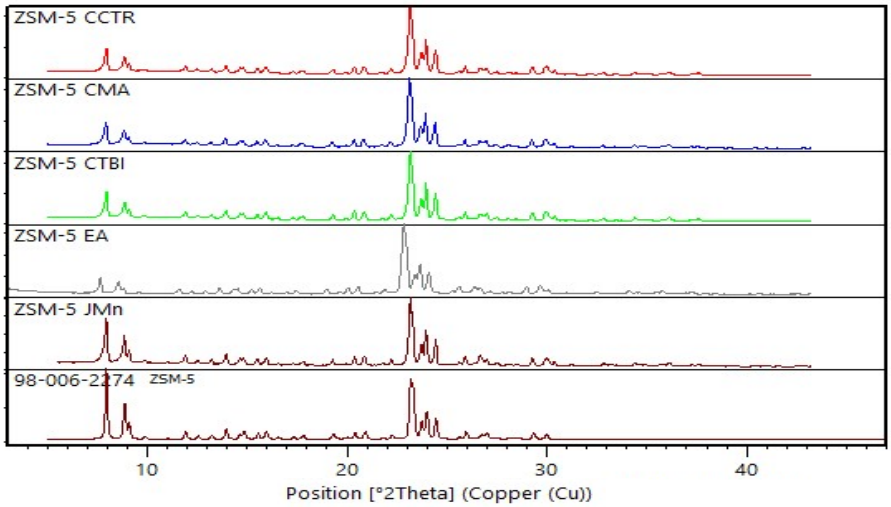

Fig 1. DRX for different zeolites ZSM-5 trough of fly ash.

4 Conclusions

The alternative use of fly ash for the synthesis of zeolite ZSM-5 by hydrothermal method was possible. The textural and crystallographic properties were examined identifying key characteristics of the material. Fly ash exposed to heat pretreatment and hydrothermal process at 190 °C and autogenous pressure for 24 hours, allowed to crystallize a MFI phase.

1 Introduction

Palladium nanoparticles play an important role in various fields such as catalysis, medicine, chemistry, biology, etc. In a number of industrial application supported palladium nanoparticles are used to catalyze reactions of hydrogenation when hydride phase of the palladium nanocatalysts may be formed. The understanding of the conditions of the hydride phase formation and obtaining a phase diagram of the nanocatalyst is an important step in order to investigate the active phase of the catalysts. In our study we used industrial Pd nanocatalysts (ChimetSpA) with average particle size about 3 nm deposited on carbon. Pressure-composition isotherms for palladium hydride nanoparticles were obtained using simultaneous in situ X-ray Absorption Spectroscopy (XAS) and X-ray Powder Diffraction (XRPD) measurements.

2 Experimental/methodology

Pressure composition isotherms were obtained for Pd Hydride nanoparticles with average particle size about 3 nm deposited on carbon. Experiments were carried out at Swiss-Norwegian Beamline of ESRF. Pd/C nanoparticles were packed in a 1mm thick capillary connetted to a pressurized system enabling to control hydrogen pressure. Vaccum pump was connected to the system for outgassing. Gas blower positoned above the sample was used to controll the temperature. Initial pretreatment of the sample was done at 125 °C in 200 mbar of hydrogen during 30 minutes. Pd foil and Pd black were used as reference samples.

In situ X-ray Absorption and X-ray Powder Diffraction data were collected at -10, 20, 50, 80 and 110 °C in a pressure range from 0 to 10000 mbar. X-ray Absorption Spectra at Pd K-edge were obtained in the transmition mode in the continuous scanning mode in the energy of the incoming photons from 24.1 to 25.4 keV. Pd foil was measured simultaneously for energy callibration. Single-shell EXAFS analysis was performed in Demeter package.

X-ray diffraction images was collected by CMOS-Dexela 2D detector. The photon wavelength was set as 0.50544 Å. The values of wavelength and sample-to-detector distance were optimized using silicon poweder and lanthanum hexaboride. The geometry of the experimental setup resulted in a 2θ angles from 0 to 52 degrees. For better statistics 5 images and 5 dark images with time acquisition of 10 seconds were collected at each of the experimental points. Rietveld refinement was performed in Jana2006 code giving the cell parameters and concentration of α- to β- hydride phases.

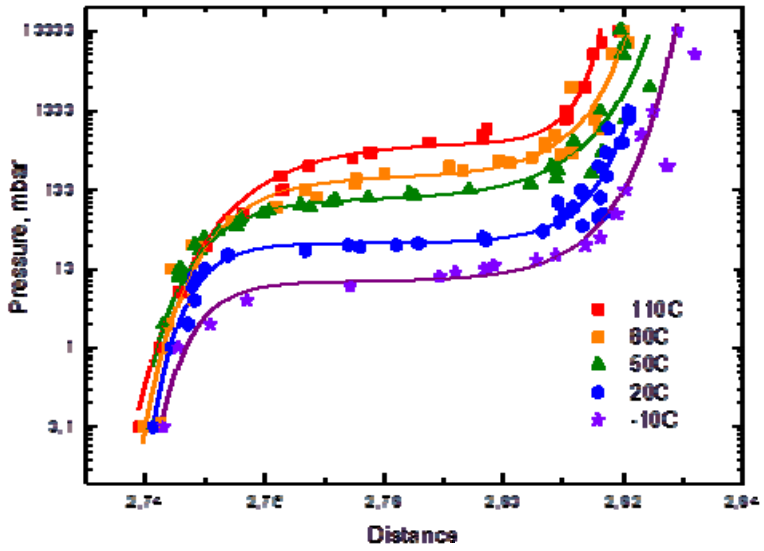

Fig. 1. Pressure-composition isotherms for Pd-H nanoparticles obtained from EXAFS.

3 Conclusions

We have performed a detailed investigation of hydride phase formation in Pd nanocatalysts using different complementary techniques: EXAFS, XANES, XRPD and volumetric measurements. The average cell parameters obtained from EXAFS and XRPD are in excellent agreement, but Rietveld analysis of diffraction data allows to separate two coexisting hydride phases, while EXAFS shows only averaged Pd-Pd distance with increased Debye-Waller parameter. The obtained results indicate that a transition from α- to β- phase occurs similarly to that in bulk Pd. XANES spectra are influence directly be hydrogen atoms and the performed fitting of XANES provides quantitative information on the amount of hydrogen absorbed in Pd nanoparticles, which correlates with volumetric measurements.

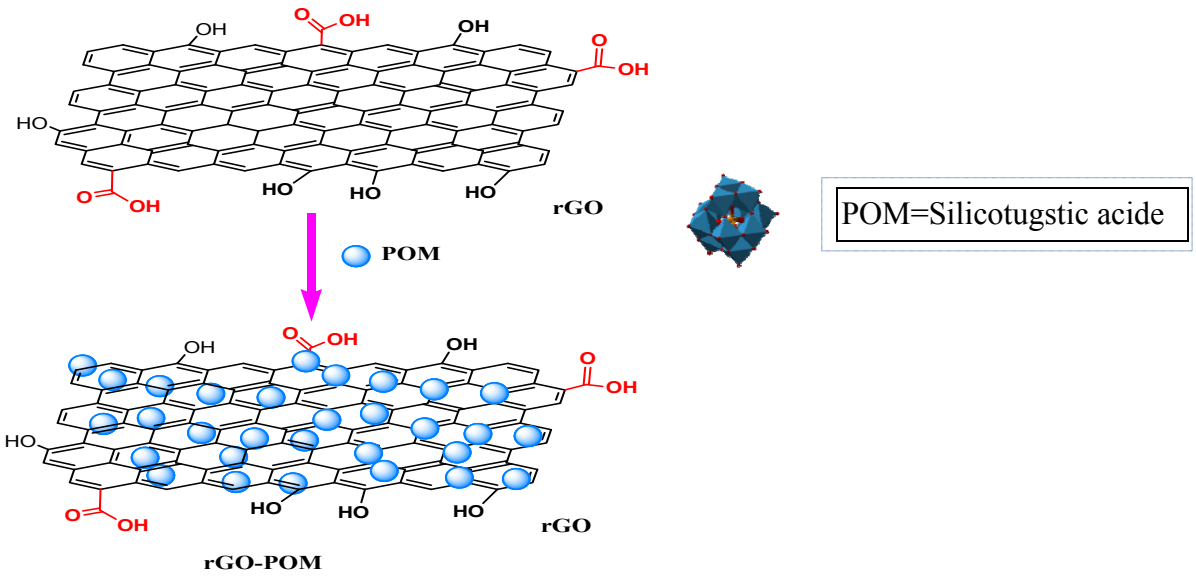
1 Introduction

Dyes in water are a major class of synthetic organic compounds released by many industries such as paper, plastic, leather, food, cosmetic, textile and pharmaceutical industries. These effluents result in significant environmental pollution impact on human and animal healt[1,2]. In recent years, different type of polyoxomatalates(POMs) have been studied as novel catalysts for dye degradation of organic dyes due to their diverse properties in molecular composition, redox potential, and solubility [3,4]. However POMs are usually soluble in many polar solvents, causing difficulties in the recovery, separation, and recycling of the catalysts. These significant aspects have prompted researchers to anchor POM on a support material such as silica, metal cations (Cs, Co, Fe, etc.), zeolite, positively charged polymer chains, nanoparticles, and carbon[5-7].

In this study, we have prepared a facile way to fabricate rGO-POM composite with high stability and good catalytic properties. In our method, POM was combined with the graphene structure. The catalytic property of rGO-POM was investigated by reducing methylene blue (MB) with $NaBH_4$ as the reducing agent. The extent of dye decomposition was monitored using UV-Vis spectroscopy technique.

2 Experimental/methodology

Graphene oxide (GO) and reduced reduced graphene oxide GO was prepared to literature[8]. The reduced graphene oxide was dispersed and sonicated in DI water. In this step, ethylene glycol was added to the reduced graphene oxide solution to disperse POM on the graphene sheet. An aqueous solution of Silicotungstic acid was added to the rGO solution and mixed, filtered and washed with DI water and then dried[5]. Catalytic activity of rGO-POM composite was investigated by means of degradation of methlylene blue by sodium borohydride in aqueous solutions and the reaction was monitored by UV-VIS spectrometry.



Scheme 1. rGO, POM and rGO-POM composite

3 Conclusions

This report has showed that the textile dye of MB in water can be degraded by $NaBH_4$ in the presence of rGO-POM composite.

Keywords: nickel catalysts, CH_4, dry reforming, epitaxial binding

1 Introduction

The reforming of CH_4 with CO_2 has attracted much attention in recent years. This process produces synthesis gas with low H_2/CO ratio which can be converted into liquid hydrocarbons in the Fisher-Tropsch reaction or in the production of methanol. Nickel is preferred metal for the catalysis the CO_2 reforming of CH_4 due to its inherent availability, low cost and high activity. However, the major problem encountered with the reaction of CO_2 reforming of methane is the coke formation leading to the catalyst deactivation. For carrying out the endothermic reactions of dry reforming of CH_4, intensive heat transfer to the reaction zone is required. Therefore, the catalyst must have a high thermal conductivity. It is most promising to use catalyst on metallic supports. This work was aimed to the studying of the nickel catalysts supported on the porous nickel ribbon with MgO underlayer for dry reforming of CH_4 to syngas.

2 Experimental

In the supported nickel catalysts the MgO underlayer (~6 wt. %) was prepared by impregnating the nickel ribbon support with a $Mg(NO_3)_2$ solution followed by drying and then by calcination at 550°C in air (support I) or flowing H_2 (support II). Catalysts I and II were prepared by supporting of nickel on supports I and II via their impregnation with $Ni(NO_3)_2$ solution or a mixture of $Ni(NO_3)_2$ and $Mg(NO_3)_2$ solutions. All the catalysts were dried, calcined at 450°C in a N_2 flow and then reduced in H_2 flow at 900°C for 1 h. The catalysts were characterized by XRD, low-temperature adsorption of nitrogen, SEM and TEM HR in combination with EDX microanalysis. Catalytic activity in CO_2 reforming of CH_4 was determined by a flow method (750°C, 1 atm, m_{cat} = 0,40 g, reaction mixture flow rate – 25 l/h).

3 Results and discussion

X-ray diffraction data showed that the reduced nickel catalysts contain the phases of metallic nickel and NiO in MgO solid solution. HRTEM data show that supported nickel catalysts have the dispersed nickel particles (3-10 nm) epitaxially bound with MgO underlayer (Fig.1).

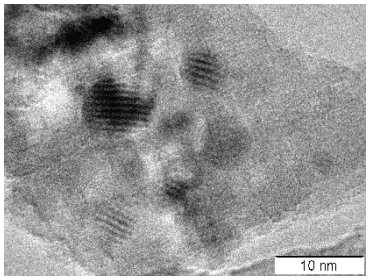

Fig.1. HRTEM image of the catalyst 2.7% Ni/(pNirb+ 6.0 % MgO) (I), 900°C, H_2.

Table shows the activity of prepared nickel catalyst in dry reforming of CH_4. The activity of nickel support with the MgO underlayer was low and decreased during the reaction (Table),

probably due to carbonization. Additional supporting of nickel onto supports with the MgO underlayer increased the catalytic activity (Table). With the increase in the content of supported nickel, the catalyst activity increased, which may result from an increase in the surface area of metallic nickel per unit weight of the catalyst. The activity of the supported nickel catalysts with high content of MgO was more stable; decreasing of conversion during the test period (9 h) was 18-20% (for the ratio CO_2/CH_4 = 1) (Table).

Table Catalytic activity of nickel catalysts in dry reforming CH_4
(750°C, 1 atm, CH_4:CO_2:N_2 = 1:1:0,86, initial mixture flow rate – 25 l/h).

Catalyst	CH_4 conversion, %	
	initial	after 9 h
pNirb+ 6.0 % MgO (II)	23	12
2.5% Ni/(pNirb+ 6.0 % MgO) (I)*)	45	22
2.3% Ni/(pNirb+ 9.0 % MgO) (I)	43	30
2.3% Ni/(pNirb+ 9.0 % MgO) (II)	53	42
4.0% Ni/(pNirb+ 11.0 % MgO) (II)	78	64

*) The catalyst was prepared by supporting of nickel on support via the impregnation with $Ni(NO_3)_2$ solution.

Figure 2 shows the methane conversion versus time-on-stream in the dry reforming of CH_4 at the various CO_2/CH_4 ratio over the catalysts reduced in H_2.

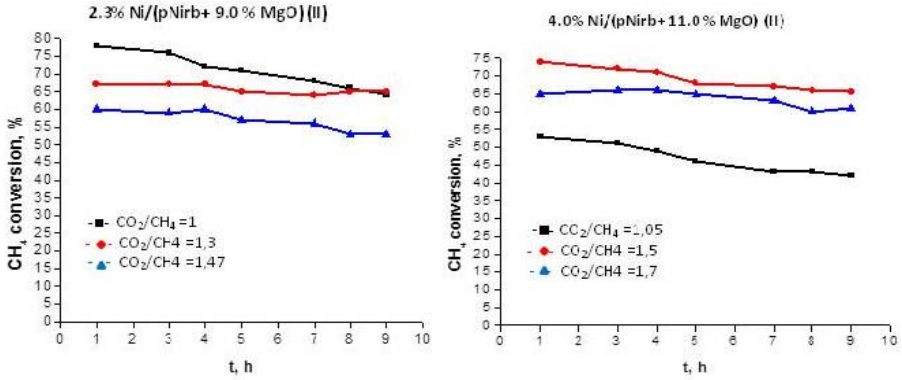

Fig.2. Methane conversion versus time-on-stream in the dry reforming of CH_4 over the reduced nickel catalysts (p = 1 atm, T = 750°C, m_{cat} = 0,40 g, V = 25 l/h) at various CO_2/CH_4 ratios.

The catalytic tests of supported nickel catalysts showed that for the catalyst 2.3% Ni/(pNirb+ 9.0 % MgO) (II) at CO_2/CH_4 ratio = 1,3 in the reaction mixture and for the catalyst 4.0% Ni/(pNirb+ 11.0 % MgO) (II) at CO_2/CH_4 ratio = 1,7 the conversion of methane was stable during the test period (Fig.2). In agree with HRTEM data some part of dispersed nickel particles (3-10 nm) epitaxually bound with MgO underlayer were in the nickel catalysts tested in the dry reforming of CH_4. It should be noted that in the catalyst 4.0% Ni/(pNirb+ 11.0 % MgO) (II) at CO_2/CH_4 ratio = 1,7 some nickel particles were extracted from the MgO underlayer and their sintering took place in the supported nickel catalysts tested in reaction.

TEM data show that carbon filaments (d ~ 50 nm) were found in the supported nickel catalysts tested in the reaction.

4 Conclusions

The nickel catalyst based on porous nickel ribbon were prepared and studied in the dry reforming of methane. At the CO_2/CH_4 ratio = 1,3 for the catalyst 2.3% Ni/(pNirb+ 9.0 % MgO) (II) and at CO_2/CH_4 ratio = 1,7 for the catalyst 4.0% Ni/(pNirb+ 11.0 % MgO) (II) in the reaction mixture the activity was stable.

Keywords: *in situ* XAS experiments, combined spectroscopies

1 Introduction

A proper understanding of structural end electronical chracteristic of the active sites plays a central role in the design and discovery of novel catalysts. To achieve this goal it is important to be able to measure the materials under the same in-situ conditions of temperature, pressure, and atmosphere that they would experience in their performance environments. In order to facilitate such experiments, B18 beamline in collaboration with Industrial Liaison Group and Research Complex at Harwell has developed several sample environments that allow the remote control of temperature and gas flow through the sample, monitoring of the reaction products and the combination of several characterization techniques combined with X-ray Absorption Spectroscopy measurements.

2 Experimental/methodology

The element-selectivity of XAS and the capability to obtain information about both electronical configuration (XANES) and atomic structure in short range (EXAFS) make this technique a valuable tool to investigate the properties of catalysts. Furthermore the time resolution of few seconds that can be achieved with continuous scanning of the monochromator in quick EXAFS mode, allows following oxidation state or coordination geometry changes during a chemical reaction. For this reason a big effort has been put to develop sample environments that allow to perform reactions and a contemporaneous data acquisition and to control the reaction parameters remotely. Currently several options are available: a capillary reactor with hot air blower to measure powders, furnaces to measure sample in pellet form and liquid cells with cartridge heating to measure solutions. Furthermore a gas mixing rig setup formed by 8 mass flow controllers and 8-port valves provides the possibility to flow through the samples complex gas mixtures and to quickly alternate between oxidizing and reducing conditions by means of a fast switching valve. Finally a mass spectrometer can be connected to the outlet to monitor the reaction products coming out of the experimental cell.

Moreover, experience shows that considerable value is added to the XAS experiment if it is possible to combine techniques to obtain complementary informations. Therefore a mythen detector is available to measure x-ray diffraction at the same time increasing the understanding on the long range order in the sample and monitoring the changes between different crystalline or amorphous phases and the formation/destruction of intermediate species during the reaction. Recently In collaboration with the Catalysis Hub the B18 team has successfully incorporated the first Raman/XAS and DRIFTS/XAS systems on the beamline. Thus it is now possible to combine the electronical and structural information provided by XAS with vibrational information achievable by Infrared or Raman Spetroscopy which can play a main role in understanding the interactions of the gases with the material.

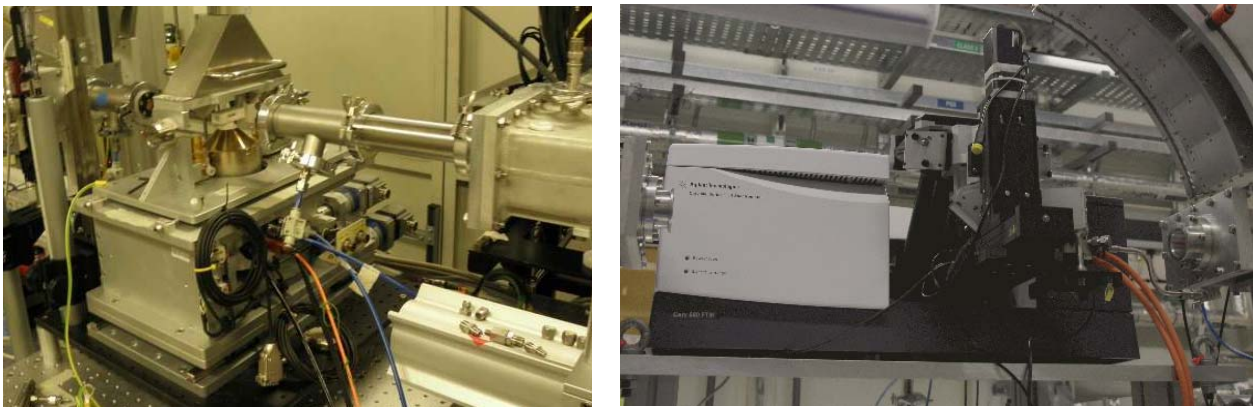

Fig. 1. a) Capillary reactor with hot air blower, on the B18 beamline b) FTIR spectrometer with Da Vinci arm and Harrick DRIFTS cell attached, on the B18 beamline.

3 Conclusions

B18 beamline at Diamond Light Source have recently developed in collaboration with Industrial Liaison Group and Research Complex at Harwell sample environments which allow the in situ study of catalysts and combination of X-ray absorption spectroscopy, diffraction and other spectroscopic techniques such as IR and Raman. B18 sum up the time resolution (in the order of few seconds) provided by quick-EXAFS scanning mode with the integrated control of catalytic conditions in capillary reactor, furnaces or heated liquid cells. A gas mixing rig setup is available to allow introducing complex gas mixtures in situ and a Mass Spectrometer to monitor the reaction products.

Keywords: palladium, propylene, oxidation, temperature hysteresis

1 Introduction

Palladium is used in various catalytic applications because of its high intrinsic activity and its relatively low price compared with other noble metals. In particular, Pd-based catalysts are used for the purification of automotive exhaust gases that contain significant amounts of unburned fuel and other hydrocarbons formed by pyrolysis. Many studies have been devoted to the combustion of hydrocarbons over Pd-based catalysts [1-2]. However, the mechanism for the oxidation of hydrocarbons over palladium is still not fully understood. The mechanism is complex and the catalyst activity and selectivity are influenced by variations in the process pressure, temperature, and the gas mixture composition. Moreover, under oxidizing conditions, Pd-based catalysts can exhibit an interesting dynamic behavior, including hysteresis phenomena, self-sustained rate oscillations, spatial pattern formation, and deterministic chaos; a fast deactivation of palladium is frequently observed as well [4-13]. It is obvious that in all these cases a change in the chemical state of palladium determines the catalytic performance, causing the critical phenomena or catalyst deactivation. To develop more-effective Pd-based catalysts with a high activity in a wide temperature range, the reasons that cause these phenomena have to be understood.

2 Experimental/methodology

The TPRS and XPS experiments were carried out at the synchrotron radiation facility, BESSY II (Berlin, Germany) using the ISISS (Innovative Station for *In Situ* Spectroscopy) beamline. The experimental station was described in detail elsewhere [14]. Its key feature is a differentially pumped electrostatic lens system of a hemispherical analyzer, which allows analysis of the sample in the low mbar pressure region.

3 Results and discussion

During TPRS studies the presence of thermal hysteresis has been revealed. TPRS profiles obtained during the heating exhibit peaks of CO, CO_2, H_2 and H_2O formation with a maximum near 700 K, while during the cooling peaks are absent. According to *in situ* XPS data, the peaks of products of complete and partial oxidation of methane during the heating is determined by the formation of a surface layer of PdO. This is confirmed by the appearance in the spectra of Pd$3d_{5/2}$ intense peak at 336.65 eV at 673 K, the intensity of which increases significantly after heating to 723 K. Further heating to 823 K leads to the recovery of palladium, the surface of the Pd(111) is partially covered by a layer of surface oxide Pd_5O_4 characterized by the Pd$3d_{5/2}$ peak at 335.55 eV. Subsequent cooling to 723 K does not lead to the formation of PdO, and as a result, the cooling curve in the TPR spectra has no peaks at all. It is important to note that the

activity of PdO in a small excess of oxygen (CH_4:O_2 = 1:2.5) at 700 K exceeds the activity of metallic palladium, partially or completely covered by the surface oxide Pd_5O_4 at 850 K. This fact clearly indicates that the PdO is more active in the reaction of complete oxidation of methane than palladium in metallic state. The obtained data are in good correlation with earlier observed oxide formation during methane oxidation [15, 16]

Oxidation of propane. The influence of the reaction media resulted in a significant surface reconstruction of palladium: before starting the experiments, the surface of the single crystal was mirrored, after heating in the reaction mixture, the surface became opaque due to significant changes in roughness. In accordance with the TPRS experiments, both in excess and in deficiency of oxygen H_2, CO, H_2O and CO_2 were observed as the products of reaction. Propylene, acetone, acetaldehyde and acetic acid were not observed. TPR spectra for the ratio C_3H_8:O_2 = 1:5 and 1:25 show that the reaction starts at 650-700 K, the main product is CO. In the excess of oxygen the conversion of propane decreases, and the release of H_2 significantly reduces, being oxidized to H_2O. TPRS data and XPS spectra obtained in the step-wise heating in the reaction media at C_3H_8:O_2 =1:1 show that the reaction starts on PdO covered surface, which reduces with increasing temperature to Pd_5O_4.

4 Conclusions

In the reactions of oxidation of saturated hydrocarbons (methane and propane) on Pd(111) it was found that the active component of the catalyst is a three-dimensional palladium oxide PdO, which formation is a prerequisite for activation of the catalyst.

Keywords: cross-coupling, copper, oxide, catalyst, morphology, polymeric, complex

1 Introduction

Methods of C-S bond formation are valuable tools in the synthetic chemistry. Copper oxide-mediated Ullmann reaction is one of the important and wide spread technique for this purpose [1, 2]. Despite the huge number of known protocols in the field of Cu_2O- or CuO-catalyzed C-S cross-coupling reactions still it is not obvious what is exactly happened with copper oxides during catalytic reaction.

2 Experimental/methodology

Detailed NMR, ESI-MS, FE-SEM, cryo-SEM, DLS, XRD patterns studies were carried out to evaluate the role of the copper center, its oxidation state and arrangement. Ligand-free copper oxides (I, II)-catalyzed reactions of thiophenol with 4-iodotoluene were chosen as a model reactions.

3 Results and discussion

In order to study the impact of the size and shape of CuO and Cu_2O in the coupling reaction a set of copper oxide nanoparticles was synthesised. There is no size and morphology influence of catalyst on sulfides yields. It is worth to note the CuO and Cu_2O surface dramatically changes after catalysis. It was revealed Ph-SH-nucleophile has strongly effected on the shape of catalyst. The treatment of copper oxides with thiophenol results in formation of polymeric homoleptic copper (I) phenylthiolate $[CuSPh]_n$ (figure 1) [3]. Use of stoichiometric amount of $[CuSPh]_n$ and 4-iodotoluen leads to formation of desirable product of C-S cross-coupling. Moreover polymeric copper(I) complex shows catalytic activity.

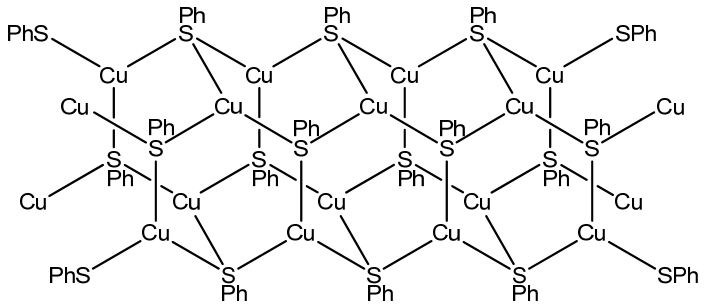

Fig. 1. Schematic drawing of polymeric complex $[CuSPh]_n$.

4 Conclusions

Indeed, whatever the copper source Cu(I) or Cu(II), copper (I) complex is the active catalyst [4]. Herein we demonstrate that CuO and Cu_2O are the precursor of Cu(I)-thiolate active complex in ligand-free C-S cross-coupling reaction.

Keywords: faujasite, zeolite, extraframework, Al, acidity, H/D exchange, NMR

1 Introduction

Zeolite Y has the faujasite topology and is widely used as an acid catalyst for hydrocracking processes in oil refineries. However, because of the high concentration of aluminium in the lattice of as-synthesized zeolite Y, it exhibits only weak acidity and limited hydrothermal stability. Both the acidity and hydrothermal stability of such zeolites can be improved by dealumination. Ultrastable zeolites Y (USY) are typically prepared by steam calcination of the low-silica NH_4Y zeolite at high temperature. During this process, part of the Al atoms (FAl) are extracted from their framework positions. The intrinsic Brønsted acidity of the resulting dealuminated zeolite is usually higher than that of the parent material because of the increased concentration of isolated aluminum framework (AlF) atoms. The Al atoms extracted from the framework are part of the extraframework aluminium (EFAl) phase. These species are thought to strongly influence the acidity and reactivity of steam-calcined faujasite zeolites.

2 Experimental/methodology

Commercial Steam-calcined zeolite EFAl (USY) and free-EFAl dealuminated zeolite (AHFSY) was used in this study. Dealuminated Y zeolite, AHFSY was prepared by treatment with $(NH_4)_2SiF_6$ (AHFSY). The USY and AHFSY zeolites were first heated to 500 ^oC at a heating rate of 2 ^oC/min and then kept at this temperature for dehydration overnight at a total pressure of less than 10-5 mbar. The dehydrated samples were deuterated by exposure to 10 mbar D_2O gas for 30 min at 150 ^oC, followed by evacuation. This procedure was repeated two times and, finally, the samples were evacuated at 450 ^oC overnight.

Benzene (C_6H_6) H/D exchange was done by loading the deuterated D-USY and D-AHFSY in a 4-mm zirconia NMR rotor in a glove box under N_2 atmosphere. The rotor was placed in a glass tube, connected to the manifold setup and evacuated for 2 hours. Thereafter, the tube containing the sample rotor was cooled to -40 ^oC and the sample was brought in contact with 4 mbar benzene gas for 1 min. The rotor was then tightly closed with a boron nitrate cap and transferred, under low temperature conditions, to the precooled (-30 ^oC) NMR probe.

3 Results and discussion

The effect of extraframework Al (EFAl) species on the Brønsted acid sites in steam-calcined USY zeolite was studied by in situ H/D exchange between benzene and deuterated zeolite using NMR spectroscopy. The spectroscopic results in combination with model periodic density functional theory calculations indicate that EFAl species are preferentially stabilized in the faujasite sodalite cages in the form of multinuclear oxygenated and hydroxylated cationic Al

clusters. No direct interaction between adsorbed benzene and EFAl is observed. The H/D exchange reaction involves only the zeolite Brønsted acid sites (BAS), whereas the AlOH and SiOH moieties due to zeolite defects remain intact upon contacting with benzene. A much higher reactivity of BAS is observed for the EFAl-containing USY zeolite. An important finding is that in the absence of EFAl species NH_4Y zeoilite treated by ammonium hexafluorosilicate (AHFS-Y), all BAS are equally reactive towards C_6H_6, whereas in the case of USY zeolite, the rates of H/D exchange with the sodalite cage hydroxyl groups is much higher than with the accessible supercage BAS Fig.1. This evidences the selective enhancement of only a fraction of zeolitic BAS neighbouring the Lewis acidic extraframework Al species stabilized inside faujasite sodalite cages.

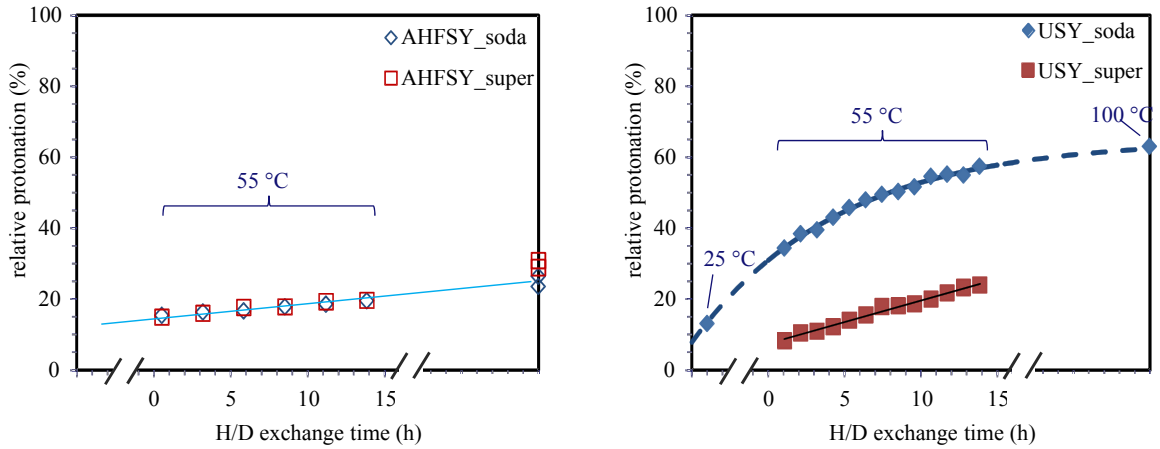

Figure 1. Plots of the relative protonation of hydroxyl sites in AHFSY (left) and USY (right) proton NMR spectra, recorded at 55 °C during H/D exchange of D-USY with C_6H_6.

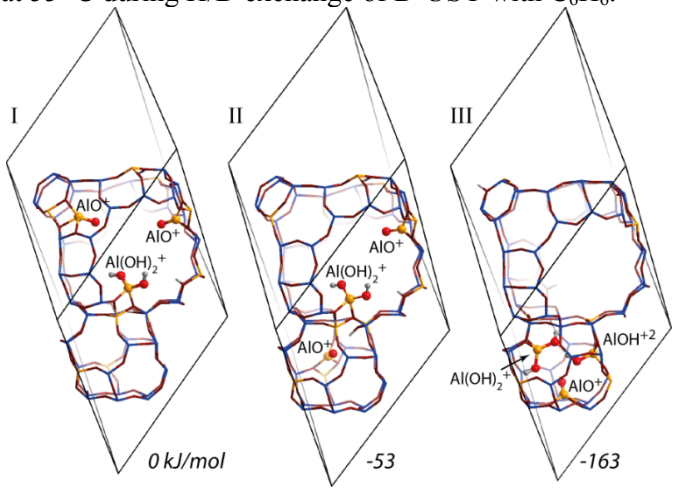

Figure 2. Optimized structures of HUSY-8 models with all EFAl species present as isolated mononuclear cations located in (I) faujasite supercage only, (II) both sodalite cage and supercage and (III) exclusively faujasite sodalite cage. Relative stabilities (italic) are given for all structures in kJ/mol with respect to the model (I) having all isolated mononuclear EFAl species stabilized exclusively at the supercage cation sites.

Keywords: heteropolyacid, mesoporous, silica, isopropanol decomposition

1 Introduction

Molybdenum and vanadium containing heteropolyacids (HPAs), $H_{3+x}PMo_{12-x}V_xO_{40}$ (x =0-3) are widely known to possess a strong Brönsted acidity and redox ability. The substitution of one or more molybdenum atoms in the primary structure of the Keggin anion by vanadium atoms leads to an enhancement of the oxidation potential of the HPA. However, owing to their small surface area (<10 m^2/g), their catalytic performances are limited. Many studies have been carried to overcome this drawback by supporting HPAs on suitable mesoporous materials (HMS, MCM-41, SBA-15 …). Such compounds offer high thermal stability, large surface area and high pore volume.

The objective of this work is to support 30 wt.% $H_{3+x}PMo_{12-x}V_xO_{40}$ (x=0-3) Keggin-type heteropolyacids on mesoporous HMS silicate material and evaluate their catalytic properties in isopropanol decomposition reaction.

2 Experimental

30wt.% $H_{3+x}PMo_{12-x}V_xO_{40}$ (x=0-3) HPAs were supported on HMS by dry impregnation method. Several physico-chemical techniques(elemental analysis, X-ray diffraction, transmission and diffuse reflectance (DR) FT-IR, Raman and X-ray photoelectron spectroscopies, nitrogen physisorption, thermal analysis (TG-DTA) and scanning electron microscopy (SEM)) were used to characterise fresh catalysts. The catalytic performances of supported HPAs were compared to those of pure one and tested in the isopropanol decomposition reaction to propene, diisopropylether and acetone products at 75°C and atmospheric pressure.

3 Results and discussion

The physico-chemical characterization of the supported HPAs showed mainly undegraded primary Keggin structure and high dispersion of heteropolyacids on the HMS surface. The BET surface area (S_{BET}) and the pore volume (Vp) of HMS decrease strongly in the presence of HPAs. The TG-DTA analysis showed that the obtained mesostructures HPA-HMS have a higher thermal stability than the HPA bulk. $H_{3+x}PMo_{12-x}V_xO_{40}$ heteropolyacids with x=0-3 supported on mesoporous HMS appear to be more active than $H_{3+x}PMo_{12-x}V_xO_{40}$ on bulk.

Otherwise, the substitution of molybdenum by vanadium atoms gives higher activity in isopropanol decomposition to propene, diisopropylether and acetone reaction especially for $H_4PMo_{11}V_1O_{40}$.

Keywords: aluminium, self-organization, acidity, DFT

1 Introduction

Zeolite Y with faujasite topology is widely used as acidic catalyst for fluid catalytic cracking (FCC) and hydrocracking in the oil refinery [1]. The catalytic activity of zeolite Y strongly depends on its Brønsted acidity. However, the as-synthesized faujasite with high Al concentration in its lattice framework only shows low Brønsted acidity and stability. Further steaming calcination to form extraframework Al-containing (EFAL) species in the zeolite matrix can significantly improve its catalytic activity and hydrothermal stability [2]. The enhancement of Brønsted acidity of the steamed zeolite is often associated with the synergy between the EFAL species and neighbouring Brønsted acid sites (BAS) in zeolite pores [3]. However, the nature of these EFAL species and their intrinsic interaction mechanism with BAS are still not understood well yet. In this study, the structure, stability and location of EFALs in faujasite zeolite have been thoroughly investigated by a comprehensive periodic DFT method combined with *ab initio* thermodynamic analysis. The dominated EFAL species at the experimental conditions of catalyst activation were identified based on these investigations.

2 Methodology

DFT calculations were performed using VASP. The PBE functional and dispersion-corrected DFT-D2 was used. The electron-ion interactions were described with projected augmented waves method. The Brillouin zone sampling was restricted to the Γ point. The energy cut-off was set to 500 eV. The EFAL was introduced in different cationic sites, and full geometry optimizations were performed with fixed cell parameters. The convergence was assumed to be reached when the forces on each atom were below 0.05 eV Å-1.

3 Results and discussion

The mononuclear EFALs may potentially be present in faujasite matrix as cationic species, e.g. $[Al(OH)_2]^+$, $[AlO]^+$, $[Al(OH)]^{2+}$, and Al^{3+} neutral complexes e.g. $Al(OH)_3(H_2O)_3$, $Al(OH)_3$, and AlOOH. The neutral EFALs show no significant preference towards specific location in faujasite structure. For the cationic complexes, a direct interaction with lattice charge-compensating $[AlO_2]^-$ units is necessary for their high stability. The stability of $[Al(OH)_2]^+$ interactive with single framework $[AlO_2]^-$ does not depend on Al distribution in the framework. The cationic species bearing a higher formal charge, e.g. $[Al(OH)]^{2+}$ and Al^{3+} show a strong preference for the stabilization in a supercage SII site.

We further considered the self-organization of mononuclear EFAL to multinuclear clusters (Figure 1). The assembly of two or three separated $[Al(OH)_2]^+$ into $[Al_2O_4H_4]^{2+}$ or $[Al_3O_6H_6]^{3+}$ is strongly thermodynamically favored (ΔE = -87 and -79 kJ/mol, respectively). The self-organization of AlOOH into $[Al_4O_6]$ is also highly exothermic (ΔE = -175 kJ/mol). Although the binuclear EFAL complexes shows similar stability at faujasite's supercage and sodalite cage, a strong preference for the migration into small sodalite cages has been identified for larger tri-

and tetranuclear cations. The $[Al_2O_4H_4]^{2+}$, $[Al_3O_6H_6]^{3+}$ and $[Al_4O_6]$ clusters can be transformed to other types of multinuclear clusters by dehydration and proton transfer processes with the assistance of vicinal BAS. The dehydration is always strongly endothermic, while the energetics of proton transfer reactions is controlled by the electronic properties of the target EFAL.

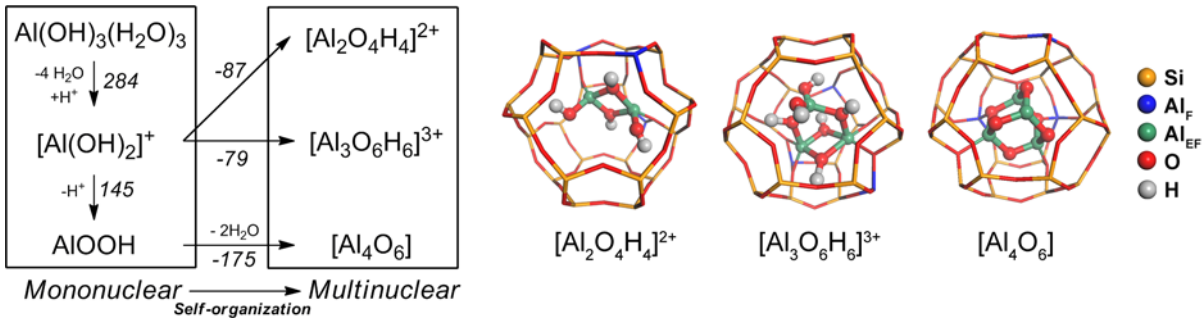

Figure 1. Interconversion of EFALs in faujasite zeolite.

To clarify the effect of temperature and the presence of water on the stability of EFALs, a statistical thermodynamic method is used. Under the typical experimental condition of hydrothermal treatment (800 K, 1 atm), the trinuclear $[Al_3O_4H_4]^{4+}$ stabilized in sodalite cage shows the highest stability. However, the reaction free energy differences among different multinuclear clusters are not very significant which indicates their stabilities are very close and different multinuclear EFALs can coexist or interconvert with each other in the system. The multinuclear EFALs with large cluster size show strong preference for the sodalite cage, which provides a better confined environment for the stabilization of these clusters due to its smaller void compared to the supercage. It is proposed that the multinuclear oxygenated and hydroxylated cationic clusters located in sodalite cage are the dominant EFAL species in faujasite zeolite. These multinuclear EFAL species may act as hubs for the proton transfer and thereby tune the charge equilibrium and modify the acidity and reactivity of zeolite.

4 Conclusions

The structural property and stability of EFALs in faujasite zeolite are studied by periodic DFT calculations combined with *ab initio* thermodynamics. The results point to a strong preference of mononuclear EFALs towards self-organization into multinuclear species. This effect is shown to be a general phenomenon for a wider range of oxygenated extraframework cations and zeolite topologies. The resulting tri- and tetra-nuclear clusters are preferentially located in sodalite cages of the faujasite structure. A*b initio* thermodynamic analysis points to the predominant formation of such species under experimentally relevant conditions. It is proposed that multinuclear oxygenated and hydroxylated EFALs located in sodalite cage are dominant species in faujasite zeolite after high-temperature steaming treatment.

Preparation and Characterization of Sr, Ca and Mg Doped Ceria Electrolyte for Solid Oxide Fuel Cells

Çalış B., Özdemir H., Sarıboğa V., Öksüzömer M.A.F.*

Department of Chemical Engineering, Istanbul University, Istanbul, Turkey

* fufu@istanbul.edu.tr

Keywords: fuel cell, sofc, electrolyte, doped-CeO_2

1 Introduction

Fuel cell systems are the fundamental subject of energy technologies which provide most important part of energy requirement of the world [1]. Amongst them, polymer electrolyte membran (PEM) and solid oxide (SOFC) fuel cells have come forth due to their advantages []. In these fuel cells, the most important part is electrolytes which effects fuel cell performance substantially. The most important problem in SOFC systems is the requirement of high temperatures (>800°C) in order to obtain high ionic conductivity with traditional electrolyte materials (i.e. 8YSZ) [2]. Thus, development of new electrolyte materials those give high ionic conductivity with stable performance at lower temperatures than 800°C is highly important. It is known that rare earth metals (Sm, Gd, Nd) doped CeO_2 structures show superior ionic conductivity, but they have a high cost [3]. Hence in this study cheap, readily accessible and which may be stable at lower temperatures Mg, Sr and Ca doped CeO_2 electrolytes were prepared and characterized. These compounds were prepared by citrate–nitrate combustion method and characterized by using XRD, SEM and impedance spectroscopy.

2 Experimental/methodology

Different amounts of Sr, Ca and Mg included cerium oxide electrolyte synthesized by using citrate nitrate combustion method. Starting chemicals used for the synthesis of powders were ceria oxide, magnesium nitrate, calcium nitrat, strontium nitrate, and citric acid. The appropriate amounts of cerium nitrate hexa hydrate, metal nitrates and deionized water were dissolved in 50 ml aqueous solution in which total metal ion concentration is 1 M. The solution was vigorously mixed and vaporized on an hot plate at 70°C, whereupon it became a transparent gel. The gel was heated until it turned into a black viscous mass, which on continued heating burned due to a vigorous exothermic reaction. Pale-yellowish ashes obtained after combustion were treated at 250°C. Obtained powders were calcined at 1400°C for 5h. The product was pressed into pellets and finally the pellets were sintered at 1400°C for 10h.

3 Results and discussion

In pre-experiments of this study, at two different concentrations (%5 and %10) of Sr doped ceria electrolyte were prepared. According to XRD results(Figure 1), no impurity peaks were observed in x = 0.05, and it is clear that there is precipitation of a second phase SrO in addition to the fluorite phase for composition with x> 0.10, in the present work. Therefore, future studies will focus on 0.05<x<0.1 Sr content.

Figure 2 shows SEM photographs of the sintered samples 1400°C. The surface photographs of electrolyte pellets sintered at 1400 °C show good densification, as shown in Figure 2 (a) and (b).

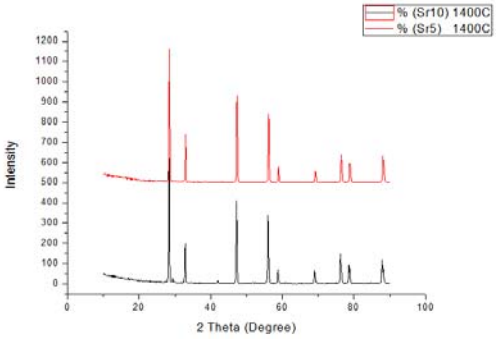

Figure 1. XRD patterns of the % 5 and % 10 Sr doped ceria

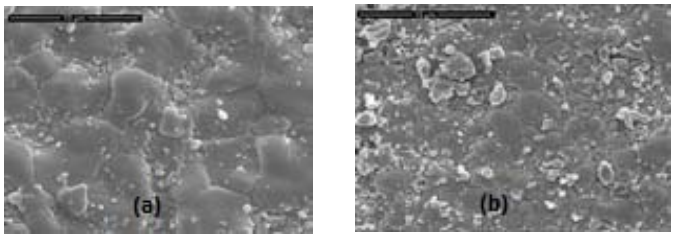

Figure 2. Surface SEM images of electrolyte sample pellets, sintered at different molar ratio of Sr (a) %5 (b) %10.

No pores are present on the surface of the pellets, which is in accordance with the relative density of the sintered pellets and beneficial for the oxygen ion transportation of the electrolyte

The O^{2-} ionic conductivities of two samples were measured by electrochemical impedance spectroscopy technique. For %5 Sr doped ceria 2.85 S m^{-1} and for %10 Sr doped ceria1.4 S m^{-1} conductivities were measured at 800 ^{o}C. Since %10 Sr doped ceria sample includes SrO insulator phase (shown in XRD pattern) which was not dissolved in ceria main phase, the conductivity of %5 Sr doped ceria shows almost two times better conductivity value than %10 Sr doped ceria. Also, %5 Sr doped ceria shows higher performance than %10 Gd doped ceria materials when compared our previous studies [8] .

4 Conclusions

In preliminary studies, the resulting conductivity results are promising. The same experiment will be done for Ca and Mg electrolytes. We will be found that CaO, MgO, SrO could not dissolve into the ceria matrix after the exact value. And conductivity of the electrolyte is measured at the exact value. Other conclusions are going to be presented at EuropaCat XII.

Keywords: X-ray diffraction, synchrotron, radiation, heterogeneous, catalyst, structure, phase, composition

1 Introduction

The X-ray diffraction (XRD) technique seems to be main source of information on the atomic structure and phase composition of functional materials, including heterogeneous catalysts. In contrast to the conventional XRD that describes structure under static conditions, the dynamical studies of the phase and structure transformations under high temperature and reaction environment look much more attractive. Time resolution of these experiments which are usually carried out with synchrotron radiation (SR XRD) rises to submicrosecond range. Most of catalytic processes have relatively low rates and one surely doesn't need such an excellent resolution. The principal advantage of SR XRD for heterogeneous catalysis is the ability to detect structure evolution of catalyst *In Situ* within the reactor cell under reaction conditions [1]. Equipping the reactor cell with gas analyzer on the inlet and outlet of the cell one can register also activity and selectivity of catalyst along with its structure and phase composition. This is an approach to *Operando* mode. However, difficulties may arise on this way.

2 Experimental

At Siberian Synchrotron and Teraherz Radiation Center XRD experiments are executed on five beamlines, one of them is mostly dedicated to studies of catalysts and catalytic processes. The beamline consists of fixed energy monochromator with set of Si and Ge crystals which determine working photon energies, and position sensitive X-ray detector providing simultaneous registration of XRD patterns in 2Θ angular range of 30°. High temperature reactor cell mounted on the diffractometer allows the experiments with oxidation or reduction environment over the sample at temperature range from room up to 900°C and gas pressure from 0.1 mbar to 10 bars to be performed.

To analyze the gas phase composition and therefore to estimate the efficiency of catalyst the quadrupole mass-spectrometer SRS UGA-100 is attached to outlet port of reactor cell. The instrumental configuration described has been applied for several experiments including self-oscillations of the reaction rate in oxidation of methane over metal catalysts, growth of nitrogen doped carbon nanofibers from ethylene-ammonia mixture over Ni-Cu alloy catalyst, etc. The results of these attempts with respect to *Operando* mode realization are considered in the report.

3 Results and discussion

Transformation of *In Situ* to *Operando* experimental mode is intended to simulate within the laboratory reactor cell the behavior of catalyst under real working conditions including the efficiency of catalyst with respect to different gas parameters (reaction mixture composition, gas pressure, gas flow rate, etc). The first experiments with *Operando* mode detected good correlations of phase composition of catalyst with gas phase content of product. Nevertheless, it

is hardly possible to estimate the conversion of initial reagents since the products are strongly diluted with initial reagents at the outlet port of reactor. It may be caused by cell volume which is much greater then sample volume, and even the conversion is high, the portion of target product in mixture is rather low whereas gas analyzer registers total ratio of components. Although the molar amount of gas and solid components are of same order of magnitude, small surface area of solid makes total conversion to be small.

The arrangement of gas flow to penetrate through the sample should be a solution in this case. It is good idea for powder sample but looks impossible when the sample is a piece of foil. Another way is to develop a reactor cell with small volume but problems may arise with uniform heating of sample and with cell windows that should be heat, pressure and reaction medium resistant and transparent for X-rays. Perhaps there should be more permanent solution.

4 Conclusion

Finally, simple attachment of gas analyzer to reactor cell isn't enough for *Operando* mode to be realized. Besides that, the first experiments on SR XRD applying *Operando* mode have demonstrated that it seems hardly possible to use any universal reactor cell for different tasks as it is widely spread for *In Situ* experiments. To succeed in *Operando* studies one should create for individual task an individual cell, which however could be suitable for solving of other problems as well.

Keywords: CO oxidation, preferential CO oxidation, *operando* XAS, *operando* NAP-XPS

1 Introduction

In recent years much attention has been paid to the development of catalysts for CO oxidation and preferential CO oxidation (PROX) that are able to lower the temperature required for CO oxidation. In particular, Co_3O_4 has turned out to be a promising catalyst[1]. Interestingly, its combination with noble metals or other reducible oxides, e.g. CeO_2, has enhanced the catalytic activity [2-4]. However, the origin of this enhancement as well as the nature of the active sites and reaction mechanisms is not fully understood, mainly because current understanding of this reaction system is mostly based only on ex situ analyses of the catalysts and kinetic experiments[1,4]. Therefore, comprehensive in situ/operando studies on the structural and electronic changes of cobalt oxide and promoted cobalt oxide are crucial.

In the present work, we combined operando infrared spectroscopy (IR), in situ near ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) and operando X-ray absorption spectroscopy (XAS) to study the structural and electronic changes of catalysts with the aim to understand the promotional effect of PdO and CeO_2 on the activity of Co_3O_4 in the CO oxidation and PROX, the nature of the active sites of the catalysts and the reaction pathways.

2 Experimental/methodology

Surface sites of the catalysts, i.e., 10 wt% CeO_2 on Co_3O_4, 2 wt% of PdO on Co_3O_4, and Co_3O_4, were investigated by operando IR spectroscopy and in situ NAP-XPS. In situ NAP-XPS was performed at the ISISS beamline at BESSY II in Berlin, Germany. The O1s, Co2p, C1s, Ce3d, Pd3d core-levels were recorded under working conditions; the total pressure was kept at 0.50 mbar. Operando XAS at the Co K edge and the Ce L_3 edge were performed at the l811 beamline at the MAX-lab II in Lund, Sweden. The temperature-dependent CO oxidation, PROX and the steady-state experiments were also performed in a fixed-bed flow reactor and an operand IR flow cell.

3 Results and discussion

Our operando IR spectroscopy results show that CO does not adsorb on Co^{3+} and Co^{2+} ions of Co_3O_4 catalyst but forms surface carbonate species (bidentate and monodentate), while during CO oxidation (CO/O_2=1/2) and PROX ($CO/O_2/H_2$=1/1/50) the amount of the carbonates decreases. We detected carbonate formation upon exposure of Co_3O_4 to CO also in NAP-XPS measurements (C1s at 288.2 eV). In addition, we observed elementary carbon at the surface (C1s binding energy at 284.7 eV) which indicates that Co_3O_4 dissociates CO already at RT ($2CO \rightarrow CO_2 + C$) depositing carbon at the surface. Interestingly, no significant reduction of Co_3O_4 was observed at RT. Upon heating the Co_3O_4 in CO atmosphere to 200 °C the elementary carbon

grows, and Co_3O_4 starts to get reduced (Fig.1). During the CO oxidation reaction (CO/O_2=1/2) over Co_3O_4 only a small amount of carbonates and carbon is observed between RT and 150 °C with NAP-XPS. Thus, a possible mechanism of CO oxidation proceeds via CO disproportionation or carbonate formation. The deactivation of Co_3O_4 at RT seems to be rather related to elementary carbon deposition than to the reduction of Co^{3+} to Co^{2+}. Interestingly, during PROX (CO/O_2/He=1/1/12) only slight cobalt reduction was observed even at 300 °C with in situ NAP-XPS, and formation of carbonates and elementary C likewise to CO oxidation on Co_3O_4 was detected. The low reducibility of Co_3O_4 in PROX reaction compared to pure H_2 that was revealed by in situ NAP-XPS and operando-XAS might exclude the Mars-van-Krevelen mechanism (redox mechanism) for PROX on the Co_3O_4.

Promotion of Co_3O_4 with PdO decreases the temperature of CO oxidation for PdO/Co_3O_4 ($T_{50\%}$ = 74 °C) compared to Co_3O_4 ($T_{50\%}$ = 105 °C). According to our in situ NAP-XPS experiments, Pd^{4+} species beside Pd^{2+} are present under reaction conditions (CO/O_2=1/2). In the C1s region we observed elementary carbon (284.7 eV) and carbonates (288.2 eV) that indicates CO dissociation during CO oxidation on PdO/Co_3O_4. Operando FTIR shows that on the PdO/Co_3O_4 a surprisingly small amount of CO was adsorbed to Pd upon CO exposure at RT and did not grow further with increasing temperature, whereas no CO peaks at all were observed during the reaction with carbonates being the only surface species present. Promotion of Co_3O_4 with CeO_2 increases the activity in PROX compared to pure Co_3O_4; selective oxidation of CO to CO_2 starts at 100 °C, when the reduction of Ce^{4+} to Ce^{3+} is observed by the Ce 3d XPS.

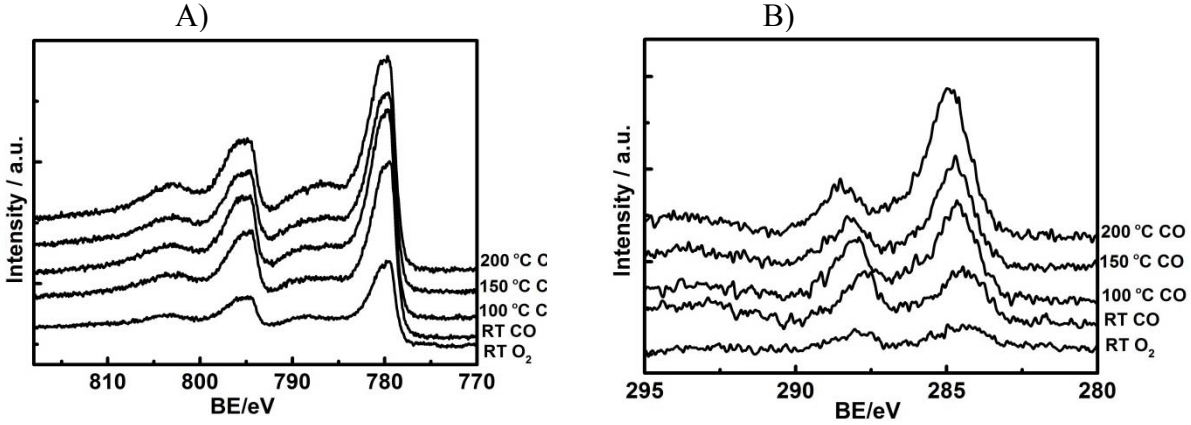

Fig. 1. XPS spectra of Co_3O_4 during CO adsorption: A) Co2p (hv=1015 eV), B) C1s (hv=465 eV)

4 Conclusions

Promotion of Co_3O_4 with PdO and CeO_2 improves the catalytic activity of cobalt oxide catalyst by enhancing CO adsorption and O_2 activation. A possible mechanism of CO (preferential) oxidation proceeds via CO disproportionation or carbonate formation.

1 Introduction

Decentralized supply of energy from renewable sources strongly relies on the efficient conversion and storage of energy in different forms, for example, in the form of H_2 by electrolysis of water and recovery of the energy during the reverse process in fuel cells, and in rechargeable metal air batteries. While the reversibility of the electrochemical reactions involving H_2 is efficient, the main challenge lies with improving the efficiency of the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER). Recently, transition metal-based catalysts such as Mn and Co oxides have attracted enormous interest as low-cost alternatives to noble-metal catalysts capable of catalyzing both the ORR and the OER. However, these oxides have high electrical resistance, which fortunately can be mitigated by the use of conductive additives such as graphene and carbon nanotubes (CNTs). In particular, N-doped carbon materials have been widely used not only to promote electron transfer but also to serve as complementary sites for the ORR thereby enhancing the ability of the materials to electrocatalyze both the ORR and the OER.

In this work, we demonstrate the synthesis of spinel Mn-Co oxide nanoparticles partially embedded in N-doped CNTs (NCNTs), which were used as bifunctional electrocatalysts for both ORR and OER under alkaline conditions. The synthesis was achieved by catalytic growth of NCNTs using Co-Mn oxides as catalyst and subsequent oxidative treatments.

2 Experimental

The synthesis of the spinel Mn-Co catalysts partially embedded in NCNTs was achieved by catalytic growth of NCNTs followed by oxidative treatment in the gas phase. Either Co-Mn-Mg-Al mixed oxide or Co-Mn mixed oxide were used as catalysts for the NCNT growth with pyridine or ethylenediamine as carbon and nitrogen precursors. The diameter of the obtained NCNTs ranges from 10 to 20 nm mostly. The catalyst nanoparticles exist in two different forms, either at the tip of the NCNTs or enclosed inside the NCNTs, where the nanoparticles are intimately in contact with carbon, or scattered over the NCNT agglomerates without intimate contact with the carbon surface due to explosion-like fragmentation of the initial catalyst particles during the rapid growth. Long-time washing of the NCNTs with dilute HNO_3 at room temperature removed the exposed metal species that were not in intimate contact with carbon. Subsequently, the washed NCNTs still containing the encapsulated catalyst nanoparticles were thermally treated under flowing air by moving the reactor into a heated furnace and withdrawing it from the heating zone after 5 min. This process causes opening and rupture of the CNTs through oxidation and thermal stress. Different temperatures from 300 to 600 °C were applied, and the heating process was repeated three times at each temperature. The obtained samples are designated as NCNT-300, NCNT-400, NCNT-500 and NCNT-600. In a separate experiment, the oxidative treatment was performed in HNO_3 vapor at

200 °C, which oxidizes both the residual growth catalysts and the NCNTs leading to a more hydrophilic surface.

3 Results and discussion

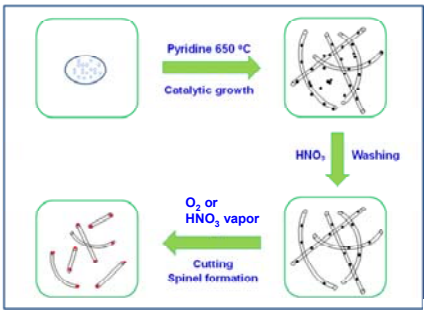

Fig. 1. The synthesis of spinel Mn-Co oxide nanoparticles partially embedded in NCNTs.(1) catalytic growth of NCNTs using the Co-Mn-Al-Mg catalyst; (2) removal of exposed catalyst nanoparticles with poor contact with carbon by washing in dilute HNO3; (3) formation of spinel oxide partially embedded in NCNTs by short exposure to air or HNO_3 vapor at elevated temperatures [1].

Fig. 1 illustrates the synthesis of the electrocatalysts. XRD and TEM studies confirmed the presence of Mn-Co spinel nanoparticles partially embedded in NCNTs. The electrocatalytic activity was evaluated in 0.1 M KOH with a catalyst loading of 210 µg cm^{-2}. The thermal oxidative cutting of NCNT drastically enhanced the ORR activity of the catalysts as indicated by the linear sweep voltammograms in Fig. 2a. Besides the nitrogen-modified carbon species, which are well known to catalyze the ORR, the spinel Mn-Co oxides formed by oxidative cutting are also expected to contribute active sites for the ORR. The ability of the obtained catalysts to catalyze both ORR and OER, that is, to serve as bifunctional catalysts, was investigated by RDE voltammetry and compared with the state-of-art catalysts: Pt/C (20% Pt on Vulcan carbon), RuO_2 and IrO_2. Studies of the OER revealed that NCNT-500 had the best activity (Fig. 2b). Remarkably, NCNT-500 showed higher ORR activity than IrO_2 and RuO_2 and very similar OER activity to RuO_2 (Fig. 2c). These results therefore underscore the huge potential of thermal oxidative cutting for synthesizing excellent bifunctional catalysts for oxygen electrodes.

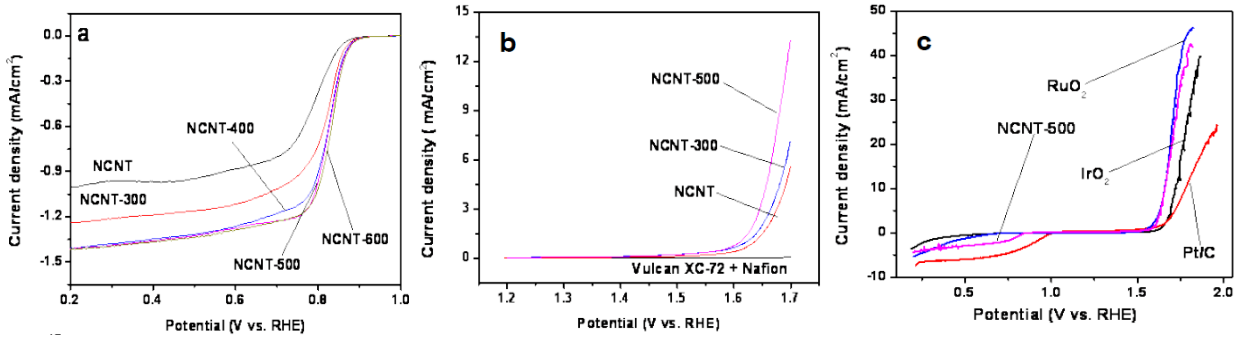

Fig. 2. (a) LSVs at 100 rpm and 5 mV s^{-1}; (b) OER current densities of blank experiment(Glassy carbon), NCNT, NCNT-300 and NCNT-500 at 1 mV s^{-1}; (c) ORR and OER activities of NCNT-500, Pt/C, IrO_2 and RuO_2 at a scan rate of 5 mV s^{-1}. Voltammograms recorded in O_2-saturated 0.1 M KOH.

4 Conclusions

Thermal oxidative treatment of catalytically grown NCNTs, in which residual Co and Mn oxide nanoparticles are buried, simultaneously ruptures the NCNTs and oxidizes the Co and Mn oxide nanoparticles forming spinel Mn-Co oxides nanoparticles partially embedded in the NCNTs. Due to a cooperative effect from the nitrogen groups in NCNT and the spinel Mn-Co oxide particles, the capability of the resulting catalysts to electrolyze both the ORR and the OER becomes tremendously enhanced producing exceptionally active bifunctional catalysts for reversible oxygen electrodes.

Keywords: photoelectrochemistry, water, splitting, buried, junction, antireflection, layer

1 Introduction

As solar energy is an intermittent energy source, energy harvested from the sun needs to be efficiently converted into chemical fuels that can be stored, transported, and used upon demand. The "Holy Grail" of solar energy conversion and storage is efficient photoelectrolysis of water using semiconductors to store solar energy in the simplest chemical bond, namely that of H_2. Indium Phosphide (InP) with a bandgap well-matched to the solar spectrum is a good candidate for photoelectrochemical (PEC) hydrogen production from water. The promise of this material is clear from the photo-conversion efficiencies (η) around 14 % for planar p-type InP (p-InP).[1,2] Herein, we show how the surface energetics and structures can be optimized towards efficiencies that compete with InP solar cells.

2 Experimental/methodology

A 1 µm-thick homoepitaxial, Zn-doped p-InP films was grown on a (100)-oriented InP wafer by Metalorganic Chemical Vapor Deposition. A 200 nm-thick heavily doped n^+-InP film was grown on the top of InP epilayer to create a buried junction (pn^+-InP). A moth-eye-like antireflection layer was created on top of pn^+-InP substrate by soft nanoimprint lithography followed by Inductively Coupled Plasma Reactive Ions Etching. Photoelectrochemical measurements were performed in a three-electrode electrochemical cell with a saturated calomel reference electrode and a Pt foil counter electrode in 1 M $HClO_4$ electrolyte. I-V curves and electrochemical impedance spectroscopy were measured by an Autolab 302N. Mott-Schottky measurements were conducted at a frequency of 10 kHz with 10 mV ac amplitude. AM 1.5G illumination was provided by a 300 W Xenon Lamp with AM 1.5G filters (Newport). Pt was photoelectrochemically deposited from a solution of 10 mM H_2PtCl_6 at a constant potential of 0.3 V vs. SCE under AM 1.5G illumination. A deposition charge of 60 $mCcm^{-2}$ was controlled for both *p*-InP and pn^+-InP electrodes (abbreviated as *p*-InP/Pt and pn^+-InP/Pt, respectively).

3 Results and discussion

Interface energetics was changed by depositing a thin layer of highly doped n^+-InP on top of a p-InP substrate (pn^+-InP). This layer forms an ohmic contact with the electrolyte on one side and a p-n junction on the other side. X-ray photoelectron spectroscopy (XPS) and Mott-Schottky measurements prove that the band-edge shifted to positive potential after n^+-InP layer deposition in vacuum and in electrolyte, respectively. As a consequence, the onset potential (V_{os}) increases from 0.7 to 0.8 V (Figure 1).

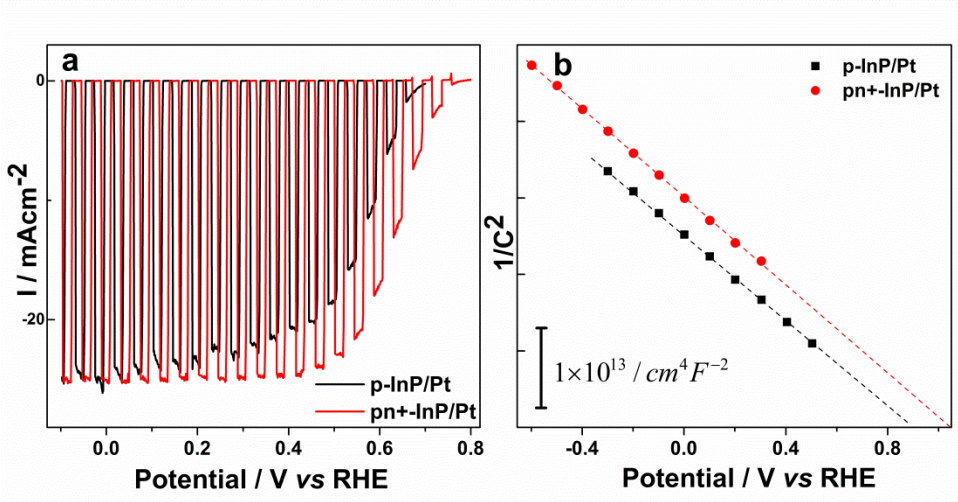

Fig. 1. (a) The current-potential (I-V) curves of *p*-InP/Pt (black line) and pn^+-InP/Pt (red line) photocathode in 1M $HClO_4$ under chopped AM1.5G illumination. (b) Mott-Schottky plots of *p*-InP/Pt (black squares) and pn^+-InP/Pt (red circles) photoelectrodes in 1M $HClO_4$ in dark. The linear fits of experimental data (solid lines) show a positive shift of band-edge after adding the n^+ layer.

The nanopillar arrays created as a moth-eye-like antireflection layer on top of pn^+-InP, are approximately 250 nm in diameter, 100 nm in height and arranged on a square lattice with center-to-center pitch of 500 nm (Figure 2). The total reflectance of pn^+-InP with antireflection layer is between 10 to 20% in the range of visible light, which is much lower than that of planar samples (above 30%). As a result, the short-circuit current (I_{sc}) of pn^+-InP_{AR} increases up to 28 $mAcm^{-2}$. Taken together, these modifications led to a photoelectrode efficiency of 15.5%, which is the highest η for water reduction by single-junction PEC cells so far.

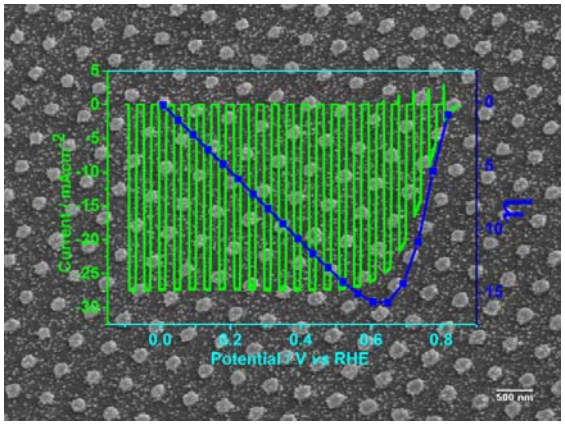

Fig. 2. 45°-tilt SEM image and I-V/efficiency curves of pn^+-InP/Pt with moth-eye antireflection layer.

4 Conclusions

A recorded photocathode conversion efficiency of water reduction by single junction PEC cells was achieved through rational design of the interface energetics and structure.

Keywords: photocatalysis, hydrogen, production, $Cd_{1-x}Zn_xS$

1 Introduction

Rapid depletion of natural raw hydrocarbons (oil, gas, and coal) determines an acute need to identify and develop alternative energy sources [1]. The unique properties of hydrogen make it a versatile and environmentally friendly chemical energy carrier, suitable for use in all types of heat engines and power generation devices. The photocatalytic splitting of water using the energy of visible part of solar light is a very attractive way for the hydrogen production. In recent years, there has been a tendency to use available organic substances as electron donors for the photocatalytic hydrogen evolution. The application of organic substances as electron donors is more advantageous from a practical point of view because most of water pollutants are organic compounds, and the production of hydrogen in this case can be combined with the purification of water. To the best of our knowledge, there are only few articles that describe photocatalytic evolution of hydrogen from aqueous solutions of organic compounds under visible light. Recently, we showed that composite photocatalysts $Pt/Cd_{1-x}Zn_xS/ZnO/\varepsilon\text{-}Zn(OH)_2$ possess a significant activity in the hydrogen evolution from aqueous solutions of ethanol and the photocatalytic activity grows with the content of $\varepsilon\text{-}Zn(OH)_2$ [2]. However, zinc hydroxide is believed to have a low stability in the photocatalytic process. Thus, the aim of present research was to study the stability of composite photocatalysts $Pt/Cd_{1-x}Zn_xS/ZnO/\varepsilon\text{-}Zn(OH)_2$ in the hydrogen evolution under visible light.

2 Experimental/methodology

The composite photocatalysts $Pt/Cd_{1-x}Zn_xS/ZnO/\varepsilon\text{-}Zn(OH)_2$ were synthesized according to the method described in detail elsewhere [2].

Photocatalytic hydrogen evolution from ethanol aqueous solution was carried out by the following method. The aqueous suspension with the catalyst and substrate was placed in a sealed reactor, purged with Ar and illuminated by a 450-nm LED (40 mV/cm^2) under continuous stirring. The photocatalyst concentration was 0.5g/L, C_2H_5OH concentration was 10% (vol.), NaOH concentration was 0.1M, temperature was 20 °C. Hydrogen was analyzed by means of gas chromatography.

3 Results and discussion

Fig. 1a shows four consecutive runs of hydrogen evolution for four photocatalysts A-D. The properties and activities of photocatalysts A-D are represented in Table 1.

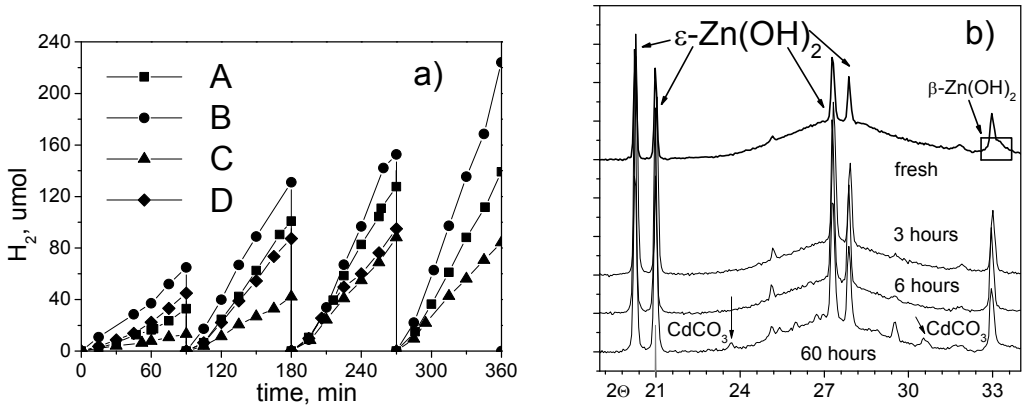

Fig. 1. Kinetics of the hydrogen evolution for photocatalysts A-D (a) and the transformation of XRD patterns of photocatalyst A during the hydrogen production (b).

Table 1. The properties and the activities of the synthesized photocatalysts.

Photocatalyst	**Phase composition after 6 h of reaction**	**Initial rate, μmol (H_2)/min**	**Highest rate, μmol (H_2)/min**	**Φ**
A $Cd_{0.6}Zn_{0.4}S$/ZnO/ε-β-$Zn(OH)_2$	$Cd_{0.6}Zn_{0.4}S$/ZnO/ε-$Zn(OH)_2$	0.54	1.70	9.4
B $Cd_{0.8}Zn_{0.2}S$/ZnO/β-$Zn(OH)_2$	$Cd_{0.8}Zn_{0.2}S$/ZnO/ε-$Zn(OH)_2$	0.72	2.63	14.5
C $Cd_{0.6}Zn_{0.4}S$/ ZnO/β-$Zn(OH)_2$	$Cd_{0.6}Zn_{0.4}S$/ZnO/ε-$Zn(OH)_2$	0.18	1.04	5.7
D $Cd_{0.5}Zn_{0.5}S$/ZnO/β-$Zn(OH)_2$	$Cd_{0.5}Zn_{0.5}S$/ZnO/ε-$Zn(OH)_2$	0.75	1.07	5.9

One can see that the rate of H_2 evolution grows with the cycle number for all photocatalysts. Thus, instead of deactivation of the photocatalysts, their activation is observed. Long-term experiments for photocatalyst A shows that the deactivation is achieved after 60 h of H_2 evolution only. XRD patterns of photocatalysts after each cycle of the hydrogen production were obtained. Fig. 1b shows the XRD pattern of fresh photocatalyst A as well as patterns of this photocatalyst after 3, 6, and 60 h of the reaction. One can observe that the content of ε-$Zn(OH)_2$ grows with the reaction time until 6 hours and then remains practically unchanged. Additionally, the $CdCO_3$ peaks appear in the XRD pattern after 60 h of reaction. For photocatalyst B, C, and D the appearance of the ε-$Zn(OH)_2$ phase after 6 h of the reaction is obsereved. XRD analysis shows that for all photocatalysts the β-$Zn(OH)_2$ phase is transformed into the ε-$Zn(OH)_2$ one during the photocatalytic reaction. The highest achieved photocatalytic activity was 2256 μmol H_2 g^{-1} h^{-1}; the estimated highest quantum efficiency (Φ) was 14.5% in respect to 450 nm.

4 Conclusions

Novel composite photocatalysts Pt/$Cd_{1-x}Zn_xS$/ZnO/$Zn(OH)_2$ with a high activity under visible light were proposed. The activation of the photocatalyst during the photocatalytic hydrogen evolution from alkaline aqueous solutions of ethanol was observed. The activation is likely caused by formation of ε-$Zn(OH)_2$ in a basic media.

The Role of Co-Catalysts in Photoelectrochemical versus Photocatalytic Water Splitting: CoO_x on $LaTiO_2N$

Landsmann S., Mägli A., Pokrant S.*, Trottmann M.

Laboratory Materials for Energy Conversion, Dübendorf, Switzerland

Keywords: hydrogen, renewable, fuel, photoelectrochemical, water splitting, photocatalytic water splitting, co-catalyst

1 Introduction

Since the demonstration of photocatalytical water splitting by Fujishima and Honda using TiO_2 in 1972 [1], the idea to produce environmentally friendly fuel by direct conversion of solar energy into hydrogen gained increasing attention. During the last years this trend became even stronger, especially since the growing awareness about the damaging effects of greenhouse gas emissions combined with the knowledge of the limited availability of fossil energy resources like oil or coal triggered an intensive search for alternatives. Shining light on a photocatalyst leads to absorption of photons and the generation of electron-hole pairs. The generated holes and electrons, that escape recombination, diffuse and migrate to the surface of the photocatalyst particle and are consumed by the oxidation of O^{2-} to O_2 or the reduction of H^+ to H_2, respectively [2]. Hydrogen has the potential to serve as next generation fuel [3]. For this purpose the implementation of water splitting in a technological large-scale solution is desirable. Several concepts have been proposed [4]: One of them is the use of photocatalytically active particles to produce H_2 and O_2, while the photocatalyst particles are either suspended in a liquid or deposited on a film. Another concept is based on the photoelectrochemical (PEC) cell in which oxidation and reduction take place on physically separated electrodes, with the advantage that the evolving gases can be separated more easily. Today, solar light is often used to produce O_2 on the photoanode [2], while the cathode can be either photocactive or a standard electrode (mostly Pt) for H_2 production. One of the well-studied photocatalysts for O_2 production (photoanode) is $LaTiO_2N$ (LTON) [2]. To enhance the performance of the photocatalyst co-catalysts were used in both, photocatalytic and the photoelectrochemical setups. For O_2 evolution Co oxides were found to be very active co-catalysts []. However, it is not entirely clear, whether co-catalysts act on the kinetics of the oxygen evolution reaction or facilitate the charge separation process by enhancing the band bending at the solid-electrolyte interface. In this contribution, we investigate whether CoO_x co-catalysts deposited on LTON (LTON/Co) serve the same function in a photocatalytic setup compared to a photoelectrochemical setup. For this purpose we compare the photocatalytic and the photoelectrochemical activity of four morphologically different LTON and LTON/Co samples.

2 Experimental/methodology

The preparation and characterization of LTON, LTON/Co and the photocatalytic activity measurements were conducted as published previously []. LTON is synthesized in four different morphologies called PC-LTON, SS-LTON, PC-LTON-FX and SS-LTON-FX, which vary in particle size, surface area and crystalline quality. These morphologies are treated with $Co(NO_3)_2$ leading to the samples PC-LTON/Co, SS-LTON/Co, PC-LTON-FX/Co and SS-LTON-FX/Co. The LTON and LTON/Co photoanodes were fabricated by electrophoretic deposition and necked as described in [8]. The PEC measurements were conducted in a three electrode configuration with the LTON film as working electrode, an Ag/AgCl (3M) reference electrode and a Pt wire as counter electrode. The

experimental details are listed in [8]. Photocurrents were acquired on a VersaSTAT 4 potentiostat at a scan rate of 10mV/s under backside illumination.

3 Results and discussion

Figure 1a shows the photocatalytic activity of LTON and LTON/Co measured by oxygen evolution of particles suspended in a scavenger solution containing $AgNO_3$, while Figure 1b displays the PEC activity of LTON and LTON/Co represented by the photocurrent obtained at a bias of $1.23V_{RHE}$. For bare LTON samples the photocatalytic and the PEC activity are

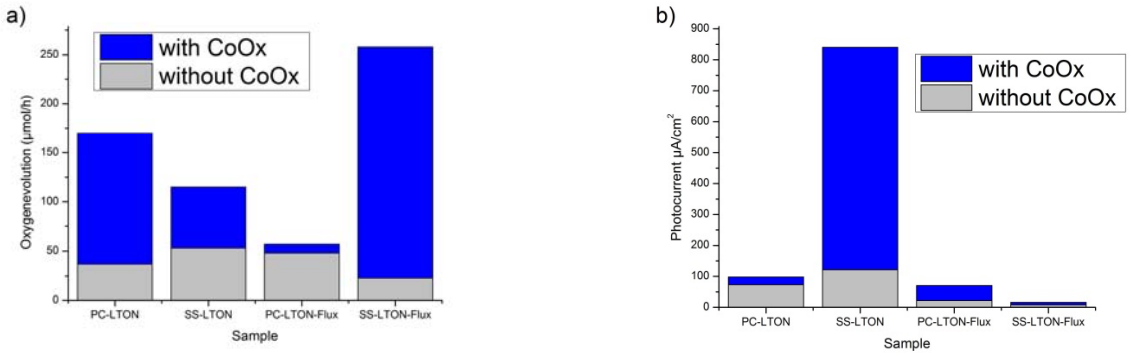

Fig. 1. a) photocatalytic activity versus b) PEC activity of LTON and LTON/Co samples

are comparable, while the effect of Co addition results in a highly different increase for both processes. The enhancement of the photocatalytic activity correlates to the surface area of the CoO_x co-catalyst nanoparticles, while for PEC electrodes large co-catalyst particles are favourable.

4 Conclusions

Our results clearly demonstrate that the co-catalyst CoO_x on LTON does not induce the same effect, if LTON/Co is used in photocatalysis or as PEC electrode. In photocatalytical experiments the co-catalysts seems to lower the kinetic barrier, while we propose that it induces enhanced band bending in the PEC case.

Keywords: photocatalysis, gallium, oxide, water splitting, chemical vapor synthesis, noble metal-free co-catalysts

1 Introduction

Direct photocatalytic water splitting using inorganic semiconductor particles is a promising way to convert sunlight into chemical energy in addition to (photo)electrochemical methods [1]. Ga_2O_3 is one of the very few materials that has the ability to perform the simultaneous stoichiometric evolution of H_2 and O_2, i.e. the overall water splitting reaction, from pure H_2O. Although this oxide has a large band gap, it is highly suitable to evaluate the properties of novel co-catalyst materials and to study charge carrier separation processes in photocatalysts with various phase compositions and structures. An improved charge carrier separation at α/β-Ga_2O_3 phase junctions was recently reported for mixed-phase Ga_2O_3 loaded with NiO as a co-catalyst [2]. Additionally, the influence of different co-catalyst systems on the performance of the two main Ga_2O_3 structures was discussed [3]. The effect of the co-catalyst composition and loading on the overall water splitting has already been demonstrated by our group using the step-wise photodeposition of Rh and Cr on commercial β-Ga_2O_3 [4]. In this contribution phase-pure α- and β-Ga_2O_3 as well as mixed phase α/β-Ga_2O_3 photocatalysts were systematically synthesized and novel binary CuO_z/CrO_y [5] and ternary $CuO_z/CrO_y/MoO_x$ [6] non-noble metal co-catalyst systems were investigated.

2 Experimental

Ga_2O_3 photocatalysts were synthesized by chemical precipitation leading to α-GaOOH followed by subsequent calcination at various temperatures between 400 °C and 900 °C. Additionally, Ga_2O_3 was synthesized in the gas phase by chemical vapor synthesis (CVS) to obtain highly crystalline materials with very well defined nanoparticles. A quantitative determination of the phase composition was achieved by X-ray diffraction and Rietveld refinement. UV-vis spectroscopy was used to determine the band gap of the materials. The synthesized samples were tested in overall water splitting using the co-catalyst systems mentioned above synthesized by photodeposition. Photocatalytic direct water splitting was performed in a semi-continuous double-walled glass reactor with a 500 W Hg-lamp (inner irradiation type) connected to an on-line gas analyzer.

3 Results and discussion

Ga_2O_3 samples obtained by precipitation and subsequent calcination exhibit various phase compositions from α- to mixed α/β- to β-Ga_2O_3, whereas the commercial Ga_2O_3 and the materials obtained by CVS are pure β-Ga_2O_3. The results of the overall water splitting confirm a significant influence of the phase composition and crystalline structure on the charge carrier separation and the activity. Figure 1 shows the H_2 and O_2 evolution rates measured for Ga_2O_3 obtained by precipitation, CVS and a commercial β-Ga_2O_3 loaded with Rh(0.1 wt%)/CrO_y(0.09 wt%) as co-catalyst.

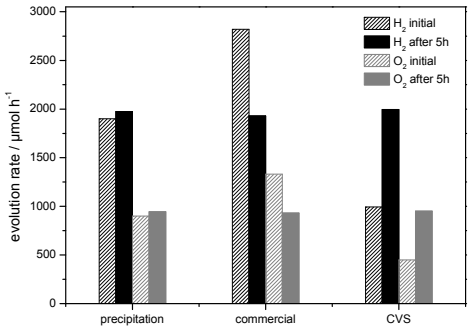

Fig. 1. H_2 and O_2 evolution rates for Ga_2O_3 obtained by precipitation, CVS and a commercial sample.

All samples produce H_2 and O_2 from pure H_2O in stoichiometric amounts. The precipitated and the CVS sample are highly active and stable during overall water splitting, whereas the commercial Ga_2O_3 significantly deactivates with time. Using a Cu_z/CrO_y co-catalyst on commercial Ga_2O_3 a maximum activity was observed for the composition CuO_z(0.66 wt% Cu)/CrO_y(0.09 wt% Cr)/β-Ga_2O_3. Different photodeposition procedures, in which the order of the CuO_x and CrO_y deposition was changed, show that the formation of a Cr_2O_3 shell on CuO_x cores is rather unlikely. Additional photodeposition of MoO_x renders the photocatalyst more active and regenerable.

4 Conclusions

Ga_2O_3 materials with various phase compositions and structures have been synthesized by precipitation and CVS and compared to commercial β-Ga_2O_3. A significant influence of the structural properties on the overall water splitting performance was determined. Synthesized Ga_2O_3 materials are as active or more active than commercial Ga_2O_3 and exhibit a significant higher stability. A ternary non-noble metal co-catalyst was found to be comparably active to a Rh-containing photocatalyst.

Keywords: photocatalysis, water-splitting, TiO_2, g-C3N4, gold, hydrogen, production

1 Introduction

Nowadays, the global energy demand continues to increase, in contrast to natural energy resources (fossil fuels) that decrease year by year. The major challenge is to find new environmentally friendly ways to produce energy that may cover the global consumption. The direct conversion of solar energy though an energy carrier (fuel), storable and usable upon request, appears as an interesting alternative [1]. Photocatalysis is an innovative and promising way to produce pure hydrogen from renewable energy sources. Indeed, the water dissociation (water-splitting) highlighted by Fujishima and Honda in a photoelectrocatalytic cell opened a promising way to produce hydrogen from light energy [2]. Hydrogen (H_2) is a selective energy carrier due to its high specific energy density [3].

In our study, we will focus on a photocatalytic titanium dioxide-based system (TiO_2), a cheap and common semi-conductor, associated with graphitic carbon nitride (g-C_3N_4). g-C_3N_4 appears as a very promising photocatalyst semi-conductor since it has been revealed that its band gap of 2.7 eV allows the valorization of an important part of the visible light spectra in the context of water splitting [4], contrary to the well studied TiO_2. Novel composite compounds such as Au/g-C_3N_4/TiO_2 will be synthesized and compared to the reference commercial titanium dioxide (Evonik, P25) and to titanium dioxide synthesized by a standard "sol-gel" process.

2 Experimental/methodology

Titanium dioxide (TiO_2) powder is obtained via a standard "sol-gel" process [5]. Firstly, titanium isopropoxide precursor [$Ti(OCH(CH_3)_2)_4$] was mixed with ethanol at room temperature. Then, water (adjusted to pH = 9 by addition of ammonia) was added dropwise to this solution. Secondly, the solution was evaporated under stirring until dry paste was obtained which was further dried overnight at 110°C. Then, the sample was thermal-treated for 3h in air at 400°C.

Graphitic-carbon nitride (g-C_3N_4) was obtained via a thermal polycondensation reaction of specific nitrogen-containing precursors [6]. First, an equimolar blend of melamine ($C_3H_6N_6$) and dicyandiamide ($C_2H_4N_4$) was mixed into an alumina covered crucible. The covered crucible was further heated at 550°C with a rate of 5°C/min during 3h.

g-C_3N_4/TiO_2 nanocomposites were obtained by introducing g-C_3N_4 (as synthesized) during the sol-gel synthesis of TiO_2 followed by a final calcination step at 400°C for 3h.

Gold nanoparticles were synthesized - directly onto the TiO_2, the g-C_3N_4 and the g-C_3N_4/TiO_2 support – by chemical reduction at room temperature of the $HAuCl_4$ precursor in an excess of $NaBH_4$ followed by final rinsing and filtration steps.

3 Results and discussion

From **Fig.1a** it can be observed that an homogeneous dispersion of well-defined spherical Au nanoparticles were obtained onto the g-C_3N_4 support. Au particles exhibited a monomodal distribution centered around 3,9 ± 0,9 nm. The same tendancy was observed with the TiO_2 and g-C_3N_4-TiO_2 (not shown here) supports. The Au deposition yield was higher than 80%.
A detailed study of the synthesis of g-C_3N_4/TiO_2 nanocomposites revealed modifications in their structural characterizations compared to the bare g-C_3N_4 and TiO_2 materials (**Fig.1b**). Without calcination, TiO_2 was entirely amorphous contrary to the composite which showed the presence of anatase phase of TiO_2 already at room temperature. However, XRD in temperature showed that in the composite, the crystallization of TiO_2 is unfavoured compared to pure TiO_2, accompanied by smaller crystallites sizes. To this, an increase of specific surface area (between 1.5 to 2 times higher than TiO_2) was also observed.

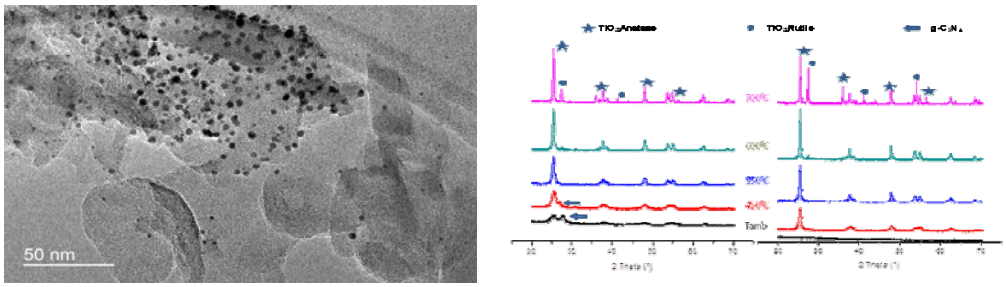

Figure 1: (a) TEM picture of Au/g-C_3N_4 sample; (b) XRD in temperature of 50wt.% g-C_3N_4/TiO_2 (left) and pure

Water-Splitting tests were carried out into a quartz reactor containing 900mL of Ultra-pure water and 250mg of sample under flowing N_2 at 100cc/min and irradiated with a 150 W halide lamp. Methanol (from 0.1 to 1 vol. %) was used as a sacrificial agent in order to increase yields of hydrogen production. The sample activity (amount of H_2 produced) was measured by a gas phase µGC. The first set of measurements of the activity of Au/g-C_3N_4 samples showed optimal gold concentration around 0.3wt.% with a hydrogen production yield of 25µmol/h after stabilization. Hydrogen production decreased to 15µmol/h for sample with 2% wt. gold. The first test on 0.3wt.%Au/50wt.%g-C_3N_4/TiO_2 composite showed a significant production of hydrogen. Compared to 0.3wt.% Au/TiO_2, a higher H_2 production is obtained (above 30 µmol/h) with 2 times less TiO_2.

4 Conclusions / Perspectives

The synthesis of new nanostructured composites allowed us to achieve better hydrogen production yield than the reference Au/TiO_2 and Au/g-C_3N_4 samples. Furthermore best hydrogen production was obtained with a gold loading of 0.3 wt. %. Future goals are to find the optimal amount of Au on the Au/g-C_3N_4/TiO_2 composites but also the optimal amount of g-C_3N_4. In the presentation, the influence of g-C_3N_4/TiO_2 ratio, as well as of Au loading will also discussed.

1 Introduction

The production of fuels by reduction of carbon dioxide using sunlight as the energy source is a potential solution to both alleviate our dependence from fossil resources and minimise the greenhouse effects caused by the current atmospheric accumulation of such gas. This strategy would also close the carbon cycle efficiently. Unfortunately, the activation of CO_2 is an extremely challenging task, due to both thermodynamic and kinetic energy barriers involved in its reduction processes.

Based on previous research carried out in our laboratories on analogous photocatalytic CO transformations, it was proven that n-type semiconductors are more active for the water gas shift reaction, which entails CO oxidation to CO_2,[1] whereas p-type semiconductors catalyse the reduction of CO to CH_4, using either H_2 or H_2O (although to a lesser extent for the latter) as reducing agents.[2] These intriguing results encouraged the investigations presented herein, focusing on the sunlight-induced reduction of CO_2 by H_2 using a series of n- and p-type semiconductors as potential photocatalysts.

2 Experimental/methodology

Photocatalysts were commercial samples, with the exception of the following NiO samples. NiO nanoparticles (diameter 12−50 nm) were prepared by a sol−gel method from nickel acetate tetrahydrate (0.5 g in ethanol, 50 mL) and oxalic acid (0.23 M in ethanol, 100 mL), followed by drying (80−110 °C, 24 h) and calcination (500 °C, 3 h). NiO nanoplates (diameter 120−200 nm, thickness 20−50 nm) were prepared by hydrothermal treatment of the solid obtained from nickel acetate tetrahydrate (0.5 g in water, 50 mL) and aqueous NaOH (5 mL, 1.25 M) at 175 °C for 16 h.

Irradiations were carried out on a uniform thin bed of powdered semiconductor (250 mg) under a mixture of CO_2 (3.7 mmol, 15%), H_2 (17 mmol, 70%), and N_2 (3.7 mmol, 15%) for 1 h, unless otherwise stated, using a solar simulator (Newport, Oriel Instruments 69921, coupled with an AM1.5 filter). Gaseous products were analysed using a three-channel Bruker gas chromatograph. The amounts of elemental carbon on the photocatalyst after irradiation were determined by elemental analysis.

3 Results and discussion

A series of nanoparticulate transition metal oxides were tested for the reduction of CO_2 by H_2 with simulated sunlight as the source of energy (see Table 1). Whereas classical n-type semiconductor such as TiO_2 proved inactive for the reaction, CO_2 undergoes efficient reduction to CH_4 on p-type semiconductors. Among these, nickel-based materials were the most active photocatalysts.[3] Particle size is an important factor regarding photoactivity, as reflected in Table 1 by the decreasing conversion observed for a series of NiO materials. Using nanopowdered NiO or $Ni/SiO_2{\cdot}Al_2O_3$ photocatalysts, the conversion of CO_2 is essentially quantitative under

simulated solar light at short reaction times (≤ 1 h). Furthermore, the selectivity to CH_4 approaches 100%. Since the reaction is exothermic, the possible effects of local heat evolution on activity could not be overlooked. In this line, dark thermal experiments were conducted and photoactivity spectra were recorded, proving that light absorption by the nickel catalysts is actually initiating the reactions. Moreover, the presence of the silica-alumina support profoundly improves photoactivity and prolongs the lifetime of the photocatalyst.

Table 1. Photocatalytic activity for CO_2 reduction on metal oxide nanopowders.

catalyst	particle size (nm)	conversion (%)	molar balance (%)	selectivity (%)[a]		
				CH_4	CO	C_2H_6

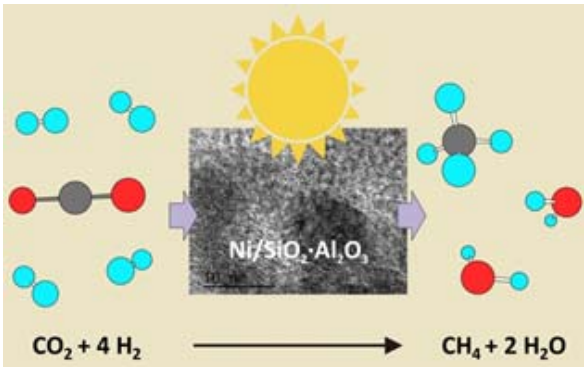

Fig. 1. Schematic representation of the sunlight-driven photocatalytic reduction of CO_2 to CH_4 on a nickel-based material, $Ni/SiO_2{\cdot}Al_2O_3$ (TEM micrograph shown in the inset).

4 Conclusions

A reaction that could potentially impact solar fuel production, namely the photocatalytic reduction of CO_2 to CH_4 with sunlight proceeds at high conversion and selectivity in short times on nanopowdered nickel catalysts. The use of a high surface area insulating support such as silica−alumina increases the efficiency and durability of the photocatalyst, due to an increase in metal dispersion and stability. The reported process can also take place under UV-free visible light.

1 Introduction

Water electrolysis, combined with renewable electric power generation technologies, such as solar electric, solar-thermal, hydro, or wind power plants, is expected to emerge as a low-emission method for storing excess electricity and for producing hydrogen fuel as part of a solar refinery. The challenge in electrocatalytic water splitting is the high overpotential required for the anodic oxygen evolution reaction (OER). Relatively low overpotential is attainable in acid electrolyzers using RuO_x and IrO_x-based electrocatalysts, however they are expensive and of limited sustainability. In this contribution, we address the challenges related to noble metal content and durability of water splitting catalysts by presenting a low-Ir content OER catalyst on a corrosion-stable oxide support with excellent electrochemical performance and durability.[1]

2 Experimental

IrNi-based homogenous thin films were prepared by spin-coating onto Ti substrates and calcination at various temperatures. Supported core-shell $IrNi@IrO_x$ nanoparticles on mesoporous antimony-doped SnO_2 (meso-ATO) were synthesized from $IrNi_x$ (x=3.3 to 3.8) metallic precursor alloys by applying potential cycles in acidic medium. The $IrNi_x$ metallic precursor alloys were synthesized using the polyol method in the presence of oleic acid and oleylamine as capping agents.[2] Meso-ATO powder was introduced into the reaction mixture before starting the metal reduction to form the precursor alloy. High surface area meso-ATO was synthesized by a combination of sol-gel synthesis and hydrothermal treatment.[3] The samples were characterized using a wide array of techniques involving synchrotron-based XPS, TPR, XRD, high-resolution imaging and mapping by STEM. The OER reactivity and stability of the electrocatalysts were evaluated using linear sweep voltammetry and chronopotentiometry.

3 Results and discussion

We found a strong impact of the Ir to Ni ratio on the electrocatalytic OER activity of IrNi mixed oxide films, with a maximal Ir mass based activity being 38 times higher than that of pure Ir oxide. The observed improvement in the OER activity was partially caused by the increased surface area; however, the intrinsic activity (activity per active surface area) was improved as well. Within the first electrocatalytic OER measurement the active catalyst state was obtained after leaching a certain amount of Ni selectively, though Ni was not completely removed. Above 21% initial Ni content, XRD measurements indicate an X-ray amorphous state for all mixed oxide compositions, and TPR suggested the presence of only one mixed-oxide phase. The amorphous mixed oxide state was conserved below the highest calcination T. XPS experiments of the IrNi mixed oxide films prior and after OER indicated a massive transformation of the

sample from an X-ray stable oxide into a labile, highly hydroxylated state with a fraction of incorporated water.

The preparation of metallic alloy nanoparticles supported on redox active oxides and the removal of surfactants require a balanced annealing protocol in order to maintain the chemical state of alloy and support. In this study, the materials were annealed at different temperatures (T = 180, 250, 300, 400, 500 °C) in inert N_2 gas to prevent the reduction of ATO support. XRD and XPS experiments indicated that high T annealing is detrimental, as it leads to phase separation.

After annealing, the supported precursor alloy nanoparticles were dealloyed and oxidized by applying potential cycles in acidic medium. Upon dealloying, the homogeneous Ir-Ni distribution yields a core shell type structure (EDX line scan with two symmetric Ir shell peaks at the particle edges). Interestingly, the morphology of the dealloyed nanoparticles strongly depended on particle size, while smaller nanoparticles favored Ni-richer core-shell structures, larger nanoparticles appear to undergo severe Ni leaching in their transition to core-shell structures (Fig.1 left).

The activity and stability of oxidized $IrNiO_x$/meso-ATO electrocatalysts were assessed in OER in comparison with IrO_x/C and IrO_x/commercial-ATO reference materials (Fig.1 right). $IrNiO_x$/meso-ATO calcined at T ≤ 300 °C (and particularly the one at 180°C) were the most active catalysts (Fig.1 right a,b); meanwhile their long-term stability were also excellent (Fig.1 right c,d). Further details to characterization, activity and stability will be discussed.

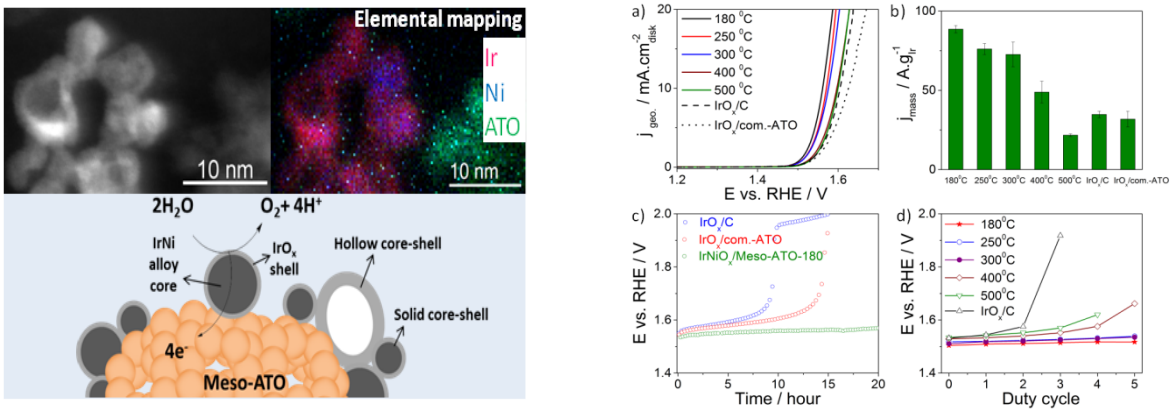

Fig. 1. Left: STEM image and EDX mapping of $IrNiO_x$/meso-ATO-180, with a schematic representation of the catalyst. Right: OER activity comparison (a,b) and stability tests (c,d).

4 Conclusions

Supported Ir-Ni oxide nanoparticles on meso-ATO with IrNi@IrO_x core-shell architectures enable low precious metal loading with excellent electrochemical performance and durability.

Keywords: Bi_2WO_6, $BiVO_4$, selective oxidation, photocatalysis, nitrite ion

1 Introduction

The direct transformation of methane into oxygenated products is a challenging alternative for its exploitation. A wide number of catalytic approaches have been reported for the direct oxidation of methane into products like methanol, formaldehyde and longer chain compounds. In this sense, the photocatalytic approach might become a good alternative for carrying out processes at milder conditions than other catalytic paths [1]. Some materials as TiO_2, NiO, WO_3 [2], mesoporous silicas and zeolites have been studied as photocatalysts for the selective oxidation of methane into methanol with several oxidizers as water, NO or O_2.

Bismuth ternary oxides can be interesting candidates for this reaction in comparison to simple oxides, because of the hybridized band structure created by the Bi 6s orbitals, which might move the band edges to more negative potentials, increase the carrier mobility and decrease the band gap value [3]. Bi_2WO_6 and $BiVO_4$ have been synthesized, characterized and evaluated in the photocatalytic oxidation of methane to methanol for the first time. Moreover, the effect of several reaction conditions and the presence of additives have also been studied.

2 Experimental/methodology

The synthesis of Bi_2WO_6 and $BiVO_4$ was carried out by a facile hydrothermal treatment at 140ºC for 20h. Solutions of $Bi(NO_3)_3$ in acetic acid and Na_2WO_4 and $NaVO_3$ in H_2O were used as precursors. Both materials were calcined at 300ºC.

XRD, SEM and BET analysis were performed. Finally, the samples were evaluated in a commercial photochemical reactor with a medium pressure mercury lamp (450W), connected to a Shimadzu GC with TCD and FID. The gas composition was analyzed at certain intervals. For each test, a suspension of Milli-Q water with 1 $g \cdot L^{-1}$ of photocatalyst was added to the reactor and stirred, while continuously sparging a CH_4/He mixture. The temperature was kept at ca. 348K.

3 Results and discussion

The most photoactive crystalline phases were obtained for both materials: russelite orthorhombic phase for Bi_2WO_6 and the scheelite monoclinic one for $BiVO_4$. In a similar manner, the two samples presented band gap values close to the expected ones (~2.8 for Bi_2WO_6 and 2.4 eV for $BiVO_4$), with BET areas of 30 and 2 $m^2 \cdot g^{-1}$, respectively, which can be explained from the difference in crystallite sizes. Bi_2WO_6 exhibited the typically reported morphology, consisting in 3D hierarchical structures formed from self-assembled nanoplates. $BiVO_4$, on the other hand, consisted of large faceted polyhedron.

Three main products were detected during the photocatalytic tests: CH_3OH, CO_2 and C_2H_6. An initial blank test with water showed that methane can be oxidized through a photolytic process in which ·OH radicals are produced from H_2O. Though, when a photocatalyst is present, different product distributions and higher conversions are observed. Figure 1 shows the rates of products obtained during the tests. There, it is possible to observe that Bi_2WO_6 led to the highest

rates of CO_2, indicating that this material is more oxidizing than $BiVO_4$. This effect can be explained from the differences in the band edges between both materials, as the valence band of Bi_2WO_6 has more positive potential than $BiVO_4$. Thus, higher selectivity values were obtained with the latter, which is an important aspect to consider for this process.

Other reaction conditions were also evaluated. For instance, the use of additives as electron or ·OH scavengers and other oxidant species as O_2 were considered. Fe^{3+} probed to have a negative effect on the selectivity, despite a significant increase in the methane oxidation probably through a photo-Fenton mechanism in which more ·OH radicals can be generated. Nitrite ion (NO_2^-) on the other hand, had a positive effect on the selectivity by completely inhibiting the C_2H_6 formation and decreasing the complete oxidation to CO_2, thanks to a double mechanism in which it acts as UV filter and ·OH scavenger. This way, through a combination of $BiVO_4$ in a solution of (1mM) NO_2^-, enhancements in the CH_3OH selectivity from ~40 to 90% can be achieved.

Lower CH_4 conversions were obtained in additional tests carried out in presence of commercial TiO_2-P25 and rutile.

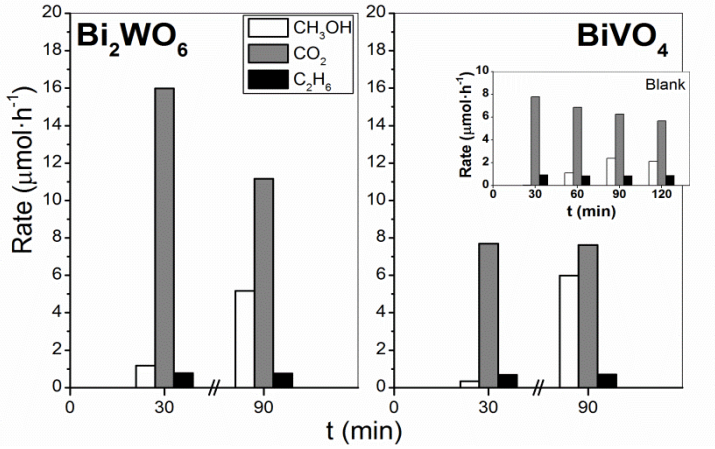

Fig. 1. Rates of products obtained during the photocatalytic tests (in the inset, the photolytic path).

4 Conclusions

$BiVO_4$ has proved to be a good candidate as photocatalyst for the selective oxidation of methane, displaying higher methanol selectivity than Bi_2WO_6, which is a more oxidizing material. The presence of low concentrations of nitrite anion might enhance the selectivity towards methanol and inhibit the ethane formation, while the addition of electron scavengers as Fe^{3+} species favors the complete oxidation path to CO_2.

Keywords: photocatalysis hydrogen, production, silver sulfide, nanoparticles, nonstoichiometry

1 Introduction

Semiconductor nanocrystalline materials are widely used in photocatalytic processes. Selective photocatalytic reactions for organic synthesis [1], photocatalytic oxidation of organic compounds [2], and photocatalytic hydrogen production have become of special significance [3]. Taking this into account, the undersanding of very details of photocatalytic hydrogen evolution from aqueous solutions of Na_2S/Na_2SO_3 under visible light irradiation is very important nowadays [4]. So, in present work the synthesis of nonstoichiometric silver sulfide nanoparticles and study of their photocatalytic activity in Na_2S/Na_2SO_3 were undertaken.

2 Experimental

The powders of nonstoichiometric silver sulfide nanoparticles with excess of silver (nano-Ag_2S/Ag) were synthesized by chemical bath deposition from aqueous solution of silver nitrate $AgNO_3$ (50 mM) and sodium sulfide Na_2S (25 mM) containing either sodium citrate $Na_3C_6H_5O_7$ (Na_3Cit) or sodium salt of ethylenediaminetetraacetic acid $Na_2H_2(CH_2OO)_4(CH_2N)_2$ (EDTA) as complexing or stabilizing agents. The concentrations of sodium citrate or EDTA in the reaction mixtures were varied from sample to sample in the range between 25 and 50 mM in order to get silver sulfide nanoparticles with different stoichiometry.

The size (hydrodynamic diameter) of nanoparticles in the as-synthesized colloid solutions was determined by dynamic light scattering (DLS). Phase composition of the samples after drying and filtration was analyzed by X-ray diffraction (XRD) using CuK_{alpha} radiation. The XRD patterns were recorded in the 2theta range from 20 to 95° with a step of 0.02° and high statistics at each point. The XRD reflexes were separated from each other and average crystallite sizes were determined with the use of Williamson-Hall technique.

The samples were studied using high resolution transmission electron microscopy (HRTEM) with accelerating voltage of 200 kV and resolution of 140 pm. The local elemental composition was analyzed with an energy-dispersive X-ray (EDX) spectrometer equipped with a detector having energy resolution of 130 eV.

The photocatalytic evolution of hydrogen from the aqueous solution of Na_2S/Na_2SO_3 was studied by the method described earlier [5]. Before the reaction, a water suspension with a catalyst, Na_2S, and Na_2SO_3 was treated in an ultrasonic bath for 10 min and purged with argon for 20 min to remove oxygen. After that, the suspension of powdered samples was placed into a sealed thermostated reactor and illuminated with a 450 nm wavelength light emitting diode (LED) with the intensity of the irradiation of 8 mW/cm^2. The concentration of hydrogen was measured with a gas chromatograph equipped with a thermal conductivity detector and a zeolite column; argon was used as the carrier gas.

3 Results and discussion

The chemical (EDX), structural (XRD, HRTEM) and morphological (SEM, TEM) characterization of silver sulfide samples synthesized with help of sodium citrate or EDTA has shown nearly the same silver enriched chemical composition with about 2 at. % deviation from stoichiometry and nearly the same size of nanoparticles of about 50 nm.

Atomic structure of nanoparticles (XRD, HRTEM) in both cases is monoclinic acanthite-like. The only difference in structure of silver impurities was found. Silver nanoparticles in samples synthesized with EDTA has cubic closed-packed crystalline structure but in samples stabilized with sodium citrate is amorphous.

High activity of nonstoichiometric nanosized silver sulfide under visible light (450 nm) for both types of synthesis samples is found but the stability of photocatalytic activity was found exclusively for samples synthesized with help of EDTA. Silver nanoparticles can act for charge separation in the system Ag_2S/Ag and increase the activity of stoichiometric silver sulfide. Taking into account that the only difference in structure for these samples is crystalline impurities of silver phase it should be concluded that this could be the reason for stable photoactivity of samples synthesized with EDTA.

4 Conclusions

A method for the synthesis of nonstoichiometric silver sulfide nanoparticles which are catalytically active under visible light irradiation (450 nm) has been suggested and explored. High catalytic activity of nonstoichiometric silver sulfide nanoparticles was measured by the photocatalytic evolution of hydrogen from the aqueous solution of Na_2S/Na_2SO_3. Higher photostability of nonstoichiometric silver sulfide nanoparticles stabilized by EDTA in compare to non-stabilized nanoparticles were found. This effect can be explained by nonstoichiometry and crystalline silver impurities on the surface of stabilized silver sulfide nanoparticles.

Keywords: CO_2, photoreduction, methanol, graphene, oxide, TiO_2, solar fuels

1 Introduction

Since 1751 approximately 337 billion metric tonnes of carbon have been released to the atmosphere from the consumption of fossil fuels and cement production [1]. The latest estimates point-out to the occurrence of all time highs every year. Liquid and solid fuels are responsible for the majority of emissions, while gas and cement contribute to lower extent, with a significant decrease of gas flaring in recent years. This massive release of CO_2 to the atmosphere is believed to result in considerable climate changes, therefore a great deal of effort is being made to reduce its concentration in the atmosphere and to prevent its emissions. Different strategies include the adsorption of CO_2 into new/functionalized materials, the increase of the quantity of green carbon sinks (plants, phytoplankton, and algae containing chloroplasts), the increase of the level of dissolved carbonate and its salts in sea water; or even the capture and transfer of CO_2 to the bottom of the sea in a supercritical state [2]. The most obvious reasonable solution is to develop an efficient process for CO_2 conversion into something valuable, but without spilling other chemicals into the Earth's ecosystems, that might damage their functions. One option lies in using solar energy, which is an abundant, clean and sustainable resource [3], to photocatalytically convert CO_2 into a solar fuel [4]. Solar fuels derived from CO_2 can contribute to neutralize the carbon balance into the atmosphere and can be converted into easily transportable liquid chemicals, such as CH_3OH [5].

In this work, composites prepared from graphene oxide (GO) and titanium dioxide (TiO_2) are applied to the photocatalytic water reduction of CO_2 into renewable fuels. The effect of copper metal as co-catalyst will be assessed and its influence on the photocatalytic reaction inferred.

2 Experimental

GO was synthesized from graphite (particle size ≤ 20 μm, from Sigma-Aldrich) by a modified Hummers method [6]. GO-TiO_2 (hereafter referred as GOT) composites were synthesized by the liquid phase deposition method at room temperature, as described elsewhere [6]. The Cu-loaded GOT photocatalysts were prepared by adapting the procedure described in the literature for Cu-loaded TiO_2 [7]. Additional TiO_2-Cu_2O composites were prepared following the same procedure but without the addition of GO.

Thermogravimetric (TG) analysis of the composites was performed using a STA 490 PC/4/H Luxx Netzsch thermal analyser. The morphology of the materials was studied by scanning electron microscopy (SEM) using a FEI Quanta 400FEG ESEM/EDAX Genesis X4M microscope. The optical properties of the samples were analyzed by UV/Vis diffuse reflectance spectroscopy using a JASCO V-560 UV/Vis spectrophotometer, equipped with an integrating sphere attachment (JASCO ISV-469). X-ray photoelectron spectroscopy (XPS) was performed in a Kratos AXIS Ultra HSA using a monochromatic Al Kα X-ray source (1486.7 eV).

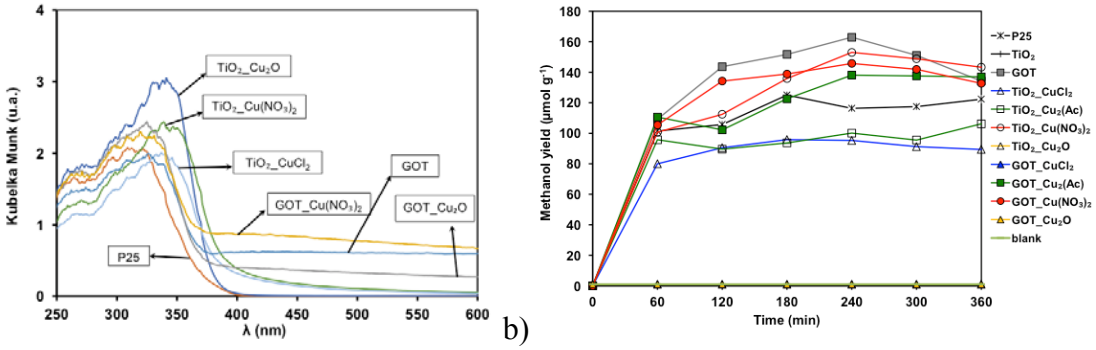
The photocatalytic runs were carried out in a cylindrical glass immersion photo-reactor (250 mL) with a Heraeus TQ 150 medium-pressure mercury vapor lamp located axially in the reactor

and held in a quartz immersion tube. The pH of the solution was controlled by adding NaOH. The photocatalyst load was typically 1 g L^{-1}.

The gaseous products were analyzed on-line, while methanol and ethanol were determined from liquid aliquots, using a gas chromatograph (DANI GC-1000).

3 Results and discussion

A higher absorption in the visible spectral range is clearly observed for GOT and Cu-loaded GOT composites when compared to GO-free materials, i.e., P25, TiO_2_Cu_2O, TiO_2_$Cu(NO_3)_2$ and TiO_2_$CuCl_2$. The increase in the absorption promoted by GO has been ascribed both to the capacity of the carbon phase to absorb light and also to the creation of an electronic inter phase interaction between GO and TiO_2, as previously observed for other carbonaceous materials combined with TiO_2 [6].



a) b)

Fig. 1. a) DRUV spectra of used photocatalysts; b) Methanol yield for photocatalytic water reduction of CO_2.

The evolution of methanol and ethanol yields during the photocatalytic experiments was measured for ten synthesized photocatalysts as well as for the commercial TiO_2 sample. In general, the photocatalysts were efficient for methanol generation with the exception of bare TiO_2, GOT_$CuCl_2$ and the catalysts prepared using Cu_2O as copper precursor (i.e., TiO_2_Cu_2O and GOT_Cu_2O, respectively).

4 Conclusions

The selectivity towards methanol formation is linked to the presence of Cu on the photocatalysts, while the visible light photo-response is assigned to the presence of GO.

Keywords: photocatalysis, hydrogen, biomass, TiO_2, ZnO, polyols

1 Introduction

Sunlight-driven hydrogen production from readily-available biomass-derived resources ('photocatalytic reforming') is a promising route to supply a non-polluting, carbon-neutral energy storage medium [1]. The technology has the potential to provide a simplified pathway compared to overall water splitting as the thermodynamically favored back-reaction during water splitting (i.e. water formation from H_2 and O_2) and the technically difficult separation task imposed by the latter gas mixture, are avoided.

Aiming at a comprehensive and general understanding of the reaction pathways of the anodic half-reactions over co-catalyst decorated semiconductors [2] (that have mostly been hypothesized to occur on the semiconductor surfaces), we have conducted a systematic study of the kinetics of photocatalytic reforming of a series of alcohol and polyol compounds (e.g. methanol, ethylene glycol and glycerol). By comparison of TiO_2-based photocatalysts and visible-light responsive oxynitride photoabsorbers (e.g. GaN:ZnO solid solutions [3]), we furthermore establish the impact of the nature of the semiconductor on reaction pathways and selectivities. The latter semiconductors having been unexplored with respect to solar biomass reforming.

2 Experimental

Oxynitride semiconductors were obtained from nitridation of corresponding oxide precursors. If necessary, the semiconductors were subjected to an additional thermal treatment in synthetic air. Co-catalyst loading was done via wet impregnation with appropriate precursors followed by drying and calcination. TiO_2-based photocatalysts loaded with co-catalysts were prepared from commercial TiO_2 under otherwise identical synthesis conditions.

The physicochemical properties of the photocatalysts were characterized by XRD, HR-SEM/EDX, TEM, BET, UV-Vis spectroscopy and elemental analysis (ICP-AES).

Kinetic experiments were conducted in a top-irradiation Pyrex photoreactor connected to a closed gas-circulation system. Photocatalyst suspensions (75 mg of catalyst suspended in 100 ml of a typically 20 mM aqueous reactant solution) were irradiated using a 300 W Xe lamp. The reactions were monitored by quantitative analysis of both gas- and liquid-phase species.

3 Results and discussion

We have deduced the reaction pathways from the photoreforming kinetics of compounds representative for biomass-derived feeds (and associated intermediates). Throughout all reaction sequences no hydrogen production in absence of irradiation was detected. Fig. 1 depicts photocatalytic hydrogen production from glycerol over 1 wt.% Rh/TiO_2. Initial glycerol conversion involves parallel dehydrogenation (the dominant reaction path) and dehydration (a side reaction) resulting in the formation of e.g. glyceraldehyde and hydroxyacetone, respectively.

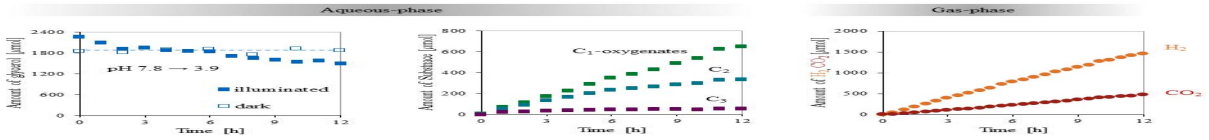

Fig. 1. Temporal profiles of liquid- and gas-phase species generated during photocatalytic hydrogen production from aqeous glycerol solution over Rh/TiO_2.

We have furthermore tracked the consecutive reactions generating C_2 and C_1 intermediates via subsequent C-C cleavage steps and followed the anodic degradation towards full mineralization (formation of CO_2). Investigations with systematically varied reactant structure (e.g. from methanol via ethylene glycol, glycerol to higher molecular weight compounds) revealed a common set of intermediates. In contrast to TiO_2-based systems, comparative investigations on oxynitride photocatalysts provide indication that multiple reaction pathways are operable. We discuss our kinetic results relating the physicochemical properties of the photocatalysts to reaction selectivities and address conceivable mechanisms for C-C cleavage.

4 Conclusions

We have compiled the reaction networks of photocatalytic hydrogen evolution from biomass model compounds over co-catalyst decorated TiO_2-based and oxynitride photocatalysts. We identified and evaluated the existence of multiple reaction pathways coupling into a joint reaction network and correlated kinetic parameters with the physicochemical properties of the photocatalyst systems.

Keywords: ethanol steam reforming, nickel, coke, evolution, hydrogen

1 Introduction

Steam Reforming of Ethanol (SRE) is an attractive route for H_2 production because ethanol is renewable, the increasing demand of H_2, and due to the growing prospects of obtaining ethanol from lignocellulosic biomass (second-generation) favored by the rapid technological development of enzymatic hydrolysis. Several supported catalysts have been studied in the SRE process and among them; Ni^0 has an outstanding C-C and C-H bond-breaking activity and a relatively low price. On the other hand, Ni^0 phases are not completely stable in the reaction conditions and they promote parallel reactions of coke formation and growth [1]. These dynamics foster the catalytic deactivation and the decrease in H_2 production rate. In this work, we have studied the morphologic and compositional dynamics of Ni and coke phases on a Ni/La_2O_3–αAl_2O_3 catalyst during the SRE process. Our aims are establishing a relationship among these dynamics and contribute to the understanding of the catalyst deactivation.

2 Experimental/methodology

The catalyst (with 10 wt% Ni and 9 wt% La_2O_3 nominal contents) was prepared by incipient wetness impregnation method [2], and it was equilibrated by means of a reaction-regeneration cycle [3] in order to achieve a reproducible kinetic behavior. The experiments were carried out in a fluidized bed reactor, with online analysis of reaction products by means of a micro-GC Agilent 3000. The SRE runs were performed at 500 ºC, steam/ethanol molar ratio = 3, W/F_0 = 0.09 g_{cat}·min/g_{EtOH} and time on stream (TOS) values of 1.5, 4, 8, and 20 h. Prior to the SRE, the catalyst was reduced in situ at 700 °C for 2 h by using a H_2–He flow (5 vol% H_2). The dynamic changes of composition and morphology of Ni and coke were characterized by XRD, XPS, Temperature-Programmed Oxidation (TPO), SEM and TEM microscopy, FTIR and Raman spectroscopy.

3 Results and discussion

The evolution of the conversion and product yields allows establishing 3 differentiated stages in the dynamics of the catalyst performance: Stage 1 (TOS < 4 h), with almost steady ethanol conversion values (> 90 %) and a steady H_2 yield (~ 40 %); stage 2 (4 < TOS < 8 h), with a severe drop in ethanol conversion (~ 49 %) as well as in CH_4 and CO yields, and less severe hydrogen yield drop; stage 3 (TOS > 8 h), with a steady and slow decrease in ethanol conversion. These stages of catalyst performance can be correlated with similar stages of coke growth schematized in Fig. 1: In Stage 1, the formation of filamentous coke is observed, which is incipient for TOS < 1.5 h. This type of coke does not block the accessibility of Ni^0 and contributes to increasing the surface area of the catalyst. The origin of this filamentous coke is CH_4 decomposition and Boudouard reaction, and its formation involves a decrease in the Ni^0 particle size due to the formation of Ni-carbides [4]. In Stage 2, there is a change in the mechanism of coke formation due to the change in the composition of the reaction medium

(decreasing amount of CH_4 and CO with parallel increase of ethanol) which originates a change in the composition of coke: the growth of filamentous coke occurs with a simultaneous formation of pyrolytic coke that fills the voids created by the filamentous coke and it is also deposited on the Ni^0 particles. This pyrolytic coke is originated from the decomposition of oxygenates, particularly ethanol and acetaldehyde, and its formation is the main responsible for the fast catalyst deactivation observed in this stage, together with the simultaneous decrease of Ni^0 particle size due to the formation of Ni-carbides. In Stage 3, the growth of filamentous coke slows down in favour of a faster growth of pyrolytic coke with high graphitization, Ni^0 particle size decrease even further and ethanol conversion reaches a value similar to these obtained without catalyst (with an inert solid) in a thermal decomposition process.

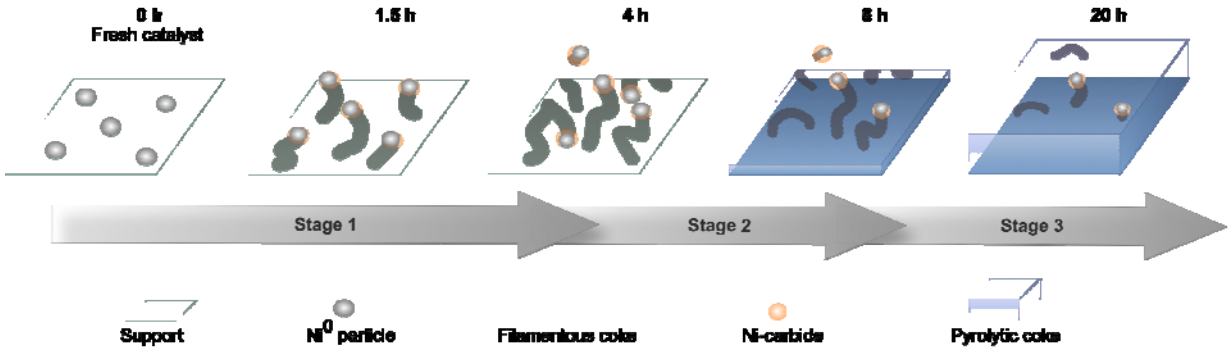

Fig. 1. Surface dynamics and deactivation stages of the Ni/La_2O_3-αAl_2O_3 catalyst during ethanol steam reforming.

4 Conclusions

The deactivation performance of the Ni/La_2O_3–αAl_2O_3 catalyst in the SRE process is strongly correlated with the surface dynamics of Ni^0 and coke, whose growth depends on the concentration of reactants and products in the gaseous phase. Three stages are differentiated during a kinetic run with Ni/La_2O_3–αAl_2O_3 catalyst (almost steady performance, followed by a severe drop in ethanol conversion and finally a steady and slow decrease in ethanol conversion), whose duration depends on the operating conditions (temperature, space time, steam/ethanol molar ratio) and that occur in parallel with the growth of Ni-carbides, filamentous and pyrolytic coke.

CO-Cleanup of Hydrogen-Rich Stream for LT PEM FC Feeding: Catalysts and their Performance in CO Preferential Oxidation and Methanation

Snytnikov P.V.[1,2*], Sobyanin V.A.[1,2]

1 - Boreskov Institute of Catalysis, Novosibirsk, Russia
2 - Novosibirsk State University, Novosibirsk, Russia

* pvsnyt@catalysis.ru

Keywords: preferential CO oxidation and CO methanation, CO clean-up, hydrogen

1 Introduction

In the last two decades, CO preferential oxidation (CO PROX) and CO preferential methanation (CO MET) are assumed as the most feasible reactions for CO removal from H_2-rich reformate for low temperature polymer electrolyte membrane fuel cells (LT PEMFC) feeding applications. Despite the existing advantages and disadvantages, both processes provide CO-cleanup to 10 ppm.

The present report summarizes the results obtained during a systematic study of catalysts, their performances and fundamental principles of the preferential CO oxidation and preferential CO methanation reactions. The most attention is concentrated on Cu/CeO_2 catalysts and their operation in a micro-channel reactor in preferential CO oxidation [1,2], and on Ni/CeO_2 catalysts and their operation in a milli-channel reactor [3,4].

2 Experimental/methodology

CO PROX was studied over supported noble mono-metal based catalysts, supported bimetallic systems prepared with the use of double complex salts, and copper-ceria catalysts [5-7]. CO MET was studied over nickel-based catalysts. The role of nickel precursor was investigated and the positive effect of chlorine on the catalyst selectivity was demonstrated. The catalysts were characterized by BET, XRD, XPS, TEM, EDX, TPR and TPD techniques.

Catalytic performance of the prepared systems in a form of grains in the fixed-bed continuous flow reactor was studied. The Cu/CeO_2 catalysts were coated on the surface of microchanel reactors and investigated in CO PROX. The structured Ni/CeO_2 catalysts supported over corrugated metal gauzes were studied in CO MET reaction in milli-channel reactor.

The effect of internal diffusion was estimated and the optimum grain size/coating thickness was found [8].

3 Results and discussion

Fig. 1a exemplifies the typical effect of temperature on the CO outlet concentration at CO PROX over 5 wt.% CuO/CeO_2 in the single micro-channel reactor at various WHSV. It is seen that the catalyst provides CO outlet concentration below 10 ppm in a wide temperature interval. An assembly comprised of 26 micro-channel reactors (Fig. 1b) demonstrated efficient operation with realistic reformate stream (containing CO_2 and H_2O) supplied at space velocities sufficient for feeding a ~100We portable LT PEM FC. The outlet CO concentration attained ~10 ppm at 100% O_2 conversion.

The temperature dependencies of the CO outlet concentration at CO MET, presented in Fig. 2a, illustrate the excellent performance of 10 wt.% Ni/CeO_2 catalyst and its ability to clean up CO to below 10 ppm in a wide temperature interval. The milli-channel reactor with structured

10 wt.% Ni/CeO_2 catalyst (Fig. 2b) provided CO deep removal from a gas stream fed to a 20 We LT PEMFC.

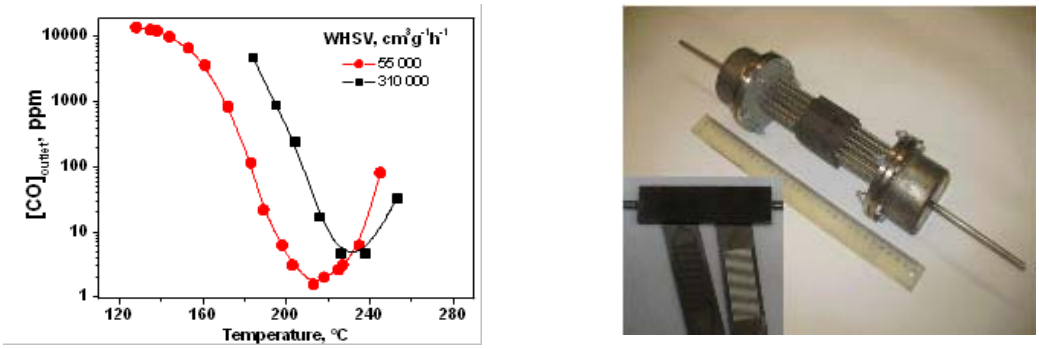

Fig. 1. The temperature dependencies of the CO outlet concentration at CO PROX over 5 wt.% CuO/CeO_2 (a), single and assembly of micro-channel reactors (b). The inlet gas mixture composition (vol.%): 1.5 CO, 2.25 O_2, 20CO_2, 10H_2O, H_2 – balance.

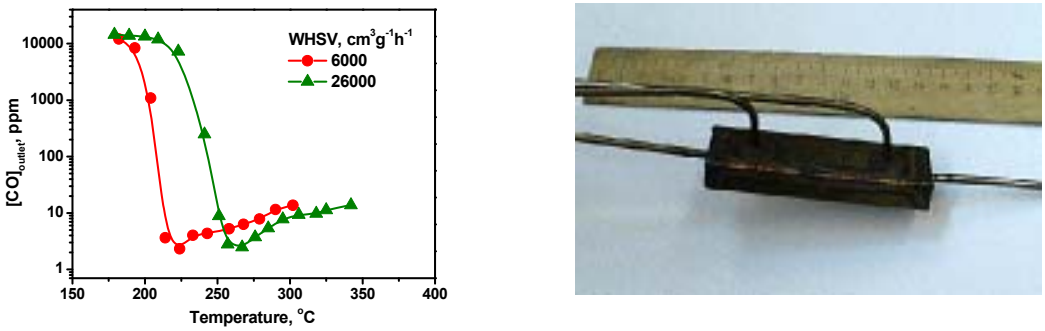

Fig 2. The temperature dependencies of the CO outlet concentration at CO MET over 10 wt.% Ni/CeO_2 (a) and general view with scheme of milli-channel reactor with structured 10 wt.% Ni/CeO_2 catalyst. The inlet gas mixture composition (vol.%): 1.5CO, 20CO_2, 10H_2O, H_2 – balance.

Based on the results obtained, the composition and structure of the catalysts' active components were determined, and reasonable suggestions on the reaction mechanisms of CO PROX and CO MET were made. The CO PROX and CO MET efficiencies were discussed comparatively.

4 Conclusions

The selected copper and nickel-ceria based catalyst provides efficient CO cleanup of H_2-rich gas streams suitable for feeding power generating units on the base of LT PEMFC.

Keywords: steam reforming, methane, hydrogen, Ni, H_2S, core-, shell

1 Introduction

The steam reforming of hydrocarbons is the most economically efficient way to obtain hydrogen and syngas required for ammonia production and petrochemical industy. Hydrogen is also a promising feed for proton exchange membrane fuel cells and solid oxide fuel cells [1].

The current steam reforming catalysts are mainly nickel supported on refractory alumina and ceramic magnesium aluminate. These supports provide high crush strength and stability [2]. However, coke formations and sulfur poisoning are two major problems associated with nickel catalyst. Nowadays, the general tendency is using the noble metals (Rh, Ru, Pt) as active catalytic components. They are less sensitive to deactivation due to carbon deposition and sulfur poisoning. However, the price of such catalysts 100-150 times higher than Ni-containing catalysts [3].

2 Experimental/methodology

The support was prepared at the room temperature by alkali precipitation of a mixed oxide obtained from acidic etching solution of vermiculite [4]. Granules formed from precipitation were dried in air for 48 h., then dried in a desiccator for 6 h. at 120°C, and finally calcined in a furnace with a fixed heating rate 10°C/min and isothermal exposure 1 h. at 600°C, 4 h. at 800°C, 2 h. at 850°C, 1 h. at 900°C. As a result, the mixed (Mg, Al, Fe, Si) oxide was obtained and used as the catalyst support.The support was impregnated by $Ni(NO_3)_2$ solution yielding 10 wt.% Ni. Wet granules were dried with the above drying procedure and then calcined at 500°C for 5 h.

The steam methane reforming was carried out on a laboratory setup with a flow reactor. 20 cm^3 of the catalyst was loaded in the reactor and reduced by hydrogen for 6 hours at 800°C. Then a mixture of hydrogen and pre-heated water vapor was supplied until 800°C temperature was reached. After that, the hydrogen feed was terminated and methane/vapor mixture was supplied (H_2O:CH_4= 2:1, P= 2.0 MPa, VHSV= 6000 h^{-1}). A part of resulting gas products was passed to a gas chromatograph Crystal-4000M where CO, CO_2, CH_4 и H_2 concentrations were measured. The activity of the catalyst was defined as the ratio between the observed methane conversion and equilibrium value for the operation temperature (800°C).. Thereafter all samples were sent to the structure analysis.

The structure and the phase composition of catalytically active components before and after reaction were investigated by XAFS, XRD, EDX, TEM and Moessbauer spectroscopy

3 Results and discussion

The catalytic tests of the Ni-containing catalyst held in the absence of sulfur compounds in the gas-vapor mixture show high activity in the SMR process. Concentrations of all products practically reached the equilibrium and remained stable during the whole operation time.

The Ni-containing catalyst shows high activity and stability in the SMR process also in the presence of H_2S in the gas-vapor mixture. For this purpose a series of tests with different concentrations of hydrogen sulfide (5.0 - 30.0 ppm) in the initial gas mixture were conducted. The increase of H_2S concentration didn't affect the catalyst activity during the experiment.

The XANES spectra indicated that nickel after calcinations stage was presented in the charge state Ni^{+2} and had a surrounding similar to that in NiO and iron was completely oxidized and was most likely located in the spinel structure of maghemite, γ-Fe_2O_3.

The most important changes occur upon the catalyst reduction in H_2 at 800°C. The phases of Mg_2SiO_4 and $Mg(Fe,Al)_2O_4$ spinel become larger in size. Nickel oxide was transformed into a metallic Ni structure but with shifted parameters that could indicate to a partial substitution of nickel atoms by iron and formation of Fe-Ni alloy. By TEM core/shell clusters with size of ~17 nm was found. The core consists of metallic clusters (both FeNi alloys and α-Fe) surrounded by the shell of 1–4 nm superparamagnetic γ-Fe_2O_3

After the catalyst test in the steam reforming of methane, containing 30.0 ppm H_2S the average size of particles of active components grew up from 17 nm (after reduction) to 40 nm. the core/shell configuration of the particle remained the same: the core consists of a FeNi alloy surrounded by a γ-Fe_2O_3 shell. The total size increase of the hybrid particle occurs due to the core growth, whereas the shell size remains in the range 1–4 nm. It should be mentioned that no elemental sulfur was found in the particle composition.

The next step in development of SRM catalysis was creation of synthetic catalytic systems based on γ- Al_2O_3. The main goal was to find optimal synthesis conditions to create catalysis which must repeat composition of catalyst from acidic etching solution of vermiculite. For this purpose series of samples was produced. They were tested in steam reforming of methane process. It was established that concentrations of all products practically reached the equilibrium during the whole operation time.

4 Conclusions

Nanoscale Ni-containing catalysts supported on spinel $Mg(FeAl)_2O_4$ show high activity in steam methane reforming (SMR) and partial oxidation of 30ppm H_2S in gas mixture.

The structural studies of the SMR catalyst by XAFS, XRD, EDX, HRTEM methods and Mossbauer spectroscopy reveal that after addition of Ni as an active ingredient and reduction in H_2 the hybrid cluster system with a core (γ-Fe_2O_3) /shell (FeNi) configuration is formed. In this case the core of the hybrid system, consisting of nano-sized particles of FeNi alloy, provides activity in the SMR process, while the γ-Fe_2O_3 clusters of the shell are the active component for the decomposition of hydrogen sulfide into elemental sulfur

Mechanistic Implications on Low Temperature Steam Reforming of Methane over Ni/La/CeO_2-ZrO_2

Angeli S.D., Lemonidou A.A.*

Department of Chemical Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

* alemonidou@cheng.auth.gr

Keywords: steam reforming, methane, ceria-zirconia, mechanism, nickel

1 Introduction

Industrial steam reforming of methane for hydrogen production is accompanied by significant GHG emissions, mainly from the burner used to supply heat to the endothermic reaction. Low temperature steam reforming can lead to significant environmental and process benefits, such as reduced energy needs, milder material stability requirements and considerably simplified process layouts. On the other hand, methane steam reforming at low reaction temperature (400-550 ^oC) results in low CH_4 conversions due to thermodynamic limitations, which, however, can be surpassed by using hydrogen-selective membrane reactors.

Previous studies showed that Ni/La/CeO_2-ZrO_2 is highly active in the low temperature range as well as coke resistant even in the presence of hydrocarbon-type impurities [1] . The performance can be ascribed to CeO_2-ZrO_2 due to the active role in the redox mechanism and the gasification of carbon depositions through the mobility of surface oxygen species. Moreover, the presence of La enhances the oxygen storage capacity and the thermal stabilization of the catalyst.

In this work, we report mechanistic implications of low temperature steam reforming of methane over Ni/La/CeO_2-ZrO_2. The mobility of surface/lattice oxygen species, which may participate in the reaction scheme, is determined by isotope oxygen hetero-exchange. Methane decomposition, which has been reported as the rate determining step over nickel catalysts [2], is investigated.

2 Experimental

The catalyst containing 10wt% Ni was prepared via wet impregnation. The metal was deposited on a support containing 78%ZrO_2, 17% CeO_2 and 5%La_2O_3 that was provided by Mel Chemicals. After the deposition and the removal of the solvent the sample was dried and finally calcined at 800^oC for 5h. Basic characterization of the catalyst was realized through XRD, and H_2-TPR. Oxygen mobility was measured by temperature programmed ^{18}O isotopic exchange experiments in prereduced sample (T_{red} = 550 ^oC). The experiments took place in a U-shape reactor in a transient unit coupled with MS detector. The kinetic isotope effect of methane decomposition in 1.7%CH_4/He or 1.7%CD_4/ 15%Ar/balance He was investigated in temperature programmed mode in a heating rate of 10^oC/min.

3 Results and discussion

XRD of the sample Ni/La/CeO_2-ZrO_2 showed peaks corresponding to the Ni in oxidic form and the crystal phase of mixed $Zr_{0.84}Ce_{0.16}O_2$. No peaks of lanthana were detected implying that the dopant is finely dispersed. The reduction of Ni can be achieved at relatively mild conditions, important for the application of the low temperature steam reforming concept, with T_{max} at 480^oC.

Figure 1a depicts the evolution of the rate of oxygen exchange as a function of temperature. Consumption of $^{18}O_2$ with onset at 220 ^oC, not accompanied initially by evolution of $^{16}O_2$ or

$^{16}O^{18}O$ is attributed to reoxidation of the reduced sample. Both simple and multiple oxygen hetero-exchange are triggered at 360 °C with multiple hetero-exchange being dominating up to 500 °C. Maximum rates of $^{16}O_2$ and $^{18}O^{16}O$ evolution were observed within the temperature range of interest for the steam reforming reaction (400-550 °C). High surface/lattice oxygen mobility may play an active role in the redox mechanism by oxidizing CH_x fragments and also prevent the accumulation of carbon species on the catalytic surface.

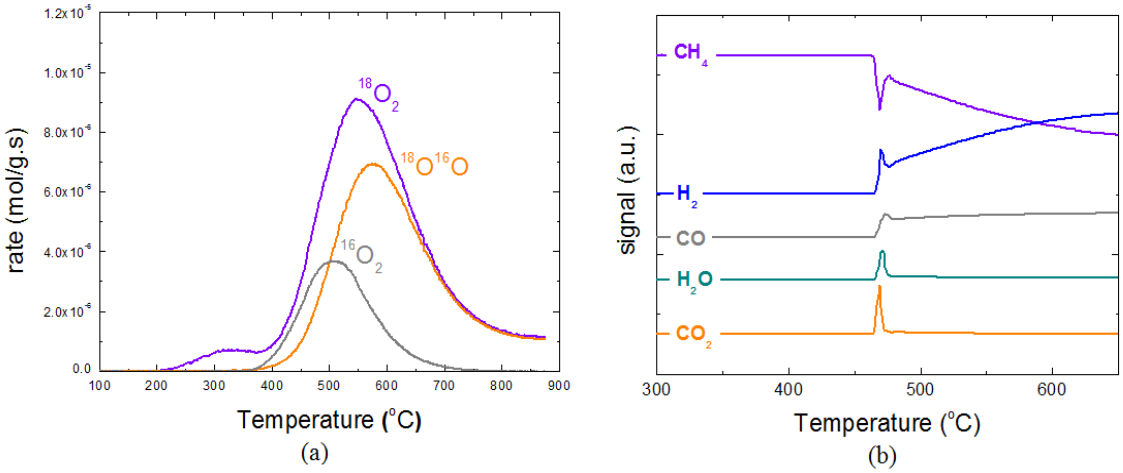

Fig. 1. (a) ^{18}O isotopic exchange profile over prereduced Ni/La/CeO_2-ZrO_2 (b) gas responses during temperature programmed methane decomposition over Ni/La/CeO_2-ZrO_2.

Methane decomposition produces hydrogen and solid carbon. However, at the onset temperature (455 °C), consumption of CH_4 leads to instant formation of H_2O and CO_2 and later to CO along with H_2 (Figure 1b). The production of oxygen-containing products in the absence of gaseous oxygen is attributed to the participation of support oxygen species in the reaction scheme. Additional experiments in methane decomposition using CD_4 instead of CH_4, which are currently in progress will allow the determination of the kinetic isotope effect and provide information about the rate-determining step. Steam reforming reaction experiments using CH_4 and CD_4 and the calculation of the kinetic isotope effect in the presence of steam, constitutes important aspects of the mechanistic study and will be conducted in the near future.

4 Conclusions

The mechanism of methane steam reforming in the low temperature range (<550 °C) is investigated over Ni/La/CeO_2-ZrO_2. H_2-TPR showed that the catalyst can be fully reduced within the temperature range of operation allowing the reduction process being conducted without the need of further heating of the reactor. At the same temperature range the catalyst showed maximum oxygen mobility as determined by oxygen isotopic exchange tests, which might contribute to the high activity and coke resistance of the catalyst. Temperature programmed methane decomposition showed that lattice oxygen of the partially reduced support participates in the reaction scheme.

Keywords: ethanol, steam reforming, syngas, complex oxides, Pt/Ni+Ru, mechanism, FTIRS *in situ*

1 Introduction

Nanocomposites based on bulk/supported fluorite-like/perovskite-like complex oxides promoted by Pt/Ni+Ru etc are known to be efficient and stable to coking catalysts of ethanol steam reforming (ESR) [1, 2]. Optimization of their composition is to be based upon knowledge of the detailed mechanism of catalytic reaction. FTIRS *in situ* is a powerful tool for identification of the nature of surface species and estimation of the rates of their transformation required for this purpose [3, 4]. This work presents results of such studies for two types of catalysts based on bulk fluorite-like oxide and supported on alumina perovskite-like oxide.

2 Experimental/methodology

$Pr_{0.15}Sm_{0.15}Ce_{0.35}Zr_{0.35}O_2$ fluorite-like oxide (Catalyst I) was prepared by polymerized complex precursor (Pechini) route and calcined in air at 900°C for 2 h [5]. Pt (1.4wt.%) was supported via incipient wetness impregnation with H_2PtCl_6 solution. 10wt.% $LaNi_{0.95}Ru_{0.05}O_3$/Mg-alumina catalyst (Catalyst II) was prepared using as a source a high purity γ-alumina prepared by decomposition of aluminium hydroxide "Disperal" (Sasol) under air at 700 °C. 10 wt. % MgO and 10wt.% $LaNi_{0.95}Ru_{0.05}O_3$ were successively supported by incipient wetness impregnation with inorganic salts solution followed after each step by calcination under air at 700 °C for 2 h. Catalysts pressed into pellets were studied in the flow IR cell with NaCl windows using a CARY 660 (Agilent) FTIR spectrometer. After standard pretreatment in the stream of 20%O_2 in He at 450 °C the catalysts were cooled in He to room temperature, and ethanol was adsorbed from the flow of 1% C_2H_5OH in He. After purging cell by He, samples were heated in the He stream by steps of 50 °C up to 500 °C with spectra recording. Dynamics of the surface species transformation under contact with the stream of 2% H_2O in He was studied in the isothermal mode in the same temperature range. Gas composition at the cell outlet was analyzed by FTIR spectrometer and on-line IR absorbance, electrochemical and polarographic gas sensors [5].

3 Results and discussion

After ethanol adsorption at room temperature, bands corresponding to molecularly adsorbed ethanol (1280 cm^{-1}), water (1600 cm^{-1}) and ethoxy species (1450, 1380-1400, 1341, 1082-1100, 1046-1052 cm^{-1}, several types of terminal and bridging forms) formed by dissociative adsorption of ethanol are observed. Desorption into the stream of He with the step-wise increase of temperature is accompanied by the decrease of intensity of bands corresponding to ethanol and ethoxy species disappearing completely at T> 250 °C. Bands corresponding to acetate species (1430-1434 and 1550-1575 cm^{-1}) emerge at ~ 200 °C, their intensity growing to the maximum at 350 °C with subsequent slow decline.

Under contact with the stream of 1%H_2O in He, ethanol and ethoxy species are consumed, acetaldehyde is formed and then consumed, while acetate species are accumulated. Estimation of efficient first-order rate constants (Table 1) revealed that ethoxy groups are very reactive, so their transformation into acetaldehyde by dehydrogenation is not the rate-determining stage (rds). Transformation of acetaldehyde via C-C-bond rupture on Me sites with CH_4 as by-product is rds of ESR [4]. Acetates are spectators formed by slow acetaldehyde oxidation [4]. At T~400 ^oC only acetates are observed on the surface of catalysts in steady-state conditions being able to react with water at these temperatures. Estimation of the efficient first-order rate constant of acetates consumption by reaction with H_2O at 400 ^oC gives value ~ 10^{-3} s^{-1}, which is much lower than the rate constant of ethanol consumption This agrees with conclusion on the step-wise red-ox scheme of ESR on these catalysts with CH_4 as by-product [5]. For Catalyst II with a lower red-ox ability transformation of ethoxy species on acid sites is also accompanied by formation of such by-products as C_2H_4 and $(C_2H_5)_2O$ via dehydration route.

Table 1. Efficient rate constants of adspecies transformation for Catalyst I.

T, ^oC	k, s^{-1} (n=1)			
	Acetaldehyde consumption	**Ethoxy consumption**	**Ethanol consumption**	**Acetate formation**
	Absorption band, cm^{-1}			
	1710	**1145**	**1036**	**1436**
150	0.043	2.125	0.058	0.0055
200	0.075	2.457	0.079	0.0103
250	0.119	-	-	0.0172
300	-	-	-	0.0262

4 Conclusions

For $Pt/Pr_{0.15}Sm_{0.15}Ce_{0.35}Zr_{0.35}O_2$ and $LaNi_{0.95}Ru_{0.05}O_3$/Mg-alumina catalysts *in situ* FTIRS studies revealed that in ESR reaction transformation of ethoxy species by dehydrogenation is a fast step, while the rate-determining stage is the C-C bond rupture in thus formed acetaldehyde. Acetate species are spectators, while transformation of ethoxy species on acid sites of alumina-supported catalysts produces C_2H_4 and $(C_2H_5)_2O$ via dehydration route.

Iron Oxide-Type Structured Catalyst for Water Gas Shift Reaction

Watanabe R., Watanabe S., Fukuhara C.*

Department of Applied Chemistry and Biochemical Engineering, Graduate school of Engineering, Shizuoka University, Shizuoka, Japan

* tcfukuh@ipc.shizuoka.ac.jp

Keywords: iron oxide structured catalyst, water gas shift reaction, redox

1 Introduction

The importance of hydrogen production, mainly from natural gas steam reforming, as a clean energy source is increasing year by year. The reformed gas contains hydrogen as well as carbon monoxide. For producing more hydrogen with removing carbon monoxide, the water gas shift (WGS) reaction is an effective approach.

$$CO + H_2O \rightleftarrows CO_2 + H_2 \qquad \Delta H^0 = -41.2\ kJ \cdot mol^{-1} \qquad (eq.1)$$

In the industrial processes, the WGS reaction is performed with a two-stage catalytic processes: a high temperature shift (HTS) with a Fe_2O_3-Cr_2O_3 catalyst and a low temperature shift (LTS) with a Cu/ZnO/Al_2O_3 catalyst. The Fe_2O_3-Cr_2O_3 catalyst has an insufficient activity at low temperatures. Furthermore, Cr, which is contained in the catalyst, is a highly toxic to humans and the environment. The Cu/ZnO/Al_2O_3 catalyst is deactivated by an oxidizing atmosphere. Therefore, the catalyst with a high activity at a low temperature and stable in an oxidative atmosphere are required. The previous work revealed that the Fe_2O_3 catalyst modified by Pd and K showed a significantly higher activity than the industrial HTS catalyst at 573 K [1].

For further enhancement of the catalytic activity, we focused on a plate-type catalyst on a metal substrate. The plate-type catalyst, which is commonly called a structured catalyst, is composed of a regularly arranged catalyst on the metal plate. The structured catalyst could overcome the disadvantage of a poor heat conductivity of the iron oxide-type material, and high activity would be obtained at a low temperature due to the effective utilization for the external heat energy.

In this study, the iron oxide-type structured catalyst was developed on a metal substrate. The WGS performance of the plate-like iron oxide-type catalyst was investigated. In addition, the effects of Pd and K supported on the iron oxide-type structured catalyst on the performance were examined for enhancing the WGS activity.

2 Experimental

The structured iron oxide-type catalyst was prepared by a hydrothermal synthesis as follows; the aluminum substrate (JIS A1100P) was activated by NaOH *aq*. and HCl *aq*. at 293 K for 5 and 2.5 min. The activated substrate was then immersed in the iron precursor solution, which was prepared with $FeCl_3$ and urea in distillated water. Subsequently, the hydrothermal synthesis was performed at 368 K for 11 h to form the iron oxide on the aluminum plate. The iron oxide-type structured catalyst was then prepared by calcinating at 573 K for 2 h under N_2 atmosphere. For loading the promoter, the structured catalyst was immersed in the CH_3COOK solution. After immersing, the structured catalyst was calcined at 773 K for 2 h. Subsequently, the promoted catalyst was immersed in the $PdCl_2$ solution, and calcined at 773 K for 2 h.

Activity tests were performed at 573–823 K after setting the structured catalyst at the center of the quarts tube. Reactants of CO and H_2O were supplied to the catalyst at 5.0 and 10.0 ml min^{-1}, respectively. The gaseous reactants and products, such as CO, CO_2 and CH_4, after the

trapping of steam in the effluent gas through the cold trap were collected by a gas-tight syringe, then injected into the off-line thermal conductivity detection gas chromatograph (GC-8A; Shimadzu Co., Ltd., Japan).

3 Results and discussion

Figure 1 shows the surface images of the prepared iron oxide structured catalyst measured by FE-SEM. From these images, the circular sheets were observed on the surface of the catalyst. The diameter of the circular sheet is about 3 μm, and the thickness of the sheet is a few tens of nanometers. Such micro-sheet is stacked in a random manner on the aluminum plate. Figure 2 denotes the elemental mapping of the micro-sheet. From the mapping, the micro-sheet was composed with aluminum and iron components. The aluminum came from the aluminum substrate because the iron precursor solution does not include the aluminum component. Namely, the aluminum component was dissolved from the aluminum substrate and was incorporated in the micro-sheet during the hydrothermal synthesis. The structure of the micro-sheet was not confirmed by the XRD measurement (not shown in this proceeding). The result meant that an amorphous phase of the iron-oxide might be formed on the aluminum substrate.

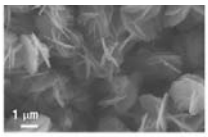

Figure 1 FE-SEM image for the iron structured catalyst.

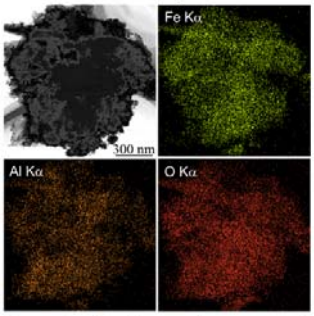

Figure 2 the elemental mapping of the micro-sheet.

Figure 3 denotes CO conversion at from 573 to 823 K over the iron oxide-based structured catalysts. To promote WGS activity, potassium and palladium were loaded on the iron oxide structured catalyst (abbreviated as Pd/K/FeO_x/Al-plate). The WGS activity over the Pd/K/FeO_x/Al-plate was obtained about 10%-conversion at low temperature of 573 K. On the other hands, other catalysts did not show any activity at 573 K. These results were satisfied with the previous study [1]. Namely, Pd, K, and Fe were necessary to show the WGS activity, and their synergetic effect was important for the WGS reaction.

Figure 4 shows the comparison of the activity of the structured catalyst with that of the Cu/ZnO/Al_2O_3 catalyst. The catalytic activity of the Pd/K/FeO_x/Al-plate increased with reaction time, while the Cu/ZnO/Al_2O_3 catalyst showed a deactivation behavior. The developed iron oxide structured catalyst had a higher stability than the commercial Cu-based catalyst.

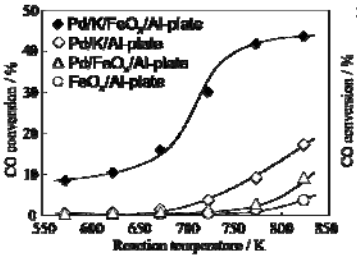

Figure 3 WGS performances of the various catalysts.

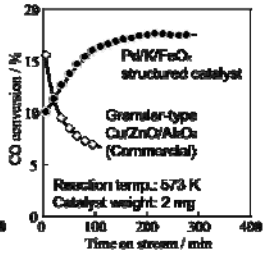

Figure 4 WGS activity of the structured and Cu-based catalysts.

4 Conclusions

The prepared iron oxide on the aluminum substrate had the characteristic morphology; the micro-sheet of iron oxide was formed on the substrate. To promote the WGS performance, Pd and K was loaded on the iron oxide structured catalyst. High activity was obtained over the Pd/K/FeO_x/Al-plate catalyst. The prepared catalyst had a superior stability to the Cu-based catalyst.

Low Temperature CH_4 Oxy-Reforming Coupled with Pd-Based Membrane for an Energy-Efficient Process for Syngas Production

Abate S.[1], Basile F.[2], Fornasari G.[2], Lombardi E.[2], Mafessanti R.[2*], Vaccari A.[2]

Keywords: hydrogen, syngas, oxy-reforming, $Rh/Ce_{0.5}Zr_{0.5}O_2$, Pd-based membrane, H_2 purification

1 Introduction

The possibility to produce H_2 and syngas from methane at relative low temperature (700-750°C) is faced by two combined approach: 1) coupling reforming and CPO reactions using low residence time in a so–called oxy-reforming with low oxygen contents and S/C ratios. The oxy-reforming allows low external heat supply, low oxygen consumption and good control of the temperature profile which avoid sintering; 2) coupling the oxy-reforming with separation by Pd dense membrane aiming to produce pure H_2 or, in case of high pressure, syngas with a second conversion step after separation. In the present experimental configuration low radial and axial ΔT (30-50°C at 150-36 ms) are present allowing the possibility of reliable catalysts comparison, enhancing catalysts differences at low residence times. Catalyst selection have been carried out on the base of activity data and their stability against carbon formation, favored by the low S/C and O_2/C (0.7, 0.2 respectively). New catalysts based on $Rh/CeZrO_2$ have been developed using inverse microemulsion synthesis, aimed to obtain the specific $Ce_{0.5}Zr_{0.5}O_2$ phase. The coupling of oxy-reforming with a Pd thin dense membrane, placed downstream the reactor for H_2 selective separation, was studied at different S/C ratios, GHSV and P, investigating the permeability and stability of the system.

2 Experimental/methodology

Catalytic tests are carried out in a plant using the operative conditions reported in Table 1.

Table 1. Catalytic tests carried out without and with the membrane placed downstream of the reactor.

Operative Parameters	Without Membrane	With Membrane
T_{oven} [°C]	750	750 ($T_{memb.}$ = 400°C)
P [atm]	1; 3; 5; 10; 20	3; 5
GHSV [h^{-1}]	24000; 50000; 100000	24000; 100000
Steam to Carbon ratio (S/C)	0.7-1	0.7 – 1
Feed composition (CH_4; O_2; $H_2O_{(v)}$) [%v/v]	52; 11; 37	45.5; 9; 45.5

The catalysts used were Ceria-Zirconia mixed oxides obtained by inverse microemulsion (Ce/Zr-m) synthesis [1] and co-precipitation (Ce/Zr-cp) with Ce/Zr 75/25 and 50/50 a.r.. The samples were calcined at 750°C and impregnated with Rh (1 wt%). The catalysts were characterized using XRD, TPR/O, Raman, SEM, TEM-EDX and porosimetry.

The research part regarding the membrane for H_2 separation was carried out in collaboration with the University of Messina, where the actual membrane preparation was performed following the Electroless Plating Deposition (EPD) technique.

3 Results and discussion

The synthesis of the $CeZrO_2$ support carried out by microemulsion showed (by TEM-EDX) a

Ce/Zr ratio significantly more homogeneous than which obtained by co-precipitation both with Ce/Zr 75/25 and 50/50. The Ce/Zr-m 50/50 allows to obtain the specific $Ce_{0.5}Zr_{0.5}O_2$ phase detected by XRD, compatible with the tetragonal *t''* phase as confirmed by Raman spectra. Otherwise the co-precipitation lead to a XRD pattern with reflections centred on $Ce_{0.6}Zr_{0.4}O_2$ phase. Furthermore both microemulsion samples have particle and pore size with a sharp mono-modal distribution leading to a very good dispersion of the Rh after impregnation (2-3 nm).

The catalytic activity of the sample characterized by the Ce/Zr-m support, calcined at 750°C and impregnated with 1wt% of Rh (Rh1IWI_CZO-m750) is shown in figure 1. Regardless the reaction conditions, this sample shows an high activity with CH_4 conversions equal (at $24000h^{-1}$) to those calculated at the thermodynamic equilibrium. At higher GHSV, experimental data do not reach equilibrium even at 5 atm, while an higher S/C ratio slightly improve the CH_4 conversion, as shown from the data recorded at 3 atm and 100000 h^{-1}. Increasing pressure up to 10 and 20 atm the equilibrium is always reached, even at high GHSV values. The samples obtained by co-precipitation give lower conversion than those prepared by microemulsion both comparing the Ce/Zr 75/25 and 50/50, probably due to the better dispersion of the Rh in the Ce/Zr-m support. The effect of the support is also clear studying the deactivation phenomena. After 30 h time-on-stream the $Ce_{0.5}Zr_{0.5}O_2$ is very stable and no carbon formation is observed. Otherwise, different deactivation grades occur in the other samples with the following scale of stability: 50/50-m > 50/50-cp and 75/25-m > 75/25-cp, demonstrating the importance of the $CeZrO_2$ phase and its homogeneity. The peculiar properties of the $Ce_{0.5}Zr_{0.5}O_2$ are most likely due to the high oxygen mobility [2].

Feeding the outlet reformate gas to the membrane module ($T_{memb.}$ = 400°C) the gas mixture is separated using a thin Pd membrane on ceramic support for which the permeability rate (125 $mL \cdot cm^2/min$) have been previously determined with pure H_2 at 400°C and different pressures. The results of the dry gas (DG) compositions before the membrane and those relative to the permeate and the retentate streams are reported in figure 2 (a) and (b). The high H_2 permeability value of these Pd membrane allows to reach an high grade of separation together with a selectivity equal to 100% and good stability (20-25h time-on-stream). Regardless the GHSV values, the H_2 permeation is limited by the H_2 partial pressure (p_{H_2}) in the retentate that reach 1atm at the exit of the membrane ($\Delta p_{H_2} = 0$). The test at 5 atm allows to obtain a lower H_2 content in the retentate (< 30% on DG basis) which can further decrease by increasing the Δp_{H_2} using a sweep gas in the permeate side.

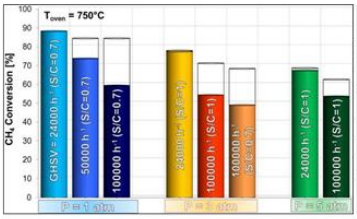

Fig. 1. Catalytic activity of Rh1IWI_CZO-m750 in function of P, GHSV and S/C ratio

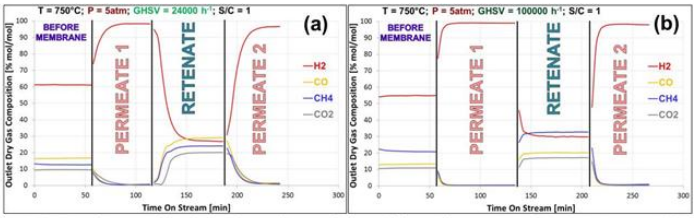

Fig. 2. DG outlet composition before the membrane and those relative to the permeate and retentate streams at: (a) $24000h^{-1}$; (b) $100000h^{-1}$

4 Conclusions

Inverse microemulsion is an interesting method for support preparation, leading to an high homogeneity both in terms of the particle size and the nature of the crystalline phase. $Rh/Ce_{0.5}Zr_{0.5}O_2$ shows the best activity due to the high Rh dispersion related with the homogeneous pore size of the support, and an high stability due to the enhanced oxygen mobility of the $Ce_{0.5}Zr_{0.5}O_2$ phase. The process for hydrogen production and separation have been demonstrated by using oxy-reforming and a downstream thin Pd membrane, which showed to be effective to obtain 100% H_2 stream, limited only by Δp_{H_2} which can be easily increased.

Keywords: hydrogen production, methanol steam reforming, bimetallic catalyst, Cu-Ni, ZrO_2

1 Introduction

Hydrogen is considered as a perspective fuel because of its high calorific value and complete absence of toxicity because the only product of its oxidation is water. It can be efficiently utilized by combining with fuel cells, which can directly convert the chemical energy into electricity. Methanol has some advantages as a hydrogen source because it is one of the commodity chemicals [1] and it can be easily transformed into hydrogen at low temperatures. Methanol steam reforming (MSR) is an efficient process for maximizing the hydrogen production and minimizing the carbon monoxide formation. A lot of works was devoted to the investigation of an appropriate catalyst. Traditionally, copper-based catalysts distinguished by high activity and selectivity are applied in the MSR reaction. It is known also, that the most active catalysts in dehydrogenation processes are bimetallic supported systems [2]. But this issue is still of current importance for catalytic science and industry.

The aim of this work was to investigate influence of a support – ZrO_2 structure and composition of Ni-Cu bimetallic catalysts in process of methanol steam reforming.

2 Experimental/methodology

ZrO_2 was prepared by precipitation method and annealed at two different temperatures. Obtained support was promoted by Y_2O_3 and La_2O_3 to stabilize a cubic structure. Bimetallic catalysts were prepared by sequential impregnation of oxide supports (ZrO_2, ZrO_2-Y_2O_3, ZrO_2-La_2O_3) by Cu and Ni salts to achieve metal ratio 1:4 and 4:1. Obtained catalysts were tested in MSR reaction for H_2 production at different temperatures. Catalysts were characterized by DSC/TGA, BET, SEM, XRD, TEM.

3 Results and discussion

According to XRD data obtained ZrO_2 had three different modifications. Samples annealed at 350º C had an amorphous structure, and at 400º C were monoclinic. ZrO_2 doped with Y_2O_3 and La_2O_3 had cubic modification. Maximum hydrogen yield (≈2 mol per 1 mol of methanol) was achieved with the use of $Ni_{0.2}$-$Cu_{0.8}$/amorphous ZrO_2 catalyst. Presence of amorphous ZrO_2 provides high active sites concentration, which greatly improves water adsorption and composite activity. Increase of ZrO_2 support crystallinity results in the decrease of a surface area, reduction of sorption properties and the drop of catalyst activity.

It was determined that selectivity of copper-based catalysts is higher than nickel-based. It can be ascribed to change of methanol adsorption mechanism on the catalyst surface. Single-center alcohol adsorption is more preferable on catalysts with a high copper content. This in turn

reduces the CO output. A lower Fermi level of the copper-based catalysts also can promote deeper methanol oxidation to CO_2. Figure 1 shows a dependence of hydrogen yield on catalyst type and a typical TEM image of Cu-Ni/ZrO_2 catalyst. The obtained data enables to conclude that the most probable mechanism of MSR process is bifunctional and includes simultaneous water adsorption on ZrO_2 support and alcohol adsorption on metal catalyst.

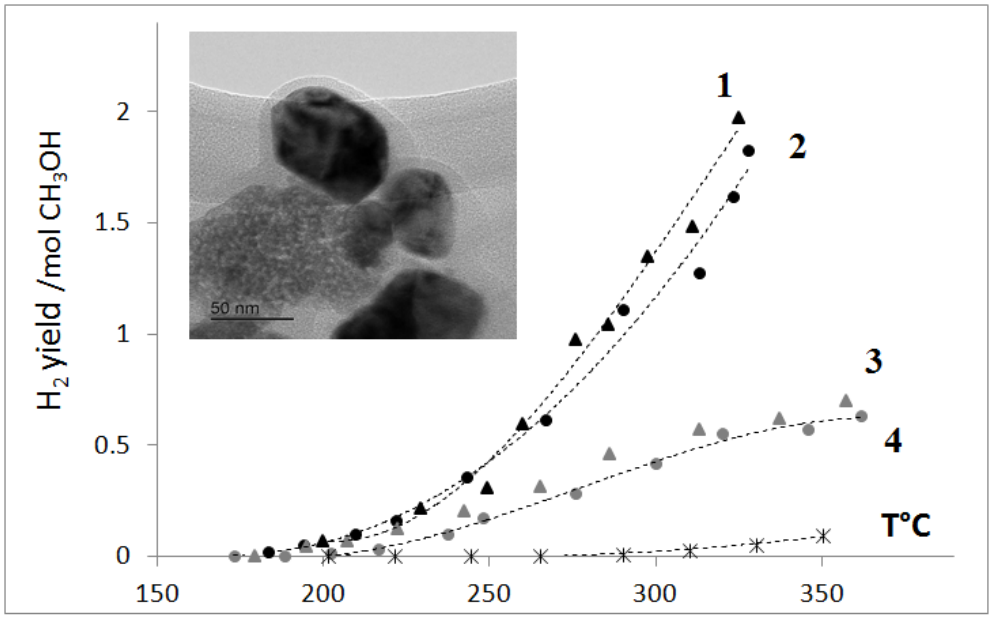

Fig. 1. Typical TEM image and hydrogen yield in SRM reaction on: 1) $Cu_{0.8}$-$Ni_{0.2}$/ amorphous ZrO_2; 2) $Cu_{0.2}$-$Ni_{0.8}$/ amorphous ZrO_2; 3) $Cu_{0.8}$-$Ni_{0.2}$/ monoclinic ZrO_2; 4) $Cu_{0.2}$-$Ni_{0.8}$/ monoclinic ZrO_2 catalysts

4 Conclusions

New catalysts ($Ni_{0.8}$-$Cu_{0.2}$/ZrO_2, $Ni_{0.2}$-$Cu_{0.8}$/ZrO_2) were developed for the methanol steam reforming process. It was confirmed that obtained catalysts are active in MSR reaction. Catalysts showed good stability without apparent deactivation during the testing. It was shown also, that support structure has the main influence on composites activity, while the nature of a dominant metal affected on the selectivity of the resulting catalysts. The influence of support structure on the mechanism of MSR reaction was discussed. The most active and selective catalyst was the amorphous sample $Ni_{0.2}$-$Cu_{0.8}$/ZrO_2. The most probable mechanism of MSR process is bifunctional and includes simultaneous water adsorption on ZrO_2 support and alcohol adsorption on metal catalyst.

Keywords: medium temperature water gas shift, Cu/Zn/Al catalysts, Zr, La, Ce

1 Introduction

H_2 is widely considered as the main clean fuel of the future and is also a relevant raw material in chemical and petrochemical industry. One of the largest sources of H_2 is the Water Gas Shift (WGS) reaction, performed after hydrocarbon steam reforming (SR) of biomass gasification reactors to reduce the CO content in the final gas stream or to adjust the H_2/CO ratio for further processes (methanol and/or higher molecular weight alcohols or hydrocarbon Fischer-Tropsch syntheses). Currently, the WGS reaction is performed in two steps to achieve highest productivity: High Temperature Shift (HTS, T > 350 °C) followed by a Low Temperature Shift (LTS, T = 230-250 °C) [1]. More recently, the industrial interest moved towards new catalysts able to operate at medium temperature (MTS, T = 300°C ca.) with high activity, selectivity and stability with time-on-stream, that allow to operate in only one reactor and with low steam/dry gas ratio (S/DG). In a previous patent [2] it was reported the doping of traditional LTS Cu/Zn/Al catalysts by Ce, La, Zr, to enhance the thermal and hydrothermal stability, although only surface area values were reported. Aim of this paper was to shed light on the effects of these elements on surface and bulk properties and catalytic activity of Cu/Zn/Al MTS catalyst.

2 Experimental

The Cu/Zn/Al/X (X= Ce, Zr or La; Cu = 20 wt.%;) catalysts were obtained by coprecipitation at 60 °C and pH = 9.0 of hydrotalcite-type (HT) precursors from the nitrates of the elements, followed by calcination at 550 °C for 6 h and reduction in programmed temperature feeding a H_2/N_2 gas mixture [3]. The catalytic tests were performed in a fixed-bed reactor (INCOLOY), operating at 1.5 MPa and 250-350°C, feeding a $CO/CH_4/CO_2/H_2$: 18.8/4.6/4.6/72.0 (v/v) gas mixture. H_2O was introduced in a preheater by using a Jasco HPLC pump, operating with two S/DG ratio (0.55 or 0.25) and contact time (τ) values (0,5 and 1.0 s). The effect of the dopants on the structure and on the performance of the catalyst before and after the reaction tests was investigated by X-ray diffraction (XRD), N_2 adsorption/desorption, H_2-TPR and N_2O titration.

3 Results and discussion

To evaluate the thermal stability of the La, Ce, Zr-containing catalyst, the dried precursors were calcined at increasing temperatures (360, 460 and 550 °C) and the BET surface area values were compared to a reference Cu/Zn/Al catalyst without promoters (CAT ref). Table 1 shows the positive effect of the promoters on the thermal stability of the catalysts, evidencing a remarkable increase of the thermal stability for all the catalysts in comparison to the reference one, with a similar trend also for Cu surface area and dispersion. Catalytic tests were carried out

on the La and Zr-containing catalysts, that showed the higher surface area values. The results obtained are summarized in figure 1, with experimental CO conversion values compared to calculated CO conversions at the thermodynamic equilibrium for corresponding outlet temperature.

Table 1. Values of specific surface area and porosity and N_2O titration as a function of the calcination temperature (in brackets). The pore volume and diameter and the Cu surface area are referred to the samples calcined at 550 °C for 6 h.

	BET S.A (m^2/g) [360 °C]	BET S.A (m^2/g) [460 °C]	BET S.A (m^2/g) [550°C]	Cu S.A. (m^2/g_{CAT})	Pore volume (cm^3/g)	Pore diameter (nm)
CAT ref	**57**	**62**	**48**	**5**	**0.35**	**28**
CAT La	95	94	70	9	0.36	16
CAT Ce	89	82	58	8	0.35	19
CAT Zr	94	91	76	9	0.39	20

The activity was similar for both promoted catalysts, with better CO conversion values than that of not promoted catalyst in all the reaction conditions investigated. In particular, for S/DG = 0.55; τ = 0.5 s, T = 250 °C the promoted catalysts showed the highest increase of activity. At the higher contact time value (τ = 1.0 s, S/DG= 0.55), both promoted catalysts reached the equilibrium values regardless of the temperature, while the decrease of the S/DG ratio to 0.25, worsened dramatically the activity of all the catalysts, with the worst results observed at 250 °C.

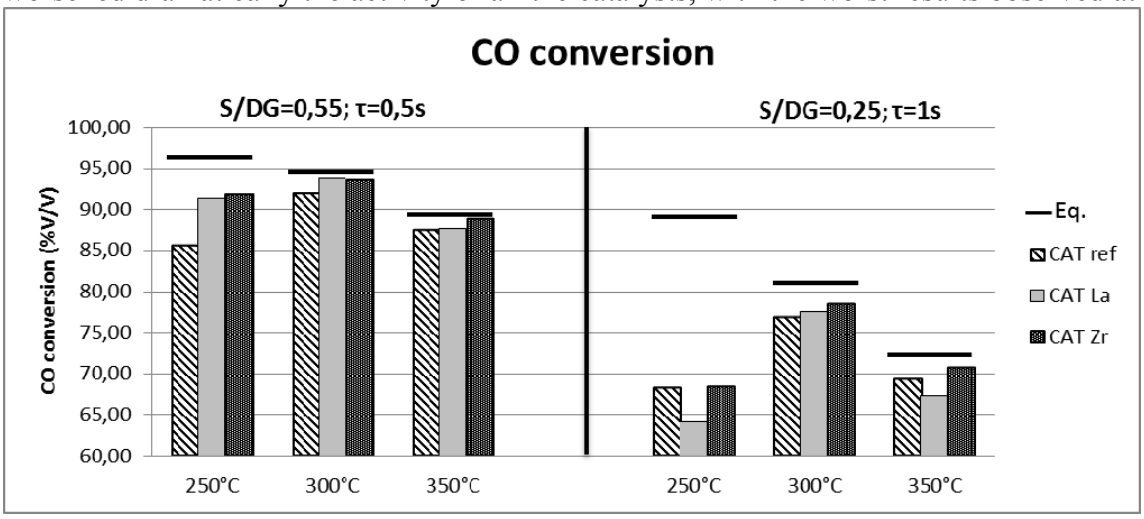

Figure 1. CO conversion for Cu/Zn/Al/La (CAT La) and Cu/Zn/Al/Zr (CAT Zr) catalysts, compared to the not promoted catalyst (CAT ref); the full lines show the CO conversion values at the thermodynamic equilibrium.

4 Conclusions

The addition of a small amount of La and Zr in a Cu/Zn/Al (Cu = 20 wt.%) catalyst promoted the surface properties and thermal stability, reflecting also on the catalytic activity in the WGS reaction at medium temperature. Significant increases of CO conversion were observed in condition of industrial interest, with a good stability with time-on-stream

Keywords: hydrogen production, formic acid, noble metals clusters, carbon, atomic, resolution, STEM

1 Introduction

Formic acid can be produced from cellulose of biomass by hydrolysis or oxidation. It can be used for hydrogen storage or directly for hydrogenation reactions instead of molecular hydrogen. The effective catalysts should perform the formic acid decomposition in mild conditions with high selectivities for H_2 production. We used nitrogen-doped and undoped supports in the form of carbon nanofibers (CNFs) and mesoporous graphene like carbon (C_M) for stabilization of metal (Pt, Pd, Ru) clusters of less than 3 nm size and showed that N-doping of the supports improves considerably the hydrogen production from formic acid.

2 Experimental/methodology

The N-doped supports with 6-7 at.% of nitrogen were synthesized by catalytic growth from a NH_3/C_2H_4 mixture or from CH_3CN while the undoped materials - from C_2H_4 or CH_3OH. Noble metals were deposited by incipient wetness impregnation from salts or by deposition-precipitation method to get 1 wt.% content. The samples were reduced in H_2 at 573 K and characterized by N_2 adsorption methods, XPS and atomic resolution STEM (Nion Ultrastem 100, Titan 60-300). Regular STEM (JEM-2100F) was used to determine the mean metal particle sizes. Vapor phase formic acid decomposition (2.0 vol.% HCOOH/He, 51 mL min^{-1}) was performed in a fixed bed reactor as described earlier [1]. Turnover frequencies (TOFs) were calculated basing on the total number of metal atoms for the supported catalysts as a considerable part of metal was in the state invisible by the regular STEM and basing on the surface number for the Pt powder.

3 Results and discussion

Fig. 1 compares turnover frequencies for the formic acid decomposition over the N-doped and undoped Pt, Pd and Ru/CNFs catalysts with the mean particle sizes of 1.1, 1.5 and 2.3 nm and Pd/C_M catalysts with - 2.6 nm, respectively. The Pd catalysts showed high activities and intermediate selectivities (94-98%) as compared to the other metals. This was valid for the catalysts supported on both CNFs and C_M supports. The selectivities for the Ru catalysts were the lowest (83 and 91%) as well as the activity.

It is important that N-doping provides a considerable increase of the TOFs for all samples (Fig. 1). The effect is the most strong for Pt (10 times), but smaller for other metals (<3 times).

The TOFs for the N-doped Pt catalyst were also considerably higher than the TOFs for an unsupported Pt powder (9.3 nm), but comparable to the TOFs for the N-doped Pd catalysts. Moreover, this Pt catalyst showed improved resistance to CO inhibition and the selectivity of 99.5% at 50% conversion as compared to 96.2% for the undoped catalyst.

The strongest effect of nitrogen for Pt can be related to the smallest metal particle sizes and, therefore, the highest contribution of isolated metal atoms and clusters with a few atoms to the total content of surface metal sites. The presence of a considerable content of such species as well as Pd particles was clearly seen by atomic resolution STEM even for the Pd/C_M catalyst with the lowest dispersion of 43% (Fig. 1). These species can be active for the formic acid dehydrogenation, but only if the support is doped by nitrogen.

An XPS study showed the presence of 3 different nitrogen species in the N-doped samples. The metal clusters exist in an electron-deficient state as a considerable shift of the binding energies towards higher values was observed for the N-doped catalysts as compared to those for the undoped catalysts (by 0.6 eV for Pt) and bulk metals (by 1.5 eV for Pt). Pyridinic nitrogen stabilizes the electron-deficient clusters and isolated atoms providing their location on the open edge sites of the CNFs and C_M supports. Formic acid can be activated on the interface of these species with the support forming a surface adduct ($>NH^+HCOO^-$) with basic pyridinic nitrogen; this can be further dehydrogenated on the neighbouring clusters and isolated atoms of metals.

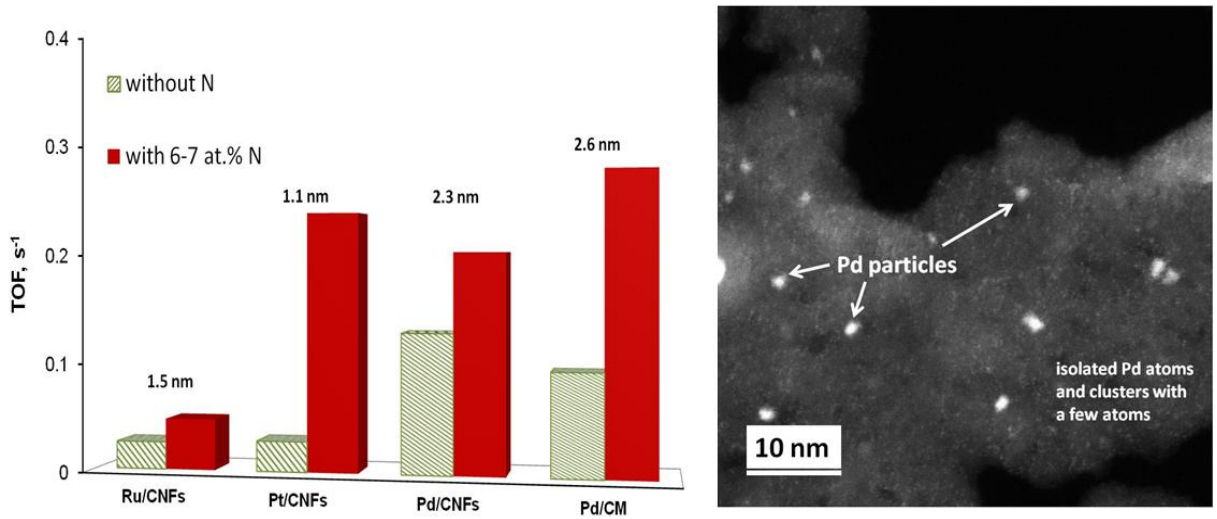

Fig. 1. Turnover frequencies of the formic acid decomposition at 398 K and atomic resolution STEM image of the 1 wt.% Pd/C_M catalyst (multiple small white dots correspond to isolated Pd atoms and Pd clusters with a few atoms).

4 Conclusions

N-doping of carbon supports for noble metals catalysts provides a considerable increase of the formic acid decomposition rate, selectivity to hydrogen and resistance to CO inhibition. This could be related to the presence of electron-deficient clusters and isolated atoms of metals stabilized by pyridinic nitrogen on the open edge graphene sites; these species can dehydrogenate the intermediate adduct of formic acid with pyridinic nitrogen to give hydrogen and carbon dioxide.

1 Introduction

Hydrogen (H_2) is considered to be a promising energy carrier due to its high energy density (142 MJ/kg), which is almost three times higher than that of natural gas (55 MJ/kg) [1,2]. However, controlled storage and release of hydrogen are still among the critical technological barriers faced by the hydrogen economy [1-2]. In this context, formic acid (HCOOH, FA), which is one of the major stable and non-toxic products formed in biomass processing, has recently attracted significant attention as a potential hydrogen carrier for fuel cells designed towards portable use [4,5]. In the presence of metal catalysts, FA can catalytically be decomposed via dehydrogenation (1) and/or dehydration (2) pathways [3,4].

$$HCOOH(l) \rightarrow H_2(g) + CO_2(g)\ \Delta G_{298K} = -35.0\ kJ/mol\ (1)$$

$$HCOOH(l) \rightarrow H_2O(l) + CO(g)\ \Delta G_{298K} = -14.9\ kJ/mol\ (2)$$

In this study, we have focused on facile synthetic route for obtaining PdAg alloy and MnOx nanoparticles (NPs) supported on 3-aminopropyl functionalized silica ($PdAg\text{-}MnO_x/N\text{-}SiO_2$) to be used in the selective dehydrogenation of FA at room temperature in the absence of ant additives.

2 Experimental/methodology

Synthesized materials were characterized by a wide range of characterization techniques such as, ICP-OES, XRD, HRTEM, STEM, HAADF-STEM, XPS, in-situ FTIR, BET analysis and UV-Vis spectroscopy. The catalytic activity of $Pd\text{-}MnO_x/SiO_2\text{-}NH_2$ in the additive free FA dehydrogenation (*af*-FAD) was determined by volumetric measurement of the rate of hydrogen evolution. The selectivity of $PdAg\text{-}MnO_x/N\text{-}SiO_2$ catalyst in the decomposition of formic acid was investigated by GC analysis and NaOH-trap experiments.

3 Results and Discussion

Herein, we present a new heterogeneous catalyst system facilitating the liberation of hydrogen at room temperature through the dehydrogenation of formic acid in the absence of any additives with unprecedented activity, converging to that of the existing state of the art homogenous catalysts. Currently utilized heterogeneous $PdAg\text{-}MnO_x/N\text{-}SiO_2$ catalyst revealed a record activity (330 mol H_2 mol catalyst^{-1} h^{-1}) as well as excellent conversion (> 99 %) close to that of the existing state of the art homogenous catalytic systems available for *af*-FAD in the literature. Incorporation of the Ag sites into the Pd lattice leads to the formation of bimetallic PdAg alloys, decreasing the CO adsorption strength and increasing the tolerance against CO poisoning. MnO_x addition leads to the generation of sacrificial CO anchoring sites where CO can strongly bind in the form of carbonates. As a result, PdAg sites remain available for FA

dehydrogenation for an extended duration of time. MnO_x domains may influence the surface composition of the PdAg bimetallic alloys and decrease the number of Ag sites exposed on the surface of the bimetallic nanoparticles. MnO_x incorporation to the catalyst composition results in additional adsorption sites for FA and enhances the extent of formate creation even after extensive CO exposures.

Table 1. Comparison of the catalytic performance data for the Pd-MnOx/SiO_2-NH_2 catalyst with the prior best heterogeneous catalyst systems reported for the dehydrogenation FA in the absence of any additives at low temperatures. **Scheme 1.** CO poisoning during the formic acid decomposition on PdAg/N-SiO_2 and PdAg-MnOx/N-SiO_2 catalysts and the promotional effect of MnO_x.

4 Conclusions

Currently presented superior catalytic system enables facile catalyst recovery and very high stability against agglomeration, leaching and CO poisoning. Through a comprehensive set of structural and functional characterization experiments, mechanistic origins of the unusually high catalytic activity, selectivity and stability of Pd-MnO_x/SiO_2-NH_2 were elucidated. Current heterogeneous catalytic architecture presents itself as an excellent contender for clean hydrogen production via room-temperature additive free dehydrogenation of formic acid in on-board hydrogen fuel cell applications.

Keywords: Cr-DOPED, ALUMINA

1 Experimental/methodology

Mesoporous alumina was doped with Cr using a coprecipitation method in order to prepare a support for hydrocracking catalysts. NiMo catalysts were prepared by impregnation on alumina (NiMo/Al2O3) and Cr-doped alumina (NiMo/Al2O3-Cr) and characterised. The presence of Cr in the support led to a better dispersion of NiMo and lower metal reduction temperatures as determined by temperature-programmed reduction (TPR) and X-ray photoelectron spectroscopy (XPS). As a consequence, a larger number of metal active sites was available in reduced form at operating conditions. The textural properties remained relatively unaffected by the coprecipitation of Cr together with the alumina. The catalysts were tested in their activity towards hydrodeasphaltenisation reactions using vacuum residue as feed in a batch reactor in two successive one-hour experiments involving reutilisation of the catalysts with fresh feed.

2 Results and discussion

It was found that Cr not only aided metal dispersion in catalyst synthesis but also coke dispersion during reaction, leading to sustained catalytic activity despite NiMo/Al2O3-Cr having a larger amount of coke deposits. Spent catalysts had a reduction in surface area and pore volume when compared to the fresh materials. Spent NiMo/Al2O3 catalysts had a decrease in average pore diameter (APD) whereas NiMo/Al2O3-Cr maintained the fresh material APD. NiMo/Al2O3-Cr could accommodate higher coke yields without significant variation in its textural properties.

1 Introduction

Methanol is one of the most important chemicals worldwide (2014 ~ 70 MMT) and is produced from syngas ($CO/CO_2/H_2$) under elevated pressures and temperatures (50-90 bar and 220-290 °C) [1]. The demand of methanol will further increase, in particular as a synthetic fuel based on the hydrogenation of CO_2, and can potentially seen as one of the key compounds for the energy supply of the future. The industrial most relevant catalyst consists mainly of $Cu/ZnO/Al_2O_3$.The role of Cu, its defective structure and influence on the active site of the catalysts, is very well understood [2]. The synergy between Cu and ZnO is crucial for the activity of the catalyst under CO_2 containing gas feeds and unique for the Cu-based catalysts [3]. Therefore ZnO can be seen as an equally important part of the catalyst. In the present work, we report on the behaviour of ZnO under different conditions and time scales, from the synthesis of the precursor until the testing of the catalysts under industrial relevant conditions. To monitor the dynamic character of ZnO in the catalyst like wetting under reducing conditions, the transformation into different modifications and deactivation relations, various in- and ex-situ techniques were used like HR-TEM, neutron diffraction, DRIFT and ambient pressure NEXAFS spectroscopy.

2 Experimental/methodology

The precursor materials were prepared by a co-precipitation route in aqueous solutions of Cu^{II}, Zn^{II} and Al^{III} nitrate and Na_2CO_3, under defined and controlled conditions (pH=6.5, T=65 °C) in a LabMax® system. The obtained zincian malachite phase was calcined in a rotating furnace at 330 °C (1 °C/min, 90 min dwell time) [4]. Additionally, we investigated commercially available catalysts.

The neutron diffraction measurements (wavelength 1.3091 Å) were conducted at BER-II at the neutron source of the HZB (Berlin, Germany).

NEXAFS and (NAP)-XPS spectra were recorded at the BESSY II facility (Berlin, Germany) at the ISISS beamline.

DRIFTS measurements at different temperatures (- 196 °C until 250 °C) with CO as a probe molecule were conducted on a Graseby Specac "Selector" attachment with environmental chamber placed in a Bruker IFS 66.

HRTEM images were taken on a FEI Titan 80-300 equipped with a Cs corrector at 300 kV. Prior to TEM investigation, the sample was reduced at 523 K and transferred to the microscope with a vacuum transfer holder under inert atmosphere.

3 Results and discussion

The influence of ZnO on the catalyst starts with the formation of the zincian malachite

precursor, in which the Zn occupies the lattice sites of higher symmetry. This leads in the calcination step to the formation of the corresponding metal oxides, homogeneously distributed and nanostructured. During the reduction of the catalyst ZnO shows an overgrowth on the metallic Cu particles and a parallel phase transformation into a graphite-like ZnO modification. Figure 1(a1) shows the layered character of this ZnO [5]. The DRIFT spectra (b) show at -196 °C a CO band at 2113 cm^{-1} confirms the presence of such a thin ZnO-layer in industrial relevant $Cu/ZnO/Al_2O_3$ catalyst. The detected vibration is assignable to CO molecules located at Zn^{II-x} cations, with a red shift of ~70 cm^{-1} compared to ZnO(10-10) [6]. Under the exposure to the electron beam of the HRTEM apparatus, a further change is observable; the layered ZnO forms a rock-salt and finally a wutzite-type ZnO structure (a2+a3). The neutron diffraction pattern of a methanol catalyst after 148d TOS shows intensive crystalline ZnO reflections (27-33 and 50-55 2Θ / °), which were formed under this long reaction time. A comparison of the other patterns (0d, 15d, 30d, 50d, 102d) give an impression of the phase transformation and deactivation mechanism of an industrial relevant catalyst. Additionally, these samples were investigated by HRTEM and other surface sensitive methods, to compare the deactivation behaviour of the catalysts with the corresponding ZnO modification and surface structure and properties.

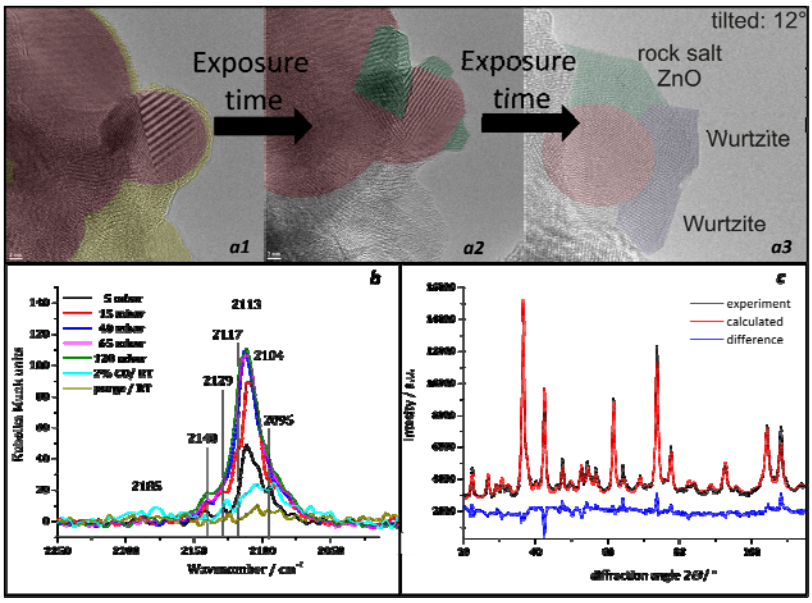

Fig. 1. (a1-a3) Aberration corrected HRTEM images of ZnO in the $Cu/ZnO/Al_2O_3$ catalyst. (b) DRIFT spectra of the $Cu/ZnO/Al_2O_3$ catalysts at – 196 °C and different CO partial pressures. (c) Insitu neutron diffraction pattern of the $Cu/ZnO/Al_2O_3$ after 148 days TOS.

4 Conclusions

This work shows with different, complementary methods detailed the enormous importance of ZnO as part of the $Cu/ZnO/Al_2O_3$ system, as an electronic and structural promoter. Fig. 1 shows exemplarily the ZnO modifications and its occurrence in different states of the catalyst. The knowledge of the dynamics at each step of the synthesis and testing procedure enables the development of new, highly stable catalysts.

Keywords: CO_2 hydrogenation, methanol, Cu-Zn-Al system, deposition, precipitation

1 Introduction

Methanol is one of the global chemical commodities which have the expected demand of 100 million metric tons for the fiscal year 2014-2015, as a chemical feedstock and transportation fuel. Industrially methanol is produced from synthesis gas ($CO+H_2$) on Cu-Zn-Al catalyst at high pressures (~ 10 Mega Pascal (MPa)). The synthesis gas predominantly produced from natural gas via catalytic steam reforming. The steam reforming products ($CO+CO_2+H_2$) catalytically converted in to methanol. However, this process yields surplus amount of hydrogen as a byproduct, which facilitates external CO_2 usage to produce additional methanol to improve the process efficiency by adding minimal capital cost [1]. Recently, the same Cu-Zn-Al system was studied for CO_2 hydrogenation reaction [2]. However, these conventional methanol synthesis catalysts are quite sensitive towards water poisoning and also the process efficiency in terms of methanol yield and selectivity has to be greatly improved [3]. Therefore, the present study emphasizes the improvement of the catalytic performance of the base Cu-Zn-Al catalyst by changing the Cu:Zn:Al ratio and also by the addition of Au. Further, our working hypothesis is focused on to reduce the reaction selectivity to CO and to study the resultant effect on methanol yield and selectivity in the presence of Au-Cu-Zn-Al system.

2 Experimental/methodology

$Cu(NO_3)_2.3H_2O$, $Zn(NO_3)_2.6H_2O$, $Al(NO_3)_3.9H_2O$, Na_2CO_3 precursors were obtained from Acros chemicals (assay ≥ 98.0%) and $AuCl_3$ (Alfa Aesar, assay ≥ 99.99%, 64.4% Au) were used without further purification.

Cu-Zn-Al samples were prepared by co-precipitation method. Gold supported catalysts were prepared by deposition precipitation (DP) method using Mettler Toledo Labmax reactor. All the dried powders were calcined at 350 ºC for 12h under static air. The base catalysts were designated as: C_2ZA, C_4ZA and C_6ZA. Here 'C' stand for copper, 'Z' for zinc and 'A' for alumina and the subscript represents the moles of copper present in these catalysts. The gold supported catalysts were named as: $0.5Au/C_4ZA$, $1Au/C_4ZA$ and $3Au/C_4ZA$. Here, the prefix 0.5, 1 and 3 correspond to the gold loading weight percentage on C_4AZ base.

Catalytic activity studies were performed using PID Eng & Tech micro reactor equipped with gas flow meter and temperature controllers. Catalytic activity tests were carried out in the temperature range of 200-260 ºC with 20ºC step size in the applied pressure range of 2-6 MPa and GHSV 7000 or 13200 h^{-1}.The reaction stream at each temperature directed to Agilent micro GC (equipped with TCD detector with column CP-Sil 5&8 CB and Pora Plot Q) to record the activity data for 30 minutes after accomplishing the steady state for 30 minutes. The calibrated results were within the sample standard deviation of ± 0.1% for CO/methanol yield and ±1.0% for CO_2 conversion.

3 Results and discussion

Fig.1a summarizes the effect of Au content in Au/C_4ZA on CO_2 conversion and CO selectivity at H_2:CO_2 6:1, GHSV 7000 h^{-1} and 4.0 MPa. Among the gold supported catalysts it seems 1wt% loading leads to promising results. The base C_4ZA showed the maximum CO_2 conversion of 25% mass with 50% of CO selectivity at 260 ºC. A slight increase (2-3%) in the CO_2 conversion was observed for 1Au/C_4ZA over base catalyst. On the other hand, the CO selectivity was reduced from 5-10% mass on 1Au/C_4ZA compared to base catalyst. The decrease in the CO selectivity on 1Au/C_4ZA might be associated with direct hydrogenation of CO to methanol on Au-Cu-Zn-Al surface where the hydrogen spill over established by TPR studies. The reduction behaviour of calcined C_4ZA and 1Au/C_4ZA were presented in Fig.1b. The base C_4ZA shows a broad signal with front shoulder at 300 ºC and a back shoulder at 325 ºC attributed to Cu^{+2} to Cu^{+1} and Cu^{+1} to Cu^0 [4]. After the addition of gold (1wt%), the reduction profile of C_4ZA shifted forward to a lower temperature. The front shoulder became more distinct and appeared at 275 ºC and the back shoulder more prominent at 325 ºC for 1Au/C_4ZA. Nano Au particles have been reported to absorb-dissociate hydrogen and further spills over to neighbouring copper oxide [5]. Hence, the addition of Au to Cu-Zn-Al lead to lower reduction temperature of neighbouring copper oxide, as observed in Fig. 1b.

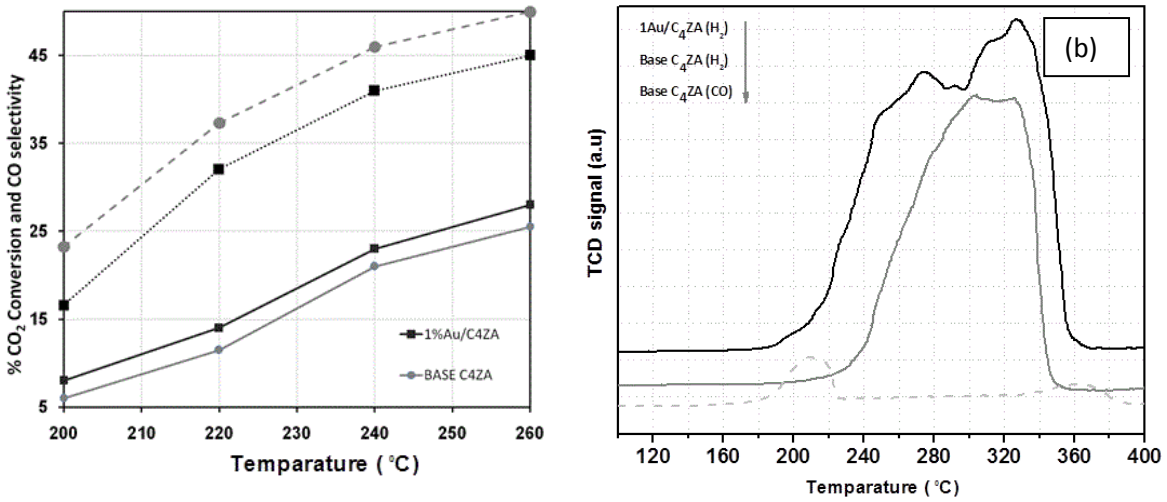

Fig.1. (a) Solid lines indicate CO_2 conversion and dotted lines indicate CO selectivity on base C_4ZA and 1Au/C_4ZA (b) TPR profiles of the calcined catalysts. Gas treatment atmosphere mentioned in brackets

4 Conclusions

Au plays a significant role in decreasing the reaction selectivity towards CO by improving the methanol yield is due to; i) spilling over the H_2 to neighbour Cu species ii) improved the adsorption capacities for H_2 and CO at Au-Cu interface.

CO_2 Methanation on Iron Based Catalysts

Kirchner J.[1,2], Kureti S.[1,2*]

Keywords: CO_2 methanation, iron catalysts, structure-activity, correlation

1 Introduction

The increasing emission of CO_2 is worldwide discussed in the context of global warming. Therefore, many efforts have been made to remove CO_2 by fixation, for instance by conversion into chemicals [1]. Following a modified SNG approach (substitute natural gas) our study focuses on the hydrogenation of carbon dioxide to methane and water (Eq. 1).

$$CO_2 + 4\ H_2 \rightleftharpoons CH_4 + 2\ H_2O \qquad \Delta_R H^0 = -\ 165\ kJ/mol \qquad \text{(Eq. 1)}$$

In the methanation of carbon oxides supported Ni catalysts are currently applied. However, these catalysts suffer from several disadvantages such as Ni sintering, coke formation and leaching of nickel carbonyl [2]. Iron catalysts have been reported to be active in CO_x hydrogenation (Fischer-Tropsch synthesis) as well as water-gas shift reaction [3]. Due to its relatively low price and toxicological harmlessness we have evaluated the potential of iron based catalysts for CO_2 methanation. It is well known that iron catalysts undergo complex phase changes during hydrogenation of carbon oxides. Several iron phases such as iron oxides or metallic iron have been found to coexist. Moreover, deposited carbon may react to iron carbides or bulk carbon species with different structures [4].

2 Experimental

In the present study, different iron oxide precursors were systematically characterized by N_2 physisorption, scanning electron microscopy, X-ray diffraction and Moessbauer spectroscopy and were subsequently tested towards CO_2 methanation to correlate structure and activity. The catalytic performance was evaluated between 250 and 450°C, whereas the H_2/CO_2 ratio was varied using CO_2 fractions from 0.1 to 20 vol.%. Prior to the methanation, the catalysts were activated by reduction or carburization. The carbonaceous species formed on the catalysts in CO_2 methanation were investigated by temperature-programmed hydrogenation (TPH). Additionally, the change in phase composition and morphology was examined by using in situ X-ray diffraction.

3 Results and discussion

The catalytic study demonstrated in Fig. 1a indicates CO_2 conversion above 75 % and CH_4 selectivity up to 85 % at 400°C when using a nano-scaled y-Fe_2O_3 precursor. This original iron oxide phase is inactive for methanation, but is activated during the exposure to CO_2/H_2. The activation implies formation of metallic iron and iron carbides, e. g. Fe_3C, whereas the former reveals highest efficiency as derived from the CH_4 formation rate (Fig. 1b). Furthermore, TPH analyses made after CO_2 methanation shows production of carbon species, whereas their nature strongly depends on the physical-chemical properties of the precursor (Fig. 2). From our studies we derive high methanation activity of nano-scaled iron oxide precursors due to the presence of reactive carbonaceous species (Cα type), whereas the deactivation by graphitic bulk carbon is suppressed.

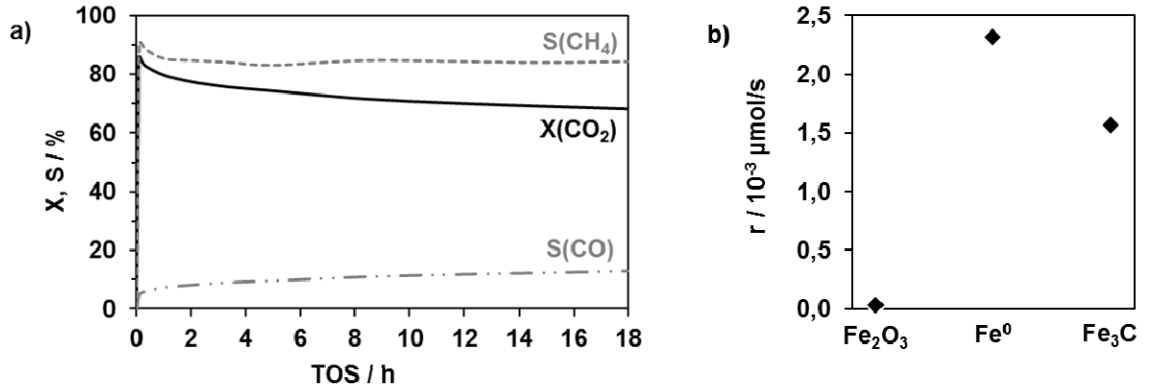

Fig. 1. Methanation activity of Fe catalysts: a) CO_2 conversion, CH_4 and CO selectivity on γ-Fe_2O_3 at 400°C, $y(CO_2)/y(H_2)=200$, GHSV=120000 h^{-1}. b) CH_4 formation rates at 350°C of Fe_2O_3, Fe and Fe_3C.

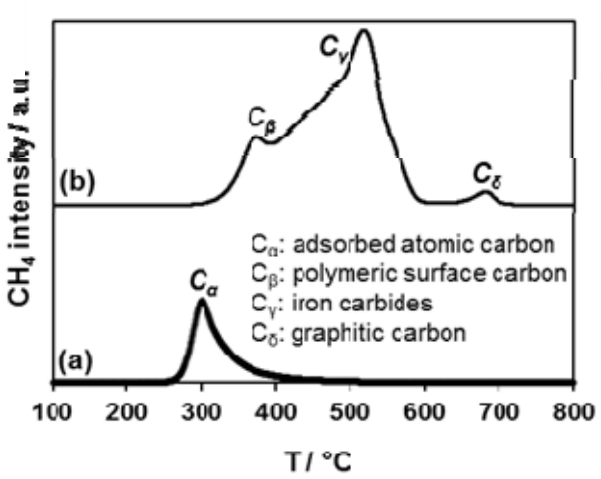

Fig. 2. TPH profiles of (a) nano-scaled Fe_2O_3 and (b) micro-scaled Fe_2O_3 used in methanation [4].

4 Conclusions

In the present study, Fe based samples were identified as promising catalysts for CO_2 methanation in order to substitute traditional Ni catalysts. The structure-activity correlation showed highest activity for metallic iron among iron oxide and iron carbide phases. CH_4 yield up to 64 % was achieved at relatively high CO_2/H_2 ratio, whereas the activity decreases with inclining CO_2 fractions.

Changes in the Oxidation States of Cobalt Oxides for the OER Studied by XPS and their Correlation to the Electrochemical Activity

Weidler N.*, Kaiser B., Jaegermann W.

Technical University Darmstadt, Institute of Material Science, Darmstadt, Germany

* nweidler@surface.tu-darmstadt.de

Keywords: oxygen evolution reaction, water-splitting, chemical vapor deposition, electrocatalysis

1 Introduction

Due to the decreasing amount of fossil fuels the interest in the field of renewable energies has increased considerably. However, energy from wind and sun has the disadvantage that it is not available on a continuous basis, i.e. it is necessary to store the generated energy employing appropriate technologies. Water electrolysis represents one possibility to convert and store electric energy in chemical energy in the form of hydrogen. One of the major obstacles, which make the process uneconomical at this time, is the overvoltage loss for the oxygen evolution reaction (OER). In terms of overpotential, IrO_2 and RuO_2 are still the best dark water oxidation catalysts but they are rare and highly priced. Our work focuses on the one hand on the production of economically competitive and highly active cobalt based catalysts for the OER and on the other hand on the development of a low temperature deposition technique for their precipitation directly onto solar devices. Fundamental studies focus on the influence of the deposition parameters on the oxidation state of the Co sites and the changes therein during the electrochemical water-splitting. The change in oxidation states can be correlated to the formation of oxo-, hydroxo-, peroxo-adsorption intermediates and their effect onto the kinetics.

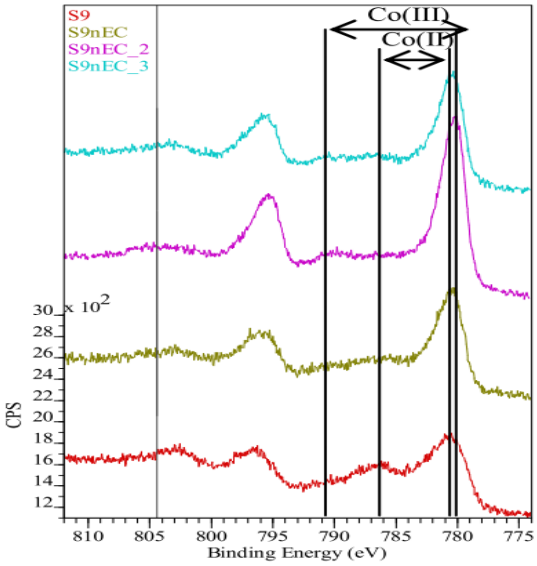
2 Experimental/methodology

Catalysts are prepared by chemical vapor deposition onto different electrode substrates (e.g. Titanium, Nickel). The CVD deposition process must be optimized with respect to several parameters like temperature, gas flow, precursor material etc. For chemical and structural characterization X-ray photoelectron spectroscopy (XPS) and high-resolution electron microscopy (HREM) are employed. The electrochemical investigation is perfomed by cyclic voltammetry, impedance spectroscopy and finally stability measurements. These experiments can also be done in an in-situ cell that allows a direct sample transfer into an ultra-high-vacuum system for further investigation by XPS.

3 Results and discussion

Two CVD methods were used to synthesize pure Co-Oxide on Ti from $Co(acac)_2$ precursor material. In a thermal CVD process the deposition and oxidation of $Co(acac)_2$ take place at the same time in an Ar/O_2 atmosphere at substrate temperatures between 290 and 430°C. In a plasma-enhanced CVD process, the decomposition of the precursor occurs in an oxygen plasma during the deposition. Both methods lead to different oxidation states in the catalyst and to different amounts of carbon contamination. Thermally deposited Co-Oxide/Ti shows a high content of Co(II)-states as well as a high carbon contamination, while plasma deposited Co-Oxide/Ti shows mixed valences of Co(III)/Co(II) and a low carbon contamination. While the plasma-oxidized catalysts show a higher electrochemical activity from the beginning of the reaction, the thermally oxidized CoOxides/Ti show an increase in electrochemical activity with

proceeding OER. To understand this difference in activity, we treated the as prepared catalysts in 0.1M KOH or 1M KOH under potentiostatic control at 1.7V vs. RHE or galvanostatic control at 10mA/cm^2 for 10minutes and investigated the change in oxidation state directly with XPS.



As an example**, Figure 1** shows the XPS spectra for thermally deposited Co-Oxide/Ti for the as prepared sample (S9) and the electrochemical treated samples (nEC, nEC2, nEC3).The red spectrum of the as prepared sample S9 shows the typical signal for Co(II), which consists of the main peak and its satellite in a distance of 6eV. After the first electrochemical treatment, S9nEC, the intensity of the satellite decreases and the Co(III) satellite in a distance of 11eV to the main peak starts to appear. After the second electrochemical treatment nEC2 the satellite of Co(III) is increased. Also a shift of the main peak is observed. The formation of Co(III) can be due to the formation of the adsorption intermediate Co-OOH, which has to be stabilized by the catalyst for good catalytic activity.[1] This observed change in oxidation states of CoOxide/Ti comes along with an increase in electrochemical activity, for a current density of 2mA/cm^2 the overvoltage decreases in the range of 90-100mV. We could show, that in dependency of the preparation method (thermal vs. plasma-enhanced-CVD) the catalysts show a different electrochemical behavior.

4 Conclusions

The correlation of the electrochemical activity with the oxidation state of the catalysts could be helpful to develop a fundamental mechanistic understanding. Beside the studies of the pure Co-Oxides, studies on pure Ni-Oxide and the binary Co-Ni-Oxide system will be presented. The mixed metal catalysts show even higher electrochemical activity compared to the monometallic systems.

Keywords: perovskite, methanereforming, nickel, rhodium, water gas shift reaction, SOFC

1 Introduction

Perovskites are currently the most popular material for SOFC cathodes [1-2]. Regarding their abilities as mixed ionic and electronic conductors (MIECs), transporting both oxygen ions and electrons effectively, they can also be used as anode materials. With this the triple phase boundary can be enlarged enormously. At the TPB the following reaction takes place:

$$CH_4 + 4O^{2-} \rightarrow CO_2 + 2H_2O + 8e^-$$

Two different perovskites, LSF ($La_{0.6}Sr_{0.4}FeO_{3-d}$) and STF ($SrTi_{0.7}Fe_{0.3}O_{3-d}$), have been selected as promising materials regarding methane chemistry and water gas shift activity. For improvement of catalytic activity and selectivity they were subsequently impregnated with various metals (Ni, Rh and Co) and investigated concerning their methanation and methane reforming activity.

2 Experimental

All measurements were done in a quartz batch reactor. The reaction mixture (CO_2, H_2 and H_2O for methanation and CH_4 and H_2O for the methane reforming reaction) was investigated up to 600 °C, after an oxidative (1 bar O_2, 1h, 400 °C) or reductive (1 bar H_2, 1h, 600°C) pretreatment. The gas phase composition was monitored continuously by mass spectrometry/ gas chromatography - mass spectrometry.

3 Results and discussion

For the pure perovskites no methanation or methane reforming activity could be observed. The fully oxidized perovskites can be reduced with methane and CO, producing CO_2. Water gas shift reaction starts for both STF and LSF at 300°C, the inverse reaction was observed above 500 °C.

For Ni-STF the methanation reaction starts at 250 °C. The methane is formed up to 400 °C. Above this temperature methane reforming yields increasing amount of carbon monoxide. Also for Ni-LSF, methanation activity can be monitored, starting at 300 °C. At 370 °C methanation competes with the inverse water- gas shift reaction and carbon monoxide is formed. Above 550 °C the methane is reformed.

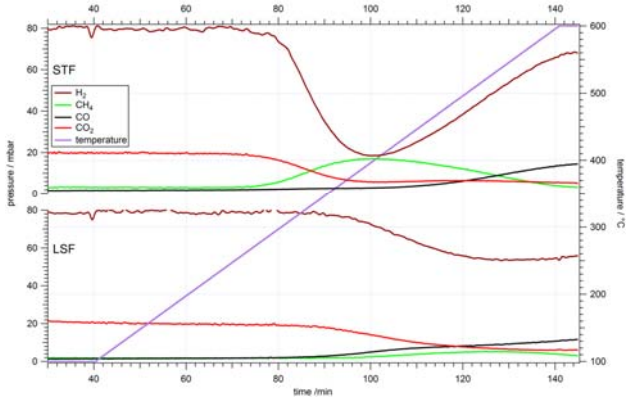

Fig. 1.: Reaction profiles of methanation reaction on Ni-STF (top) and Ni-LSF (bottom)

4 Conclusion

Both perovskites show water gas shift reactivity. Methanation / methane reforming reactivity on perovskites can only be achieved after impregnation with metals whereby STF shows better performance regarding methane production.

Redox Catalysts for Electrochemical CO_2 Reduction: the Role of Local Proton Source

Nervi C.*, Gobetto R., Minero C., Franco F., Cometto C., Sun C., Nencini L., Sordello F.

University of Turin, Department of Chemistry, Turin, Italy

* carlo.nervi@unito.it

Keywords: carbon, dioxide, redox catalyst, electrochemical reduction, organometallic complexes

1 Introduction

The reduction of CO_2 emissions and the need for a green and sustainable energy source are among the most important world's strategic research topics. The conversion of CO_2 into "Solar Fuels" [1] via the so-called artificial photosynthesis proceed by the photoactivation of a dye that generates a electron–hole pairs, which provides the thermodynamic driving force for the subsequent electron transfer reactions. A convenient approach is to optimize separately the catalytic and light-harvesting properties. This is possible because the photocatalytic mechanism usually proceed via a reductive quenching pathway [2], i.e. the real catalyst is the reduced form produced in situ; thus the search of an efficient catalyst for CO_2 reduction and its study can be pursued using electro-chemical techniques. To reduce the large overpotentials required for CO_2 reduction, the use of catalyst able to take advantage of proton-assisted processes [2] is mandatory [1]. In this communication we would like to show our recent findings on the use of Re and earth-abundant transition metals (Mn, Mo, W) organometallic complexes as redox catalyst for CO_2 electrochemical reduction.

2 Experimental/methodology

The complexes were synthesized and characterized in our laboratory [3]. Cyclic Voltammetry experiments were performed normally in 1 mM MeCN solutions, containing tetrabutylammonium hexafluorophosphate ($TBAPF_6$) as supporting electrolyte (0.1 M). Brønsted acids with different strength (MeOH, H_2O, CF_3CH_2OH) were added to test the proton-assisted ability of the catalysts. Photocatalytic measurements were performed in a Pyrex cell filled with a mixture of dimethylformamide and triethanolamine (DMF/TEOA 5:1 v/v; 6 mL) with the catalyst (2 mM). Experiments were carried out whilst stirring and with a constant flow of CO_2. The cell was irradiated with a Philips PLS 9 W/52 lamp. CO and H_2 were detected and quantified by GC. A Smart Trak 100 (Sierra) flow controller C100L was used during the electrochemical and photocatalytic experiments. Formic acid production was evaluated with ion chromatography.

3 Results and discussion

The effect of an antenna on Re^I complex catalytic properties has been explored and contrasting results have been observed. For example, the covalently linked non-conjugated Ru^{II}–Re^I dyad is a superior catalyst to the corresponding mixture of Ru^{II} and Re^I complexes; however, the Zn–porphyrin and Re^I complex mixture seems to be a better catalyst than the corresponding covalently linked dyad [4]. We herein compare the redox and photochemical catalytic properties of a series of Re^I carbonyl complexes that contain α,α-diimine ligands covalently linked to a highly delocalized 4-piperidinyl-1,8-naphthalimide (PNI) moiety for the CO_2 reduction process. The photochemical data parallel reasonably well the electrochemical one. But the most interesting catalytic features has been obtained in homogeneous solutions with a Mn^I catalyst carrying a local proton source. While the Re^I catalysts can work in CO_2 reduction also in

absence of Brønsted acids, the Mn^I catalysts normally cannot. However, the Mn^I catalysts **1**, characterized also by single crystal X-ray diffraction, showed a substantial catalytic activity in anhydrous media induced by the presence of a local proton source [3]. Bulk electrolysis at the end of the catalytic plateau (–1.8 V) under CO_2 showed an unusual change in selectivity for CO_2 reduction by the Mn(I) catalyst, giving a mixture of CO and HCOOH.

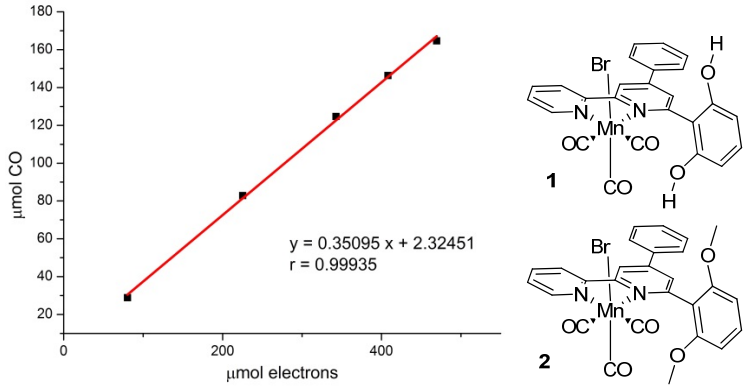

Fig. 1. CO production against the charge passed during bulk electrolysis at –1.8 V vs. SCE of a 1 mM solution of **1**. The slope of about 0.35 corresponds to a faradic efficiency of 70%.

The catalytic activity is inhibited in **2**, where the two local protons are substituted by methyl groups. We also performed a series of controlled potential electrolysis with different Brønsted acids, showing that their strengths can drive the selectivity of the catalyst towards the formation of CO or formic acid.

4 Conclusions

The introduction of a PNI group in certain Re^I complexes allowed a second electron transfer to occur at much less negative potentials than the corresponding parent derivative. For these redox catalysts, the two-electron reduction mechanism might also proceed as the formal $[PNI]^-$ group worked as an electron reservoir. The importance of local factors is evidenced by the strong catalytic activity of Mn^I complex **1**. This represents the first reported experimental evidence of an intramolecular proton-assisted catalytic process for a Mn^I catalyst, in which the key factor is the spatial closeness of protons to the active site rather than their bulk concentration in solution.

Keywords: electrocatalysis, nickel, hydrogen oxidation, hydrogen evolution, alkali

1 Introduction

Electrocatalytic hydrogen oxidation and hydrogen evolution reactions (HOR/HER) for many years have attracted strong research interest due to their fundamental and applied significance. An increasing interest in low-temperature alkaline membrane fuel cells and electrolyzers gives a new impetus to the development of efficient and stable electrocatalysts for the HOR/HER in alkaline media. The main advantage of an alkaline medium in comparison with acid one is the possibility to use non-noble metal catalysts, among which Ni seems to be the best candidate due to its relatively high activity in the HER as well as its low cost [1]. However, Ni is passivated with time under a moist air atmosphere or in an alkaline solution when supposedly irreversible β-$Ni(OH)_2$ is formed, which blocks active sites and thus decreases of the HOR/HER activity [2]. On the other hand, several scientific groups [3, 4] suggested that the addition of Ni oxide/hydroxide to metal electrodes results in a strong increase of their HER activity, supposedly due to more facile dissociative adsorption of water. In order to provide deeper insight into the influence of the composition and structure of Ni particles on their activity in the HOR/HER, in this work we study electrodeposited Ni nanoparticles with different sizes and compare them with polycrystalline Ni disk electrode, as well as carbon-supported NiCu particles. We also developed a kinetic meanfield model which provides some insights into the mechanism of the hydrogen electrode reactions.

2 Experimental/methodology

Electrodeposition technique was applied for fabrication of a set of model supported Ni catalysts of various particle size. Glassy carbon electrodes were used as supports for a 3 step (E_1 = -0.77; E_2 = -0.20; E_3 = -0.52 V vs. reversible hydrogen electrode) deposition of Ni from the 0.01 M $NiSO_4$ + 0.10 M $(NH_4)_2SO_4$ solution at 25 ^oC. The size of Ni particles was controlled by varying the duration of different deposition stages. Ni/C and NiCu/C (with different Ni:Cu molar ratio) catalysts were prepared by the incipient wetness impregnation of the support (carbon black Vulcan XC-72) with $Ni(OAc)_2$ and $Cu(OAc)_2$ solution followed by drying and reduction with H_2 at 300 ºC.

The composition and structure of Ni based catalysts were studied by various physicochemical and electrochemical methods. Kinetics of the HOR/HER was studied in H_2 saturated 0.10 M NaOH solution at very low sweep rate of 2 mV s^{-1} in order to minimize the influence of non-stationary processes.

For kinetic modelling we used Langmuir isotherms for the adsorption step and Butler-Volmer kinetics for the charge transfer processes, assuming that the hydrogen electrode reactions follow Tafel-Volmer mechanism.

3 Results and discussion

Study of the properties of polycrystalline Ni disc electrode in alkaline media using different electrochemical techniques revealed several important features. It is known that after contact with air the surface of metallic Ni is oxidized to form several layers of NiO covered by α-$Ni(OH)_2$ [2]. It was found that air-formed NiO/α-$Ni(OH)_2$ can be easily reduced electrochemically by applying potential at which hydrogen evolution occurs. However prolonged contact of α-$Ni(OH)_2$ with alkaline or even water solution results in its transformation into β-$Ni(OH)_2$, which cannot be fully reduced even by applying strong cathodic polarization. So β-$Ni(OH)_2$ blocks the surface resulting in a decrease of the specific catalytic activity of Ni electrode. On the other hand, it was found that the formation on the surface of Ni of such reducible species as NiO/α-$Ni(OH)_2$ increases its activity in the HOR/HER several times, even if the specific surface area does not change noticeably. Studying of electrodeposited Ni nanoparticles with varying sizes revealed the influence of the size on their activity most likely due to the differences in oxophilicity of the particles. The latter results in higher activity of small Ni nanoparticles in comparison with the polycrystalline Ni disc electrode.

Preparing of bimetallic Ni-based materials provides another way of increasing the activity of Ni in the HOR/HER. NiCu/C catalysts studied in this work revealed, that addition of Cu (less than 50 wt%) during the synthesis results in an increase of the specific surface area of Ni as well as its specific activity in the HOR/HER.

Kinetic meanfield model was applied taking into account the Ni oxide formation and reduction as well as the hydrogen electrode reactions. A good agreement between the experiment and modeling was obtained. We propose that formation of α-$Ni(OH)_2$ goes through the formation of intermediate NiOH species. We also suggest that the mechanism of the HOR over the Ni surface comprises a reaction between NiH_{ad} and $NiOH_{ad}$ species.

4 Conclusions

Formation of reducible Ni oxide/hydroxide species on the Ni surface leads to significant increase of its activity in the HOR/HER at potentials below 0.20 V vs. RHE. At higher potentials Ni oxide/hydroxide species inhibit the HOR activity;

Electrodeposition technique allows to prepare glassy carbon-supported Ni nanoparticles with controllable size and higher HOR/HER activity in comparison with that of a polycrystalline bulk Ni electrode;

Addition of Cu allows to considerably change mass-weighted and specific catalytic activity of Ni in HER/HOR as well as its specific surface area;

Mean-field modeling using Tafel-Volmer mechanism can reproduce qualitatively the experimental HOR/HER data on Ni electrodes.

Keywords: natural gas, syngas, GTL, partial oxidation, oxy-cracking, carbonylation

1 Introduction

Despite the significant progress in industrial GTL technologies, even the world class GTL plants have only marginal limits of profitability. Manufacturing of GTL products remains extremely expensive. The main reason is the high expenditures for syngas production, which is the most energy intensive step of traditional GTL that comprises more than 50% of the total GTL capital cost. Therefore, there are no expectations of the significant increase of traditional GTL in the nearest future. To increase the possibilities for practical application of gas chemistry two alternatives can be suggested. The first one is decreasing the cost of syngas, e.g. by matrix conversion of hydrocarbon gases [1]. But the more evident is the developing of alternative "without syngas" GTL routes via direct partial oxidation or oxy-cracking of hydrocarbons with subsequent catalytic carbonylation and/or oligomerization of oxidation products [2,3].

2 Results and discussion

Direct partial oxidation and oxy-cracking of hydrocarbon gases give, respectively, mixtures of oxygenates, mainly methanol, with carbon monoxide and light olefins, mainly ethylene, with carbon monoxide. But the assortment of chemicals obtained from natural gas by partial oxidation can be significantly enlarged by means of subsequent catalytic carbonylation and/or oligomerization of oxidation products including co-polymerization of ethylene and CO.

The most perspective for the alternative GTL processes are the addition reactions of CO to the low-molecular substrates, such as carbonylation of methanol to acetic acid and methyl acetate; production of ethylidenediacetate; hydroformulation of ethylene to propanal; formation of methyl propanoate during ethylene methoxycarbonylation and vinyl acetate by reaction of ethylene with acetic acid; co-oligimerization of ethylene and CO with the formation of oligoketones and oligoesters. A number of carbonylation processes operate industrially in the presence of platinum group metals based catalysts (PGM catalysts).

By special experiments both for high pressure low temperature partial oxydation of natural gas to oxigenates and low pressure high temperature oxy-cracking of complex hydrocarbon mixtures that imitate real natural and associated gases it was shown the possibility to regulate in a wide range the ratio of main products depending on stohiometic ratio necessary for subsiquent carbonylation.

Of especial importance is that the specific activity of carbonylation catalysts 2-3 orders of magnitude higher than that of Fisher-Tropsch processes, which let to significantly decrease reactor's dimensions and cost.

The common scheme of new type of GTL-processes, some of possible chemicals that can be thus obtained, most effective catalysts and reaction conditions are presented in Fig. 1.

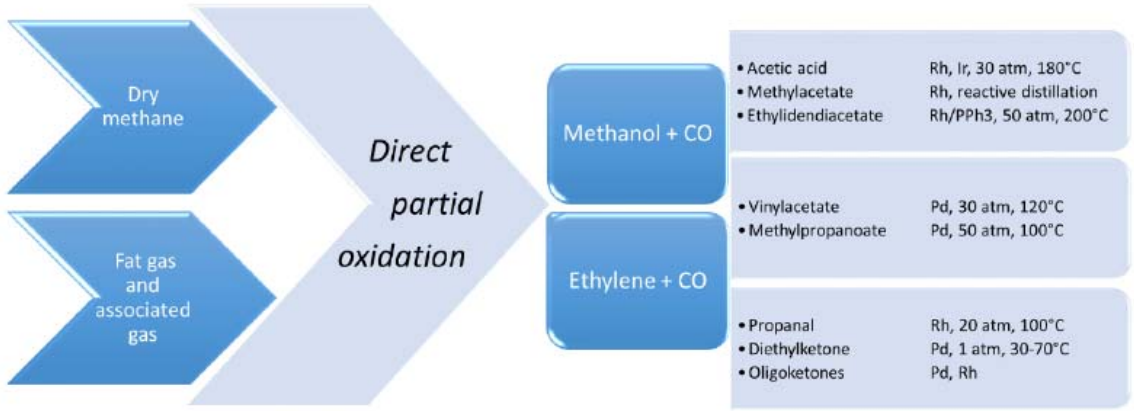

Fig. 1. New type of GTL-processes based on the carbonylation and/or oligomerization of products of partial oxidation and selective oxy-cracking of natural gas.

The first step of alternative GTL processes consists of direct oxidative conversion (for example, the partial oxidation methane to methanol); the partial oxidation of heavy components of associated petroleum gas to methanol and CO; or the oxidative cracking of heavy components of associated petroleum gas to form ethane and CO. The further processing of gas-vapor mixtures of methanol, ethene and CO (final step of alternative GTL) may give a broad assortment of high value-added marketable products. Moreover, the process simultaneously gives dry fuel gas with high methane index (Fig. 2).

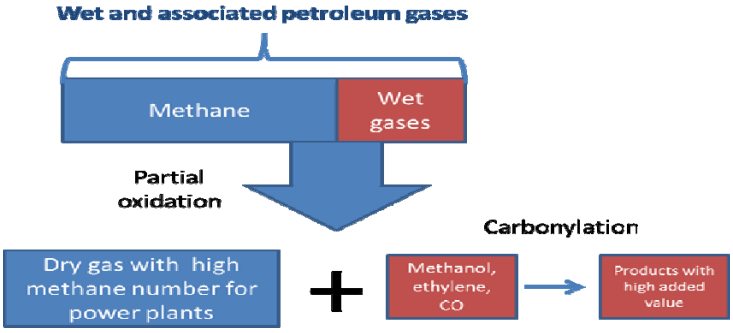

Fig. 2. Conversion of wet natural gas or associated petroleum gas yield high value-added petrochemical products and dry fuel gas with high methane index.

3 Conclusions

Direct partial oxidation of wet natural or associated petroleum gas with subsequent carbonylation and/or oligomerization of oxidation products can be considered as an alternative route for Gas-To-Liquids processes which let to avoid syngas production - the most costly and energy consuming stage of traditional GTL.

Keywords: hydrogen, storage, hydrogen generation, sodium, borohydride, ammonia, borane, catalyst

1 Introduction

Electronic devices (electronic tablets, navigators, communicators and others) have become indispensable in today's every-day life. For their safe operation, energy sources are needed with an energy-storage capacity exceeding that of the usual batteries. A promising solution to the problem is use of portable PEM fuel cells. However this would require creation of systems for storage and generation of high-purity hydrogen. Boron-containing hydrides – sodium borohydride ($NaBH_4$) and ammonia borane (NH_3BH_3) containing 10.5 and 19.3 wt. % of hydrogen, respectively, belong to compounds most rich in hydrogen. Their interaction with water in the presence of catalysts produces hydrogen at ambient temperatures without supply of heat. There may be two variants of the catalytic hydrogen generators: (I) using a flow reactor and (II) a batch reactor. Each type of reactor imposes its own requirements on the geometry, size, composition and strength of the catalysts. This work presents the results of our study of catalysts used in flow-reactor hydrogen generator and of the catalysts added to the "hydrogen" pellets used in batch-reactor hydrogen generator.

2 Experimental/methodology

All granular catalysts were prepared by incipient wetness impregnation of supports using aqueous solutions of corresponding metal chlorides and reduced directly in the reaction medium of boron-containing hydride solutions (*in situ*). The powder catalysts were synthesized from cobalt chloride and cobalt oxide under *in situ* conditions.

Catalytic hydrolysis of hydrides was performed in two ways.

Hydrogen generator with a flow reactor – solution of boron-based hydrides: The process of hydrogen generation was studied using a 15 wt% solution of $NaBH_4$ stabilized by sodium hydroxide or a 15 wt% solution of NH_3BH_3 at 20°C. The catalysts were tested in a flow apparatus at a feed rate of the solution of 1 cm^3/min.

Hydrogen generator with a batch reactor – solid $NaBH_4$-based pellet: At 20°C a solid-state $NaBH_4$ pellet (0.0465 g of $NaBH_4$ with the powder cobalt catalyst) was placed into a batch reactor and then 10 mL of distilled water was added. The volume of the produced hydrogen gas was measured with a 100 mL gas burette.

HRTEM with EDX analysis, FTIR spectroscopy, XRD, magnetic susceptibility, neutron scattering and EXAFS were used for characterization of *in situ* formed catalysts.

3 Results and discussion

Hydrogen generator with a flow reactor - solution of boron-containing hydrides:

Generation of large amounts of hydrogen over a prolonged period of time is best achieved in a hydrogen generator with a flow reactor [1] where a concentrated solution of hydride passes through a fixed bed of granular catalyst. The catalytic activity of VIII group metals on

granulated Sibunit, TiO_2, Al_2O_3 supports has been studied. The activity of the metals was found to decrease in the series Rh>Ru>Pt>Co>Ni on each of the studied supports, Rh/TiO_2 showing the highest activity. Its calcination (300°C) considerably accelerates $NaBH_4$ decomposition thanks to the formation in the reaction medium of electron-deficient nanoparticles of rhodium on the TiO_2 surface [2]. Among the non-noble metal catalysts the most active in $NaBH_4$ and NH_3BH_3 hydrolysis were cobalt catalysts reduced *in situ* in a medium of hydrides. Using EXAFS, neutron scattering and magnetic susceptibility it was established, for the first time, that the catalytically active phase of cobalt catalysts represents tetramers of cobalt atoms with Co-Co distances of 2.33 and 2.48 Å imbedded in a B-O-H matrix. Such a model has been called a "jelly".

It was shown that in an alkaline reaction medium the catalytically active phase of the cobalt catalysts gets destroyed to form non-active Co^0 and $Co(OH)_2$ [3]. This leads to a drop in H_2 generation rate during long-term stability tests. For a better stability of the cobalt catalyst it was modified by ruthenium as a result of which the Ru-Co catalyst becomes as stable and active as is highly effective rhodium system. According to HRTEM data the active component of the modified catalyst represents cobalt-ruthenium particles of an average size of 3.2 nm consisting of a cobalt core and a shell enriched in ruthenium. This leads to an enhanced activity of the catalytic system and prevents cobalt deactivation in the alkaline medium during the long-term stability tests [4].

Hydrogen generator with a batch reactor - solid $NaBH_4$-based pellet

Such type of hydrogen generator is needed for a short-time (to two hours) generation of hydrogen at a low generation rate which is important when charging batteries of portable devices in the field. Here the source of hydrogen is a "hydrogen" pellet representing a compressed mixture of solid hydride and a powder of active cobalt catalyst [5]. It was found that the rate of hydrogen generation upon addition of water to the $NaBH_4$-based pellet is determined by the hydride/catalyst/water ratio, the nature of the catalyst and the content of different specialized additives. It was shown also that no hydrogen losses occur during a prolonged storage of $NaBH_4$ pellets.

4 Conclusions

The obtained results show a promise for employing granulated cobalt-ruthenium catalysts in flow-reactor hydrogen generator and of powders of cobalt catalysts in batch-reactor hydrogen generator operating with $NaBH_4$-based pellets. The structure of the catalytically active phase of cobalt-containing catalysts which form *in situ* in the reaction medium under the action of hydrides has been established and the influence of different factors were determined.

Dry Reforming of Propane over NiO-CeO_2 Loaded Anodized Aluminum Oxide(AAO) Catalysts

Jayakodi Karuppiah J., Young Sun Mok Y.S*

Jeju National University, Department of Chemical Engineering, Jeju, South Korea

* smokie@cheju.ac.kr, smoke@jejunu.ac.kr

Keywords: anodic alumina oxide, synthesis gas, dry reforming, carbon deposition, CeO_2

1 Introduction

Synthesis gas (syngas), a fuel gas mixture consists of hydrogen and carbon monoxide is important intermediate for production of value-added oxygenated chemicals and liquid fuels [1]. Recently, it has been proven that the noble metals are less sensitive for carbon deposition on the surface therefore it is more important to develop novel catalyst with desired catalytic performance as compared to the noble metals. Among various metals nickel is catalytically active for the reforming reaction. However the deposition excess carbon on metal surface degrades their catalytic activity. Therefore, much attention has been focused on the development for Ni-based catalysts or metal oxide as well as changing supports, suppressing the carbon deposition. In order to reduce the carbon deposition, the metal-support is the key factor and needed to be improved. Recently, anodic oxidation technology was applied to produce monolith-like catalyst support which offers strong metal-support interaction. Porous anodic alumina oxide (AAO) template, are one of the most interesting structures, due to their unbranched, regular, controllable and nearly parallel pores. The above benefits of AAO show advantages for mass and heat transfer. Topology of the catalyst pore structure 10 nm–100 nm can influence reagent flow, the sequencing of catalytic active sites, and the contact time between reacting gas and catalyst. Hence, AAO is a highly promising support structure for the application in catalytic reforming reaction. In this investigation simultaneous loading of Ni and CeO_2 on AAO was studied as the catalyst for propane dry reforming reaction.

2 Experimental

Catalysts preparation

AAO templates with ordered pores were prepared by an anodization process using freshly prepared oxalic acid solution [2]. Nickel and ceria were loaded onto the AAO supports by impregnating the plates with aqueous solutions of Ni $(NO_3)_2$ and Ce $(NO_3)_3$ dissolved in 250 ml de-ionized water to keep the molar ratio changed from 0.2 to 1. Then the prepared catalysts were calcined at 450°C. The loaded metal oxide concentration was about to 4 wt% (obtained by measuring the weight of the support before and after catalyst loading) with respect to support weight.

Catalytic reaction and characterization

The dry reforming of propane with CO_2 was carried out in a thermo-catalytic reactor packed with catalyst plate (10 g, 5 × 6 cm) was cut into pieces with a size of 2–3 mm^2 and loaded into the reactor. The catalytic activity was studied in the temperature range of 480–580°C for all the catalysts. The reactant gases were fed into the reactor at the proportion of 10:30:60 ($C_3H_8/CO_2/N_2$). The total flow rate was fixed at 300 ml min^{-1} throughout this work. During the reforming reaction, the concentrations of relevant components were analyzed by a gas chromatograph equipped with a thermal conductivity detector (TCD). Numerous techniques, such as N_2 adsorption–desorption isotherm, X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM) and transmission electron microscopy (TEM), and Temperature

programmed reduction (TPR) and temperature programmed oxidation (TPD) were applied for characterization of fresh and spent catalysts.

3 Results and discussion

The catalytic performance of AAO supported catalysts with various nickel and Ceria loadings at different reaction temperatures. The obtained results show that both C_3H_8 and CO_2 conversions increased with increasing ceria loading up to 80 %(0.8M) and 20 % (0.2M) NiO/CeO_2-AAO catalysts showed the highest activity for dry reforming reaction.

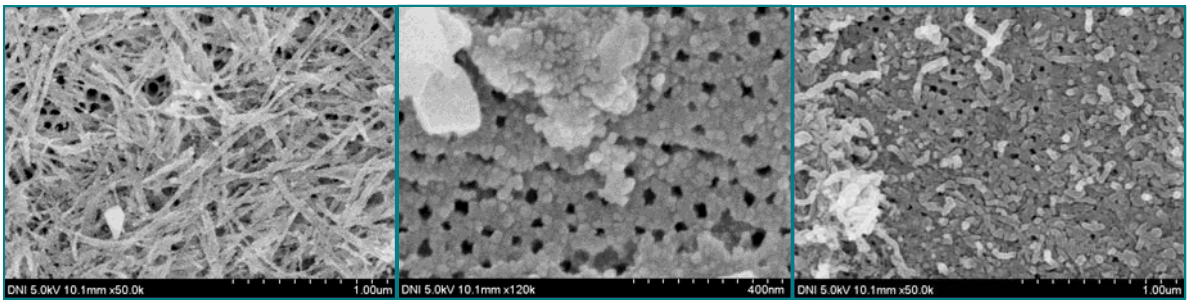

Fig. SEM images of (a) $NiO_{(0.2M)}$-$CeO_{2(0.8M)}$/AAO, (b) (b) $NiO_{(0.8M)}$-$CeO_{2(0.2M)}$/AAO catalysts and (c) $NiO_{(0.8M)}$-$CeO_{2(0.2M)}$/AAO after the reforming.

The results of catalyst testing revealed that the catalysts with higher ceria loading catalyst (0.2M NiO+0.8M CeO_2) have superior catalytic performance for activity and stability than other loading. After 12 h under stream at 540^{o}C, CeO_2 catalysts, showed a stable operation in presence of a deposited amorphous carbon. Carbon deposition on spent catalysts was analyzed by the temperature programmed oxidation (TPO). The structural and phase modification of the catalysts after the reforming reactions were further examined with XRD, SEM, TEM and TPO.

4 Conclusions

It is then noted that, the use of electroless deposition to prepare bimetallic oxides of AAO catalysts for DR provides a useful technique for synthesizing highly functional metallic catalytic systems. The main advantage of a plated catalyst is effective heat exchange and the formation of the NiO and CeO_2–bimetallic oxides on AAO support, which brings about the improvement in catalytic activity. The plated catalyst made from an equimolar concentration of metal solution forms a better NiO-CeO_2 interaction over AAO and leads to higher propane conversion and high H_2/CO ratio. High dry reforming activity of CeO_2-promoted and exhibited good stability for anti-sintering and coke resistance.

Keywords: Fischer-Tropsch synthesis, bifunctional catalyst, mesoporous zeolite, selectivity control, isoparaffins, hydrocracking

1 Introduction

Fischer-Tropsch (FT) synthesis is a crucial process in the transformation of non-petroleum carbon resources into clean hydrocarbon fuels via syngas. Over conventional FT catalysts, the products generally follow the Anderson-Schulz-Flory (ASF) distribution, which is wide (C_{1-80}) and unselective. The integration of acidic zeolite and conventional FT catalyst can lead to high C_{5-11} selectivity (gasoline-range) without resorting to very complex designs. However, the selectivity of light hydrocarbon (C_{1-4}) is generally unacceptably high over zeolite-supported catalysts, probably due to the diffusion limitation and the overcracking caused by the narrow and long micropores. Using mesoporous zeolites as the supports of Ru catalysts, we succeed in suppressing the C_{1-4} selectivity.[1,2] Herein, we report our recent studies on the development of highly selective mesoporous H-ZSM-5 (H-meso-ZSM-5)-supported Co catalysts by coupling Co nanoparticles with uniform particle sizes and mesoporous ZSM-5 with tunable mesopore sizes and acidities for FT synthesis. The hydrocracking of *n*-hexadecane, a model compound of heavier hydrocarbons, will also be investigated to provide deeper insights.

2 Experimental

Mesoporous ZSM-5 was prepared by post-treating a Na-ZSM-5 (Si/Al = 18) using NaOH aqueous solutions. The obtained Na-form meso-ZSM-5 was exchanged to H-meso-ZSM-5 by an ion-exchange method. Co nanoparticles were loaded onto H-meso-ZSM-5 by an impregnation with $Co(NO_3)_2$ aqueous solutions, followed by heat treatment in NO/He and H_2 reduction. The catalysts were characterized by various techniques including XRD, N_2-physisorption, H_2 chemisorption, H_2-TPR, TEM, NH_3-TPD, pyridine-adsorbed FT-IR and pulse oxidation. FT synthesis was performed on a high-pressure fixed-bed reactor at 513 K with a syngas (H_2/CO = 1/1) pressure of 2 MPa. Hydrocracking of *n*-hexadecane was operated in the same reactor at 513 K with a H_2 pressure of 2 MPa. The products were analyzed by gas chromatography.

3 Results and discussion

Fig. 1a shows that the synthesized ZSM-5 possesses a sheet-like morphology, which may be beneficial to mass transport. After post-treatment by NaOH aqueous solutions, abundant mesopores were generated over the ZSM-5 crystals (Fig. 1b).

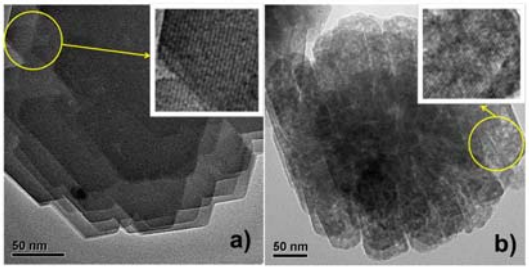

Fig. 1. TEM images of a) H-ZSM-5 and b) H-meso-ZSM-5-0.5M.

Crystalline fringes could be observed in the HRTEM images of the H-meso-ZSM-5, indicating that the crystalline structure was maintained. We clarified that the size and pore volume of mesopores increased with an increase in the concentration of NaOH aqueous solution.[3] Our pyridine-adsorbed FT-IR and NH_3-TPD studies revealed that the density of Brønsted acid sites decreased gradually with an increase in the concentration of NaOH solution.

We clarified that the post-treatment of the $Co(NO_3)_2$/H-ZSM-5 composites affected the size distribution of Co particles loaded and found that the heat treatment under NO/He could provide uniform sizes of Co particles.[3] TEM measurements further revealed that the mean sizes of Co particles loaded on H-meso-ZSM-5 with different mesopore sizes were in a range of 7.7-10.5 nm, which were beneficial to FT synthesis.[4]

Fig. 2a shows that the Co/H-meso-ZSM-5 exhibits significantly lower CH_4 and C_{2-4} selectivities and higher C_{5-11} selectivity than the Co/H-ZSM-5. The selectivity to CH_4 decreased from 22% to 8% and that to C_{5-11} increased from 51% to 70% when an optimized concentration of NaOH (0.5-0.8 M) was used for H-meso-ZSM-5 synthesis. It is also of interest that the main products in C_{5-11} are isoparaffins. The conversion of *n*-hexadecane verified that our bifunctional catalysts could catalyze the hydrocracking of *n*-hexadecane under the conditions similar to those used for FT synthesis. Fig. 2b shows the selectivity to middle-distillate products, in particular, C_{7-11}, increases significantly by using Co/H-meso-ZSM-5 instead of Co/H-ZSM-5, which mainly produced lighter hydrocarbons. The ratio of isoparaffins to n-paraffins in the cracking products was high. It can be concluded that the increment of C_{5-11} isoparaffins in FT synthesis stems from hydrocracking/isomerization of C_{12+} hydrocarbons formed on Co nanoparticles.

We further studied the roles of acidity and mesoporosity through a series of studies using meso-ZSM-5 with different mesopore sizes and different H^+-exchanging degrees. We clarified that the Brønsted acidity accounted for the hydrocracking of heavier hydrocarbons, whereas the mesoporosity mainly contributed to suppressing the formation of lighter hydrocarbons.

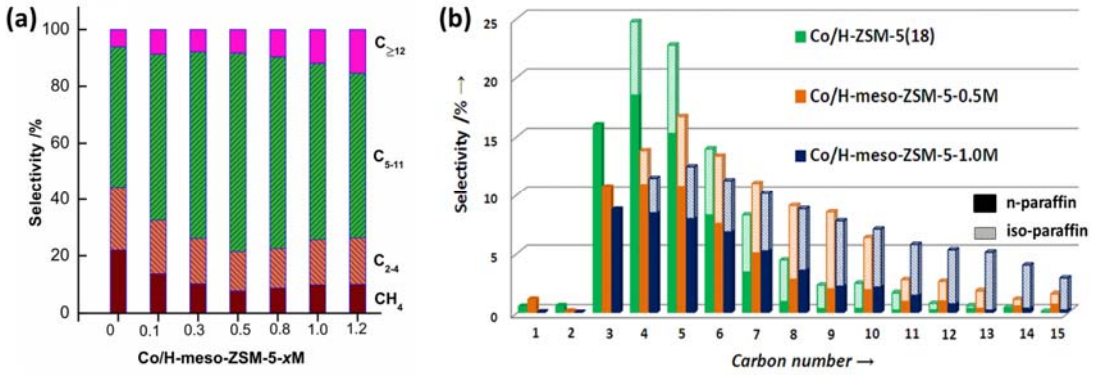

Fig. 2. Product distributions. (a) FT synthesis, (b) *n*-hexadecane hydrocracking.

4 Conclusions

The coupling of mesoporous H-ZSM-5 and uniform-sized Co nanoparticles significantly increased the selectivity to $C_{5–11}$ gasoline-range hydrocarbons (70%) with a high fraction of isoparaffins. The Brønsted acidity was required for the hydrocracking of heavier hydrocarbons (C_{12+}), whereas the presence of mesoporosity contributed to suppressing the formation of lighter hydrocarbons. Using *n*-hexadecane as a model compound, we confirmed the roles of Brønsted acidity and mesoporosity in hydrocracking/isomerization and in determining the selectivity.

CO Activation on Cobalt Fischer-Tropsch Catalyst

Chen W.*, Zijlstra B., Filot I.A.W., Ligthart D.A.J.M., Van Hoof A.J.F., Pestman R., Hensen E.J.M.

Laboratory of Inorganic Materials Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

Keywords: cobalt catalyst, CO activation, transient kinetics, microkinetic modeling

1 Introduction

Fischer-Tropsch (FT) synthesis is not only the enabling technology that can convert a wide range of carbon sources into liquid fuels, but also presents an entry into the synthesis of organic intermediates [1]. It is of fundamental importance to understand the mechanism underlying the FT reaction. CO hydrogenation and FT share the same CO dissociation step that initiates the surface polymerization process and production of other chemicals with C-C bonds [2]. Modern insights into the relation between surface topology and reactivity dictate that direct CO dissociation can only occur with reasonable activation barrier on step-edge sites of transition metals such as Co, Rh and Ru [3]. Hydrogen assisted CO dissociation has been recently explored as an alternative route for less reactive planar surfaces [4]. In the present work, transient experiments combined with theoretical calculations were employed to understand CO hydrogenation on Co catalysts.

2 Materials and Methods

The catalyst containing 20 wt% Co and 0.04 wt% Pt was prepared by incipient wetness impregnation on SiO_2 (Shell). The turn over frequencies (TOF) were determined based on hydrogen chemisorption (ASAP 2000). $^{13}C^{16}O$ (Cambridge Isotope Laboratories, ^{13}C 99%, ^{18}O 95%) and $^{13}C^{18}O$ (^{13}C 99%, ^{18}O <2%) isotopes are used in transient experiment and $^{12}C^{16}O/^{13}C^{18}O$ scrambling experiment, respectively.

Plane wave density functional theory (DFT) calculations with projector-augmented wave (PAW) method were performed using Vienna ab initio simulation package (VASP) to determine all activation energies of elementary surface reactions. The microkinetic modeling (MKM) was carried out by an in-house written C++ software suit for heterogeneous catalysis. Transient data fitting was performed by Matlab (MathWork).

3 Results and discussion

The mechanism of CO activation was studied by a new approach that combines transient techniques (Fig. 1), *i.e.*, steady state isotopic transient analysis (SSITKA)and chemical transient analysis. Together with the first-principle based MKM (Fig. 2), these transient data can be interpreted in terms of the mechanism of both direct and H-assisted CO dissociation. Degree of rate control analysis of MKM suggests that CH_2O dissociation controls the methanation rate for Co(0001) surface, and CO dissociation and CH_3 hydrogenation contribute to the rate control on Co(1121). Combined transient data show better correspondence of direct CO dissociation with the kinetics than hydrogen assisted CO dissociation does. Transient data fitting based on direct CO dissociation mechanism is in agreement with first-principles calculation. By $^{12}C^{16}O/^{13}C^{18}O$ isotope scrambling experiments [5], we found that the CO scrambling TOF is close to that of the methanation rate, indicating that direct CO dissociation is the main mechanism of CO activation.

Combined, these results highlight the importance of direct CO dissociation on Co nanoparticles.

Fig. 1. Modeling of normalized methane response throughout transient experiments. Points are experimental results; lines are modeling results. The different feeds are shown on top.

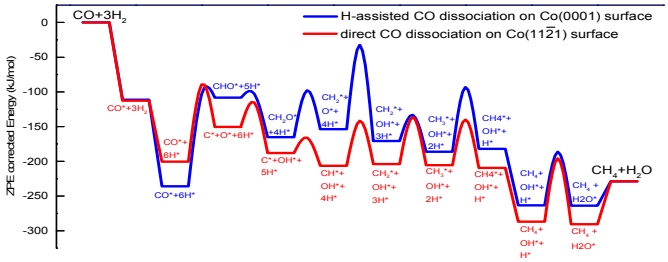

Fig. 2. Reaction energy diagram for hydrogen assisted CO activation on the Co(0001) surface (blue) and direct CO activation on the Co(1121) surface (red)

4 Conclusions

Transient kinetic experiments (SSITKA, CTKA and $^{12}C^{16}O/^{13}C^{18}O$ isotope scrambling) were combined with first-principles based microkinetics approaches to investigate the mechanism of CO activation that initiates the Fischer-Tropsch reaction. The results provide strong support for the importance of direct CO dissociation for obtaining CH_x building blocks relevant to methanation and the Fischer-Tropsch reaction.

Keywords: biomass, lignin, supercritical, ethanol, depolymerization, alkylation, Guerbet reaction

1 Introduction

Lignocellulosic biomass is a low-cost renewable feedstock that is uniquely suited for the production of sustainable liquid fuels. One approach to valorize the carbohydrate fraction is to convert the constituent sugars to ethanol by fermentation. Different from cellulose and hemicellulose, technologies to upgrade lignin into useful products are in early stage of development. Cellulosic ethanol production is approaching commercial practice. A considerable issue associated with large-scale ethanol production from lignocellulosic biomass is the co-production of large amounts of lignin; these amounts exceed both the internal energy needs of biorefineries and the world market for lignin-derived specialty products by a large margin. Therefore, new processes to add value to lignin beyond its combustion heat are needed. We have earlier reported a one-step valorization of soda lignin in supercritical ethanol using a $CuMgAlO_x$ catalyst, resulting in 23 wt% monomer yield (300 °C, 8 h) without char formation [1]. Alkylation was found to play an important role in suppressing repolymerization[1]. In the present work, we will reveal evidence for the role of ethanol to suppress repolymerization, explaining high monomer yield.

2 Experimental/methodology

Three types of lignin (Soda, Alcell, Kraft) were used as feedstock. The reactions were conducted in a batch reactor under supercritical ethanol using a mixed non-noble-metal oxides catalyst ($CuMgAlO_x$). A comprehensive workup procedure was developed to distinguish the smaller (THF-soluble) and larger (THF-insoluble) lignin fragments and char. GC-MS, GPC, ^{1}H-^{13}C HSQC NMR and elemental analysis (CHO) techniques were used to characterize the lignin products. In addition, phenol and guaiacol were also used as model reactant in order to understand the mechanistic insights during lignin depolymerization.

3 Results and discussion

We compared the solvent effect of lignin reaction using methanol and ethanol as solvents. It was found that much less monomer (8 wt% vs 17 wt%) and much more THF-insoluble lignin residue (39 wt% vs 18 wt%) were formed in methanol than in ethanol after reaction at 300 °C for 8 h. It indicates that catalytic depolymerization of lignin is much more effective in ethanol than in methanol. To understand the role of the solvent, we compared the conversion of phenol into high-molecular-weight products in methanol and ethanol. Consistently, we found that polymerization of phenol took place in methanol, but not in ethanol. This is because methanol can be readily dehydrogenated to form formaldehyde, which easily reacts with phenol to form

resins. This explains why the use ethanol is significantly more effective in producing monomers and avoiding char than the use of methanol. Furthermore, we proved that ethanol also acts as formaldehyde scavenger that reacts with the formaldehyde formed from methoxy group cleavage from the lignin during supercritical ethanol-mediated reactions. This explains the absence of char formation in ethanol. After optimizing the reaction conditions, we found that monomer yields between 60 wt% and 86 wt% (depends on the lignin used) can be obtained after reaction of lignin in ethanol at 380 °C for 8 h.

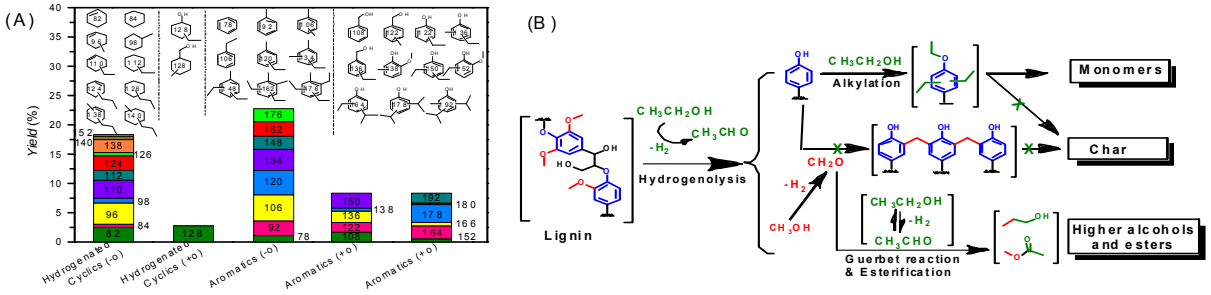

Figure 1(A). Monomeric product distribution following (soda) lignin reaction at 380 °C for 8 h over the $CuMgAlO_x$ catalyst in ethanol solvent. **Figure 1(B).** The roles of alkylation, the Guerbet reaction, and esterification on suppressing char formation during lignin depolymerization over the $CuMgAlO_x$ catalyst in ethanol solvent.

4 Conclusions

We have demonstrated high-yield production of monomeric aromatics from lignin using a $CuMgAlO_x$ catalyst in supercritical ethanol with little char formation. The monomeric products are mainly composed of alkylated aromatics and cycloalka(e)nes. The oxygen-free aromatics can be used as chemical building blocks and as octane boosters when blended with gasolines. Oxygenated aromatics may serve as valuable compounds for the chemical and polymer industry. They can also be used as low-sooting diesel fuel additives [2]. Different types of lignins, including sulfur-containing Kraft lignin, can be used as the feedstock. Importantly, we revealed new mechanistic insights about lignin depolymerization and highlighted the role of alcohol solvents. Ethanol is effective as a capping agent and formaldehyde scavenger, suppressing repolymerization and char-forming reactions. We believe that these insights provide new impetus for the design of better processes to valorize lignin.

Biofuels Production from Glycerol and TBA Using an Innovative Catalytic Membrane Reactor

Cannilla C.*, Bonura G., Feminò G., Drago Ferrante G., Frusteri F.

National Council of Research, CNR-ITAE, Messina, Italy

* catia.cannilla@itae.cnr.it

Keywords: glycerol, biofuels, membrane reactor, diesel additives, acid solid catalysts

1 Introduction

Glycerol *poly*-*tert*-butyl ethers can be produced by etherification of glycerol with *tert*-butyl alcohol by employing an acid catalyst. This synthesis represents a new route for the production of oxygenated additives for diesel fuels [1]. Since the reaction is controlled by equilibrium and water is formed as *by*-product, irrespectively from the catalyst used, the reaching of high glycerol conversion and *poly*-ethers yield is limited by thermodynamic constraints. A study regarding the optimization of the reaction conditions is here reported by exploiting an innovative batch reactor coupled with a permselective membrane to remove the water from the reaction medium and to promote the formation of *poly*-ethers. The attention has been addressed on the obtainment in one step of a mixture, containing a low amount of *mono*-ether suitable to be added to the diesel fuel.

2 Experimental/methodology

Etherification reaction of glycerol was carried out by using both a commercial acid ion resin A-15 and a acid catalyst, H730/SiO_2, prepared by impregnation of a microspherical silica with Hyflon® Ion S4X perfluorosulphonic ionomer. The reaction was performed at 80°C in liquid phase in a stainless steel reactor coupled with a permeoselective tubular membrane (furnished by Pervatech) used to remove the water formed during the reaction by recirculation of gas phase. The liquid phase was analyzed *off line* by a gas chromatograph provided with a capillary HP Innowax column.

3 Results and discussion

The etherification of glycerol generates a set of consecutive equilibrium reactions and, at the same time, secondary reactions could occurs too; in particular, when TBA is the *O*-alkylant agent, the following scheme should be considered.

Main consecutive reactions with TBA		*Main consecutive reaction with IB produced by eq.4*	
Gly + TBA ⇆ Mono + H_2O	(1)	Gly + IB⇆ Mono	(7)
Mono + TBA ⇆ Di + H_2O	(2)	Mono + IB ⇆ Di	(8)
Di + TBA ⇆ Tri+ H_2O	(3)	Di + IB ⇆ T	(9)
Secondary reactions		*Secondary reactions with IB produced*	
TBA ⇆ IB+ H_2O	(4)	IB + IB ⇆ DIB	(10)
Mono + Mono ⇆ GLY + Di	(5)	IB + DIB ⇆ TRIM	(11)
Di + Di ⇆ Tri + Mono	(6)	DIB + DIB ⇆ *poly*-isobutene	(12)

In a recent paper [1], it has been reported that with A-15, an acid-exchange resin, the best results in the etherification reaction were obtained at 70°C, with a glycerol conversion (X_{Gly}) of 80% and a selectivity to *mono*-ethers of 70%. By increasing the reaction temperature to 80°C, the X_{Gly} decreased to 67% likely due to faster accumulation of water which prevents the activation of glycerol by competitive absorption on the acid sites of the catalyst.

Then, once the equilibrium is reached, reaction no longer goes on towards *tri*-ethers

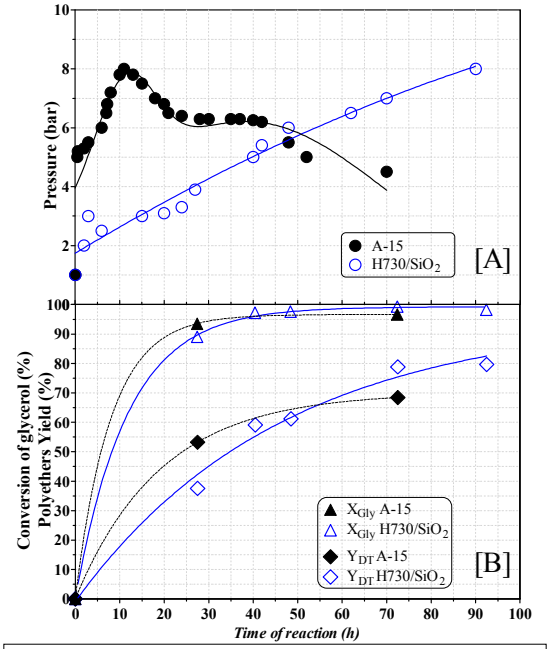

Fig. 1. Etherification reaction as a function of reaction time. T_R=80°C; $R_{cat/gly}$= 7.5 wt.% with respect to glycerol weight; $R_{TBA/gly}$= 8 mol/mol

formation; rather the dealkylation reaction of *poly*-ethers to *mono*-ethers becomes significant [2]. Therefore, the water produced affects the thermodynamic equilibrium preventing the formation of *poly*-ethers and consequently the total glycerol conversion [2]. The results previously obtained also showed that to perform the etherification of glycerol, the catalyst should be characterized by a not excessive acidity in order to avoid the occurrence of secondary reactions. Furthermore, the surface properties must be adequate to allow a high accessibility of acid sites for the activation-desorption of reaction intermediates featured by high steric hindrance. Fig. 1 shows results obtained in the etherification of glycerol with TBA both in presence of A-15 and H730/SiO_2 catalysts in terms of glycerol conversion, reaction pressure and yield to *poly*-ethers (Y_{DT}) along the time using the batch reactor coupled with the membrane. With A-15, the reaction pressure drastically increases up to 5 bar in 30 min thus confirming that the dehydration of TBA to IB takes place at high rate; pressure reaches a maximum value after 10h and then it decreases with time. On the contrary, in case H730/SiO_2 catalyst is used, the reaction pressure linearly increases with time thus suggesting that IB is formed at a lower rate, reaching higher values after very long reaction time. This result is mainly linked to the difference between the rates of IB production and consumption and confirms that, with H730/SiO_2, IB slowly accumulates into the reactor; besides χ_{Gly} progressively increases with time reaching almost the total conversion after 25h while the Y_{DT} increases up to 80% after 70h. Differently, with A-15, χ_{Gly} never reaches values higher than 96% and Y_{DT} value remains lower (68%) than that obtained with the H730/SiO_2 system. This is due to the fact that the lower rate of IB formation observed with H730/SiO_2 doesn't promote the production of byproducts by IB oligomerization (eqs.10-12) which, in case of A-15, negatively reflect on the cumulative Y_{DT}.

4 Conclusions

The use of a novel batch reactor assisted by a permselective membrane resulted to be a winning idea to produce ethers from glycerol by etherification with TBA. In fact, the removal of water allowed to shift the equilibrium towards the *poly*-ethers formation. By setting the appropriate reaction parameters and employing a proper solid catalyst (Hyflon/SiO_2), it was possible to carry out the etherification of glycerol with alcohol (TBA) to obtain a clean ethers mixture without glycerol and containing about 80 wt.% of *di*- and *tri*-ethers.

Keywords: diphenyl, ether, lignin, C-O cleavage, solvent, hydrogenolysis, hydrolysis

1 Introduction

Catalytic cleavage of the C-O bond in aromatic ethers of lignin is a critical process for the conversion of lignin to fuels, and chemicals [1]. Diphenyl ether is commonly chosen as the simplest model compound for exploring the mechanism of catalytic conversion of 4-O-5 ether bond in lignin, which has the highest bond dissociation energy. Considering the higher tolerance to water and the easier application for industrial utilizations, Ni-based catalytic system in the aqueous phase were intensively studied by various groups [2,3]. These recent advances towards C-O bond cleavage in lignin model compounds have been focused exclusively on the development and screening of catalysts [4]. Much less attention has been to the influence of substituted groups and solvents. In this contribution, we will systematically explore the influence of solvents (H_2O and *n*-hexane) on the reaction pathway (hydrogenolysis, hydrolysis and hydrogenation) and kinetic parameters (initial TOFs, apparent activation energies, reaction orders) of three di-aryl ethers with various substituted groups like di-*p*-tolyl ether (-CH_3), diphenyl ether (-H) and 4,4'-dihydroxyldiphenyl ether(-OH)) on Ni/SiO_2 at 393 K and 0.6 MPa H_2. In addition, the adsorption heats of diaryl ethers on Ni surface were calculated in different environments. Furthermore, DFT calculation was also applied to determine the sequence of reaction rate of C-O bond cleavage and hydrogenation of all three diaryl ethers in apolar phase and in aqueous phase.

2 Experimental

Reagents. All the chemicals used in this study were obtained from commercial suppliers. Ni/SiO_2 catalyst was synthesized *via* deposition precipitation (DP) method.

Kinetic methods. In a typical experiment, the substrates were converted in a Parr autoclave reactor (Series 4848, 300 mL Hastelloy) in H_2O and *n*-hexane, respectively, at 393 K in the presence of 0.6 MPa H_2. Diphenyl ether (0.010 mol), 57 wt.% Ni/SiO_2 (0.30 g, 2.91×10^{-3} mol Ni in H_2O or 0.15g, 1.45×10^{-3} mol Ni in *n*-hexane), and solvent (H_2O or *n*-hexane, 80 mL) were added into the autoclave.

3 Results and discussion

Figure 1 shows the reaction proceed *via* hydrogenolysis and partial/full hydrogenation in the apolar phase. In contrast, hydrolysis appeared as a new major reaction pathway in aqueous phase. Furthermore, the full hydrogenation of diphenyl ether was not observed in water. In aqueous phase the reaction rates (C-O cleavage or hydrogenation) showed the order of $TOF_{\text{4,4'-dihydroxyldiphenyl ether}} > TOF_{\text{diphenyl ether}} > TOF_{\text{di-}p\text{-tolyl ether}}$. In aqueous phase the reaction rates (C-O cleavage or hydrogenation) followed the order of $TOF_{\text{di-}p\text{-tolyl ether}} > TOF_{\text{diphenyl ether}} > TOF_{\text{4,4'-dihydroxyldiphenyl ether}}$. In a comparison to aqueous phase, the apolar solvent will greatly enhance the selectivity to hydrogenation in a competition between hydrogenation and hydrogenolysis.

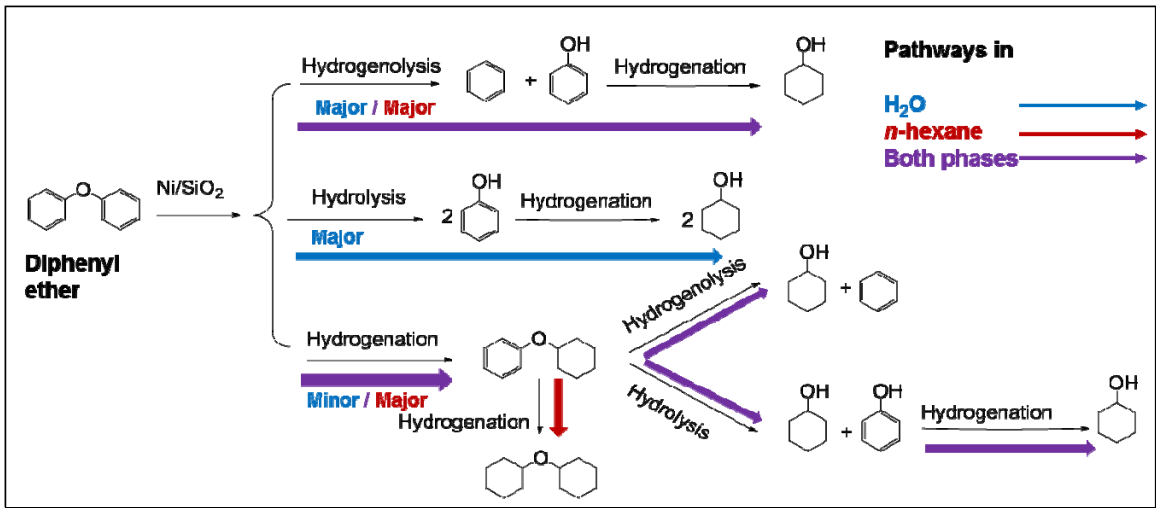

Fig. 1. The proposed reaction pathways for diphenyl ether in water and *n*-hexane.

4 Conclusions

The catalytic conversion of three di-aryl ethers with different substituted groups (diphenyl ether (-H), di-p-tolyl ether (-CH_3) and 4,4'-dihydroxydiphenyl ether (-OH)) have been explored over Ni/SiO_2 in aqueous and apolar phase (*n*-hexane). C-O bond cleavage and hydrogenation were two competitive parallel reactions over Ni/SiO_2 in the reaction conditions. Substituted groups and solvents influenced not only reaction pathway and selectivity to C-O bond cleavage and hydrogenation, but also the rates of catalytic C-O bond cleavage and hydrogenation of diaryl ethers by altering the reactant solubilities, solvent-reactant interactions, as well as by competitive solvent/reactant adsorption on the Ni surface.

Keywords: zeolites, methylation, dimethyl ether, methanol, MD, simulations, methanol-to-hydrocarbons

1 Introduction

Methylation of benzene and other aromatics are key reactions in several important industrial processes such as methanol conversion to gasoline or olefins (MTG/MTO) [1] and xylene production from toluene [2]. Microporous acid materials such as zeolites are commonly used as catalysts in these processes. This work combines experiments and theory to investigate the behaviour of methanol and dimethyl ether (DME) during benzene methylation over catalysts with different structures (MFI and AFI) and acid strength (AFI). Previous studies have revealed higher methylation rates for DME than methanol over H-ZSM-5 [3], but the methylation mechanisms are usually assumed to be similar. This study not only confirms a difference in methylation rates, but also reveals large differences in selectivity towards secondary products for methanol and DME.

2 Experimental/methodology

Catalytic experiments were performed in a fixed bed quartz reactor with 5 mg catalyst powder diluted in 40 mg quartz (particle size 250-420μm). Typically, 60 mbar of benzene was co-reacted with 60 mbar of either methanol or DME at differential conversion (WHSV = 205-375 h^{-1}, conversion < 2%) at 250-300 °C. The effluent was monitored continuously by on-line MS and a detailed analysis was performed by on-line GC-FID/MS after 10 minutes of reaction.

Ab initio molecular dynamics calculations were carried out with the CP2K simulation package to sample all relevant configurations of the guest molecules in the pores. The periodic DFT-D3 calculations were performed in a 1x1x2 H-SSZ-24 and H-SAPO-5 super cell and H-ZSM-5 unit cell, at 350 ºC and 1 bar. Rare event sampling was enhanced with a metadynamics approach [4].

3 Results and discussion

Net product formation rates obtained during benzene methylation at 250°C are shown in Figure 1. In agreement with previous studies on H-ZSM-5 [3], the use of DME led to higher total product formation rates than methanol. Furthermore, Figure 1 shows that the product distribution varied significantly based on the choice of methylating reactant. While DME predominantly yielded (sequential) methylation and dealkylation products (toluene, polymethylbenzenes and alkenes), the use of methanol led to a high selectivity towards diphenylmethane (DPM) and its methylated analogue. Similar trends were observed at 300°C for H-ZSM-5 and H-SSZ-24. DPM has previously been suggested as an intermediate during methylbenzene transmethylation reactions [5]. Preliminary results indicate a larger release of H_2 during the reaction when using methanol, indicating that DPM may be formed by phenylation of

toluene accompanied by loss of H_2.

Figure 2 illustrates the proposed reaction scheme, where formed toluene is either methylated further or phenylated to form DPM. The reaction mechanisms and kinetics of toluene phenylation are currently under investigation. In addition, ab initio molecular dynamics simulations of co-adsorption and reaction of methanol and DME with benzene, toluene and xylene have been performed in order to obtain a deeper understanding of the experimental observations. Important differences in the stability and reactivity of different co-adsorption complexes formed between methanol or DME and aromatics with an increasing degree of substitution may be possibly linked with the observed selectivity and reactivity differences.

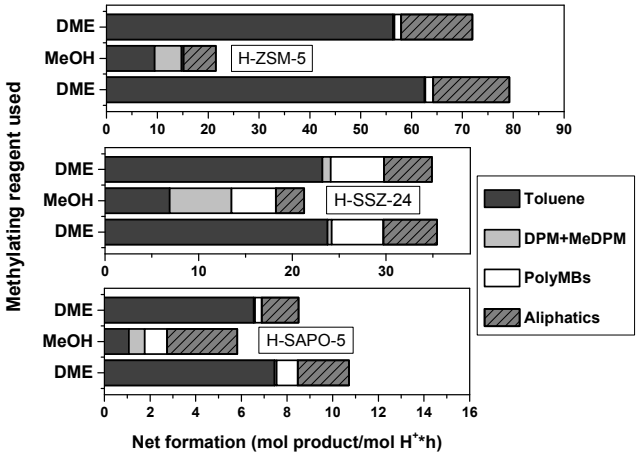

Fig. 1. Net product formation rates during benzene methylation over H-ZSM-5 (top), H-SSZ-24 (middle) and H-SAPO-5 (bottom) at 250°C. Experiments were run sequentially (e.g. DME-MeOH-DME).

4 Conclusions

This study shows that use of methanol or DME in benzene methylation led to different reaction rates and product distributions. Similar behaviour was observed irrespective of catalyst topology or acid strength. Compared to DME, the use of methanol led to lower rates of methylation and significantly higher yields of diphenylmethane. In depth experimental and theoretical studies are in progress to elucidate the reason for the observed selectivity differences and will be presented.

Keywords: kinetics, characterization, CPO, Raman, coke, logistic, fuels

1 Introduction

The Catalytic Partial Oxidation (CPO) of hydrocarbons is a promising solution for the small-scale and on-board production of H_2 or CO/H_2 mixtures (syngas). The reaction is highly exothermic and extremely fast, and is typically carried out under autothermal conditions, in compact reactors, at millisecond contact time. Fuel flexibility is a major goal for the success of CPO: the reactor should be able to process fuels spanning from NG and LPG (CH_4, C_3H_8 and C_4H_{10}) up to logistic (gasoline and diesel) and biomass-derived fuels. The main drawbacks hampering a wide-range use of hydrocarbons (larger than C_1-C_3) are the high temperatures reached in the reactor (>1000°C) and the formation of C-deposits, which lead to catalyst deactivation even when noble metal are employed. Depending on the nature of the fuel, high temperatures also enhance the activation of gas-phase cracking reactions, which form coke-precursor intermediates, such as C_2H_6, C_3H_6 and C_2H_4. In this work, we analyze the CPO of C_3H_8 (representative of LPG), C_3H_6 (C_{2+} coke-forming fuel) and n-C_8H_{18} (logistic fuel): focus is given to the reaction kinetics and the coke formation tendency. The formation of C-species as a function of temperature is followed by combining kinetic investigations performed in an annular micro-reactor with Raman measurements of the catalyst surface.

2 Materials and Methods

2 wt% $Rh/\alpha Al_2O_3$ catalysts were prepared by dry impregnation of $Rh(NO_3)_3$ of the αAl_2O_3 support (10 m^2/g BET SA). The CPO experiments were performed in an annular micro-reactor, at 1 atm, between 300 and 850°C, at high space velocity, under isothermal conditions. A MicroGC (Agilent 3000) was used to analyze the composition of the inlet and outlet gas streams. Ex-situ Raman measurements were carried out with a Raman i-Raman BWTEK instrument (785 nm laser excitation, 5 cm^{-1} resolution, 175 – 3250 cm^{-1} spectral range, TE Cooled 2048 Pixel CCD detector). The Raman measurements were taken at room temperature according to the following procedure: after stable conditions were achieved in the annular reactor at a significant temperature, the reaction was quenched under inert N_2 flow to room temperature; the reactor was extracted from the furnace and kept under inert flow; the Raman signal was measured by focusing the beam directly on the catalyst layer through the quartz wall of the reactor.

3 Results and discussion

Previous experimental and microkinetic studies on CH_4 and C_3H_8 CPO [1] pointed out strong analogies regarding the nature of the active sites and the rate determining step in the activation of these fuels. Under oxidative conditions (O_2/C = 0.5-1), the C-H bond breaks on O*-O* pairs, i.e. on a Rh surface saturated by adsorbed O* (Regime I, as defined in Ref. [2]). In the absence of O_2, under reforming conditions, the C-H bond breaks on a free Rh site pair *-* (Regime IV). Coherently, Raman characterization suggests that the Rh surface maintains

reasonably clean in C_3H_8 CPO and CH_4 CPO: very weak signals of C-structures (amorphous and graphitic) appear only in the spectra collected at T > 600°C. As well, the fuel conversion curve measured as a function of T shows a smooth transition between the oxidative and the reforming regime, around 400°C in the case of C_3H_8 (■ in Fig. 1a and b).

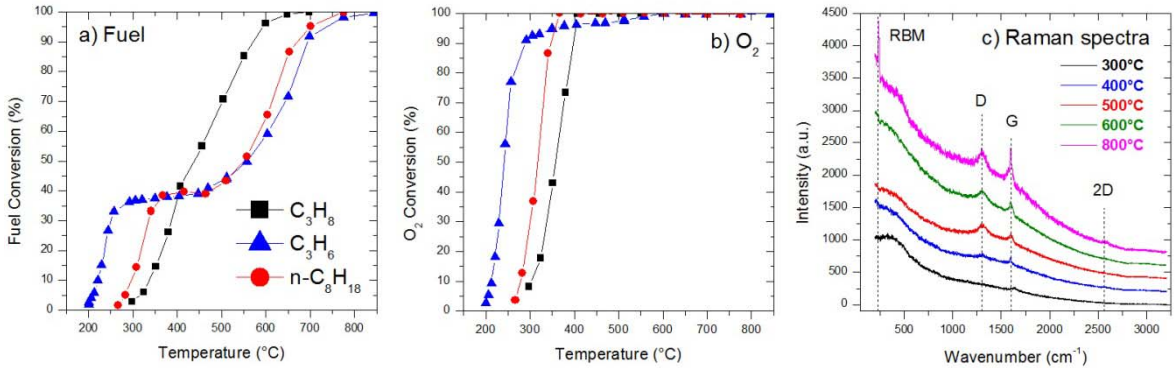

Fig. 1 - Panel a and b: CPO of C_3H_8 (■), C_3H_6 (▲) and n-C_8H_{18} (●). Panel c: Raman spectra in n-C_8H_{18} CPO at increasing T. $O_2/C = 0.56$, $O_2 = 1.7\%$, GHSV = $2*10^6$ Nl/kg_{cat}/h

Much different features characterize the kinetics of C_3H_6 CPO (▲ in Fig. 1a and b). C_3H_6 has a very high oxidation activity (O_2 is completely consumed at ~250°C), followed by a flat plateau in C_3H_6 conversion (300 – 450°C) and by a delayed onset of the reforming activity (T > 450°C). Kinetic analyses [3] indicate that the oxidation rate has an inverse dependence on O_2 and a positive quadratic dependence on C_3H_6 concentration, suggesting that C_3H_6 activation occurs on a surface only partially saturated by O* and that the dissociative adsorption of C_3H_6 on a O-* pair is the determining step (Regime II). In the absence of O_2, C_3H_6 strongly adsorbs on the surface, forming different C-species, as detected by Raman. These C-species do not partake in the reforming process and lead to surface C-poisoning and to kinetic inhibition. A positive dependence on H_2O is found for the rate of reforming, as a consequence of the beneficial effect of H_2O gasification in contrasting the accumulation of carbon.

The results of n-C_8H_{18} CPO show an intermediate behavior. Total oxidation is fast, the consumption of O_2 starts at ~250°C and completes at ~325°C (● in Fig. 1a and b). Kinetic tests indicate that the oxidation rate is directly proportional to n-C_8H_{18} concentration and independent of O_2, fully in line with C_3H_8 and with the activation of n-C_8H_{18} on O*-O* site pairs (Regime I). Instead, similar to C_3H_6 CPO, a plateau is observed in n-C_8H_{18} conversion between 300 and 450°C, with a delay of the reforming activity to high T. Inhibition by n-C_8H_{18} adsorption and C-poisoning are again suggested, and supported by Raman spectra (Fig. 1c): in the presence of O_2, the surface is almost free of C, whereas, once O_2 is consumed, amorphous deposits and graphitic-like platelets form (G, D, 2D lines) with nanotubes (sharp G component, RBM and 2D lines) gradually growing at increasing T.

4 Conclusions

Combined application of Raman characterization and kinetic tests in the annular reactor allows to individuate the nature of site active for the fuel activation (O*-O*, O*-* or *-* pairs) as well as the tendency of the fuel to stick on the catalyst surface and form C-species.

Keywords: ammonia decomposition, cobalt, alumina, nanorods, nanoparticle, stabilisation

1 Introduction

The use of chemical molecules, such as ammonia, as hydrogen vectors has the potential to unlock a pseudo hydrogen economy overcoming the transport and storage issues associated with in-situ use of hydrogen in fuel cells.1 Ammonia has traditionally been used for agricultural fertilisers and refrigerants, with an existing distribution infrastructure becoming a promising alternative fuel associated to its carbon-free high hydrogen content (17.6 wt.%).2 In addition, ammonia has a small explosive range and can be liquefied at room temperature under mild pressure or stored in solid metal ammine complexes.3

Based on the substantial catalytic research carried out on the synthesis and decomposition of ammonia during the last decades, this work aims to design a catalytic system from first principles able to release the potential of ammonia as a hydrogen storage medium using readably available metals such as Fe, Ni, Pt, Ir, Pd, Co as alternative to Ru-based catalysts, which, are currently the most active systems for this reaction.4

2 Experimental/methodology

Commercial carbon nanotubes (CNTs), microporous Ax-21 carbon and γ-Al2O3 nanorods (NR) are used as catalytic supports. One dimensional γ-Al2O3 nanorods are synthesised by hydrothermal treatment using Al(NO3)3·9H2O) and 1M NaOH solution at 200 ºC for 20 hours, followed by calcination at 500ºC for 3 hours.5 Cobalt is loaded by incipient wetness impregnation (IWI) followed by reduction at 450 ºC. NH3 decomposition reactions are carried out in a plug flow reactor through a packed-bed of 25 mg catalyst using 2.77 nml/min NH3 and 5 nml/min He over a range of temperatures up to 850 K.

3 Results and discussion

The decomposition of ammonia on ruthenium nanoparticles is believed to take place on B5 active sites, a specific arrangement of five ruthenium atoms. The concentration of such sites is optimum on particle sizes between 2-4 nm. This specific particle size range is selectively stabilised on CNTs support and in combination to their high conductivity, constitute the best catalytic system for ammonia decomposition reported in the literature to the date.1 Figure 1 shows that such systems can decompose ammonia at temperatures above 640 K without further optimisation. Substitution of ruthenium for more readily available cobalt on CNTs is translated in a considerable loss of ammonia decomposition activity, especially at low temperatures.

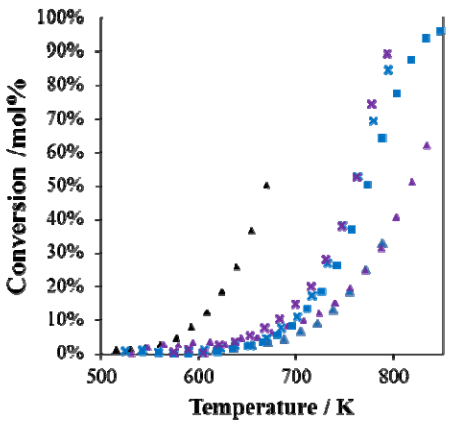

Fig. 1. Activity of ammonia decomposition catalysts. ▲- 7 wt. % Ru/CNT, ▲- 7 wt. % Co/CNT, ▲- 7 wt. % Co 7 wt. % Cs /CNT, ■ - 15 wt. % Co/ NR-γ-Al_2O_3, X – 14 wt. % Co/Ax21, X – 14 wt. % Co 14 wt. % Cs/Ax21.

However, interestingly, the use of microporous carbon support (Ax21) with a mean pore size of 2.3 nm leads to a considerable enhancement of the cobalt system, with activities at temperatures as low as 670 K. The optimization of active cobalt-based catalysts depends on the stabilisation of small particle sizes (< 2 nm), well below the optimum size previously observed for ruthenium-based systems.

High aspect ratio 1D nanostructured materials are well-known to be able to stabilise small metal nanoparticles by a combination of spatial confinement on their outer surface and specific metal-support interaction.6 Here, we present the use of γ-Al2O3 nanorods as a suitable support for cobalt nanoparticles with ammonia decomposition activity at similar temperatures as for cobalt supported on microporous carbon supports (670 K). Spatial confinement allows tuneable metal particle sizes by variation of the cobalt loading and the metal particle : support diameter ratio.

The addition of Cs to Ru/CNT catalysts has been reported to electronically modify the ruthenium particle size enhancing its activity for low temperature ammonia decomposition.1 Interestingly, this promotion effect is not applicable to the cobalt based systems. Further studies related to the effect of alkali-metals in cobalt based systems with a focus on cobalt accessibility blockage will be reported.

Table 1. Pore size, specific surface area, activation energy (E_a) and turnover frequency (TOF) at 700 K.

Support	Metal loading	Pore size / nm	S_{BET} / m^2/g	E_a / kJ/mol	TOF / mol_{NH3} $mol_{Cat}^{-1}s^{-1}$ (@700 K)
CNT	7 wt.% Ru	27.3	250	102.8	0.0366
γ-Al_2O_3 rods	15 wt.% Co	N/A	100	40.1	0.0024
Ax21	14 wt.% Co	2.3	2200	66.9	0.0039
Ax21	14 wt.% Co – 14 wt.%Cs	2.3	2200	44.3	0.0050

4 Conclusions

Cobalt is presented as an abundant and cheaper alternative to ruthenium-based catalysts for ammonia decomposition for in-situ production of H_2. Stabilisation of small particles with sizes below 2 nm is crucial to reveal its potential. High aspect ratio γ-Al_2O_3 nanostructured supports are presented to successfully stabilise cobalt nanoparticles with tuneable sizes to guide future catalyst design in this field.

Keywords: higher alcohols synthesis, synthesis, gas, copper, cobalt, Na, promoter

1 Introduction

Higher alcohol synthesis (HAS) via hydrogenation of carbon monoxide is a promising route for providing important basic chemicals, alternative fuels and additives in gasoline blends. Although Rh is well known to be highly active in HAS, catalysts based on non-noble metals such as Cu, Co and Fe are considered promising systems for large-scale application. As Co and Fe adsorb CO dissociatively, while the adsorption on Cu occurs molecularly, both functions combined in one bimetallic catalyst may provide a cost-efficient alternative to precious metal-based systems [1]. Doping of modified methanol synthesis or modified Fischer-Tropsch (FT) synthesis catalysts with basic promoters such as alkali compounds is known to increase the selectivity towards higher alcohols.

Institute Français du Pétrole (IFP) first reported on selective alkali-doped Cu-Co-based catalysts in HAS [2]. However, the activity was moderate and large-scale application has not yet been realized. Our recent results indicate that these catalysts undergo severe structural changes during the reduction of the oxide precursor and during the first hours under reaction conditions. Therefore, the thorough characterization of the spent catalyst after activation and/or after HAS provides important information to further adjust the optimum reaction conditions and catalyst compositions to enhance product selectivities and the degree of conversion. The present contribution describes structure-activity correlations of high relevance for HAS revealed by thorough characterization of the catalysts in the reduced state.

2 Experimental

Cu-Co-based catalysts were prepared similar to the coprecipitation method described by IFP. The activated and spent catalysts with different Na loadings were characterized by X-ray photoelectron spectroscopy (XPS), temperature-programmed techniques (TPR, TPD), reactive frontal chromatography (RFC) and X-ray diffraction (XRD). Activation and HAS were performed in a 4-fold parallel test facility, which allows the transfer of the activated and spent catalyst under inert conditions excluding re-oxidation and contamination by air. The catalytic tests were performed at 280 °C, 60 bar and a ratio of $H_2/CO = 1$.

3 Results and discussion

An initial deactivation was observed for the samples with low Na loadings within the first 10 h in HAS. In contrast, for samples with higher Na loading the initial degree of conversion

remained essentially constant. Additionally, the product distribution strongly depends on the alkali loading since the selectivity to higher oxygenates increases significantly with increasing Na content. The XPS analysis of the spent catalyst revealed major modifications of the surface composition compared with the reduced catalyst. The main observation is a decreased Cu/Co surface ratio. The decrease in the surface Cu concentration is assumed to be caused by the migration of Cu into the bulk. The surface modification during reaction was more pronounced for Na-free samples, whereas the decrease of the Cu/Co ratio was rather low in presence of Na. Characteristic reflections of ZnO and metallic Cu were found in the XRD patterns of all spent catalysts. The degree of crystallinity increases with increasing Na loading indicating larger particles. Moreover, with increasing Na loading the intensity of reflections assigned to Co_2C increases, while these reflections are not observed for the Na-free catalyst.

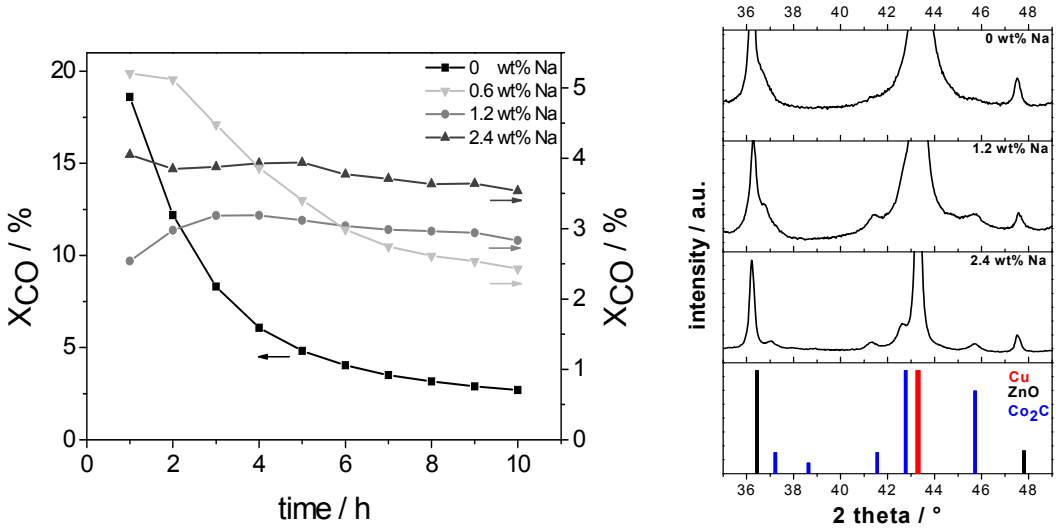

Fig. 1. CO conversion during the first 10 h on stream (left)and XRD pattern of the spent catalysts with different Na-loadings (right).

4 Conclusions

Na-modified bimetallic Cu-Co-based catalysts for HAS were successfully prepared by coprecipitation and subsequent alkali loading by incipient wetness impregnation. The thorough characterization of the reduced and spent state enabled the evaluation of different catalyst properties and their correlation with the performance in HAS. The initial deactivation observed for the Na-free catalysts is explained by strong surface modifications under reaction conditions. In contrast, the surface composition is stabilized in the presence of the Na promoter resulting in a constant degree of conversion and a constant product distribution during HAS. Obviously, the presence of alkali promoters favors the carbidization of Co, which is assumed to improve the catalyst properties with respect to deactivation and product distribution.

Effect of Ni on the Hydrogenation Mechanism of Polyaromatic Hydrocarbons over (Ni-)MoS_2/Al_2O_3

Keywords: hydrogenation, phenanthrene, (Ni-)MoS_2/γ-Al_2O_3, isotopic, H-D exchange, DFT

1 Introduction

Transition metal sulfides, particularly MoS_2 promoted with Ni, have been extensively studied as hydrotreating catalysts. Especially for hydrodesulfurization, detailed reaction pathways and models for active sites exist [1]. Hydrogenation of polyaromatic hydrocarbons has been less investigated despite its growing relevance for heavy oil conversion. The present contribution investigates the hydrogenation of phenanthrene as a model aromatic compound aiming at a deeper insight into the hydrogenation mechanisms on (Ni-)MoS_2/Al_2O_3.

2 Experimental

Ni-MoS_2/γ-Al_2O_3 was prepared by impregnation and thermal treatment in H_2/H_2S and characterized by a series of standard and advanced techniques as reported elsewhere [2]. The catalytic activity was explored in the hydrogenation of phenanthrene (Phe), or dihydrophenanthrene (DiHPhe) at differential and integral conditions in a trickle-bed reactor at 60 bar, 553-583 K, and in the presence of H_2S.

The energetics of adsorption of the hydrocarbon on MoS_2 and Ni-MoS_2 were determined by density functional theory calculations using the QUANTUM ESPRESSO code employing ultrasoft pseudo-potentials to represent the core electrons. The BEEF-vdW [3] exchange correlation functional was used throughout.

3 Results and discussion

MoS_2/Al_2O_3 and Ni-MoS_2/Al_2O_3 with similar Mo content, the bimetallic catalyst having a molar Ni/(Mo+Ni) ratio of 0.3, were studied. The Phe hydrogenation network given in Figure 1A was derived from experiments at integral conditions with Phe and DiHPhe as reactants. The mechanism is identical for MoS_2/Al_2O_3 and Ni-MoS_2/γ-Al_2O_3. However, the contribution of the deep-hydrogenation pathway (k_2, k_4, k_5) is significant only in the presence of Ni, which also increases the Phe and DiHPhe consumption rates by a factor of 2.2.

The reaction order in Phe (see Fig. 1B), around ~0.65, was not influenced by the presence of Ni while the H_2 reaction order (see Fig. 1C) increased from 0.68 for MoS_2/Al_2O_3 to 1.2 for Ni-MoS_2/Al_2O_3. Interestingly, the presence of H_2S had no effect on the reaction over MoS_2/Al_2O_3 (zero order in H_2S) whereas it has a negative impact over Ni-MoS_2/Al_2O_3 (reaction order of -0.2). Combining the kinetic analysis and characterization of SH groups at the sulfide surface by IR-spectroscopy (which evidenced an acid character), allows to conclude that the hydrogenation of Phe occurs via stepwise proton addition and electron transfer in concerted mode. The rate determining steps are the first and second addition of hydrogen pairs for DiHPhe and tetrahydrophenanthrene (TetHPhe), respectively.

Combined IR and isotopic H-D exchange experiments showed that the concentration of

active surface hydrogen increased by 30% in presence of Ni. This may explain the increased rate of DiHPhe formation. However, it does not account for the dramatic increase of TetHPhe production rates and the concomitant change in rds. Deep hydrogenation is concluded to occur on the Ni-decorated MoS_2 edges (characterized by IR-spectroscopy of CO) where DiHPhe and TetHPhe are formed at comparable rates.

In line with this proposal, DFT calculations indicate that Phe adsorbs strongly on the basal planes of MoS_2, where it may tilt towards the edge and undergoes hydrogenation without the participation of exposed cations. In contrast, the restructured Ni-decorated MoS_2 edges offer adsorption modes that lead to the activation and multiple hydrogenation of the terminal rings of Phe.

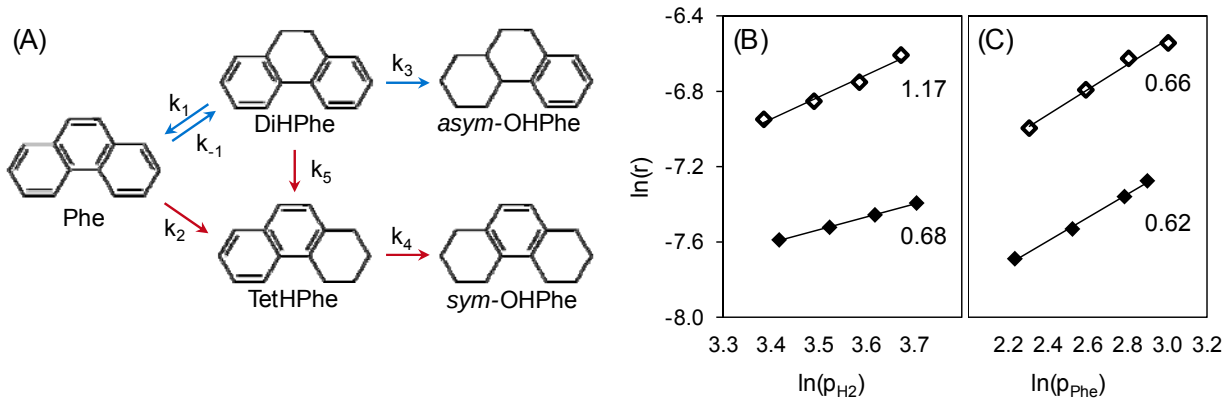

Fig. 1. (A) Reaction network for the hydrogenation of phenanthrene. The blue arrows denote steps occurring on MoS_2/Al_2O_3 and Ni-MoS_2/Al_2O_3 while red arrows denote steps occurring only on the latter. (B) Reaction order in H_2 and (C) reaction order in phenanthrene during the hydrogenation of phenanthrene on MoS_2/Al_2O_3 (◆) and Ni-MoS_2/Al_2O_3 (◇) at 573 K and 60 bar.

4 Conclusions

The promotion of MoS_2/γ-Al_2O_3 with Ni increases the concentration of active surface hydrogen and changes the rate determining step of hydrogen addition. Moreover, the combination of IR spectroscopy with DFT calculations points to a particular adsorption mode of phenanthrene on the Ni-promoted edge of MoS_2 which leads to multiple hydrogenation of the terminal rings of Phe. Thus, Ni increases the hydrogenation rates of polyaromatic hydrocarbons and modifies the surface concentration of the most abundant reaction intermediates.

Keywords: CO-PROX, monolith, hydrogen, copper/ceria

1 Introduction

Hydrogen to be fed to PEM fuel cell requires ultra-low CO content (10 – 50 ppm); consequently, if H_2 is produced via a reforming process, a purification step as preferential oxidation of CO (CO-PROX), in addition to WGS is required [1]. Especially for mobile applications, compactness, robustness and low pressure drops are required[2], thus suggesting the use of monolithic reactors. Indeed, although monoliths have been widely used in exhaust gas cleaning, their application in PROX process is at the early stage and only few papers have been published on this topic especially concerning copper/ceria catalysts [3-5]. Despite of the interest, the effect of the preparation method and geometrical features has not been systematically addressed. In this work our aim is to cover this lack of knowledge by reporting the effect of the preparation method, of geometrical features (as cell density) and of the thermal conductivity of the substrate material on the activity of monolithic catalysts towards CO-PROX reaction.

2 Experimental/methodology

Structured catalysts were prepared from commercial honeycomb monoliths of extruded cordierite (200 , 400, 600, 900 cpsi) and SiC (200 cpsi) cut in the desired shape and dimensions. A ceria washcoat was deposited onto monolith walls by modified dip coating procedure. Subsequently, copper oxide was supported by wet impregnation in an aqueous solution of copper acetate monohydrate (Sigma-Aldrich); drying at120°C for 1 h and calcination in air at 450°C for 2 h were carried out to obtain copper oxide. The nominal CuO load was about 4 wt.% with respect to the active layer. Different slurries were prepared to study the effect of the ceria particle size distribution by changing the milling procedure. Slurries S1 and S2 correspond to dry and wet milling respectively. We also studied the effect of colloidal ceria (Nyacol Nano Technologies Inc.) used as the only ceria precursor (slurry S4) or added to finely milled CeO_2 (slurry S3). Hereafter, monoliths will be labelled as Sx-y, where Sx and y indicate the used slurry and the cell density respectively (i.e. S1-400 is a 400 cpsi monolith prepared by dip coating in the slurry S1).

Slurries and monoliths were fully characterized by N_2 adsorption at 77K (BET and pore distribution by BJH method), Hg intrusion porosimetry, ICP-MS analysis, SEM, adhesion tests by sonication. The lab-scale set-up used for CO-PROX experiments was described elsewhere [31]. Catalytic tests were conducted at fixed flow rate or contact time. H_2, CO and O_2 concentrations were generally fixed at 50, 0.5 and 0.9 vol.% respectively; the effects of O_2 concentration and CO_2 and H_2O addition were also studied. Reaction temperature ranged from 80 to 200 °C to explore the whole temperature range of interest for CO-PROX.

3 Results and discussion

With respect to S1 slurry, wet milling and colloidal ceria addition reduce the mean particle dimension of the powder used to prepare the slurry and improve the specific surface area. The

last feature results in a larger copper dispersion, while the presence of ultra-fine particles, dominant in colloidal ceria, results in a partial intrusion of the washcoat into the cordierite macropores. The above structural modifications affect the catalytic performance. Figure 1 shows CO conversion and selectivity as a function of the reaction temperature for monoliths prepared starting from different slurries; powder catalyst performance is reported as reference. The partial intrusion of the catalyst into the cordierite macropores causes a reduction of the catalyst amount available for the reaction and, consequently, S1-400 shows the best catalytic activity. On the other hand, a larger copper dispersion is related to improved selectivity of monoliths different from S1-400. It is worth noting that at high conversion monoliths show better performance than powder, suggesting that internal diffusion is not limiting on structured catalysts. The results of experiments carried out on monoliths with different cell density and thermal conductivity (not reported) showed that high cell density and thermal conductivity lead to improved performance in terms of process intensification, selectivity, temperature control (by reducing hot spots).

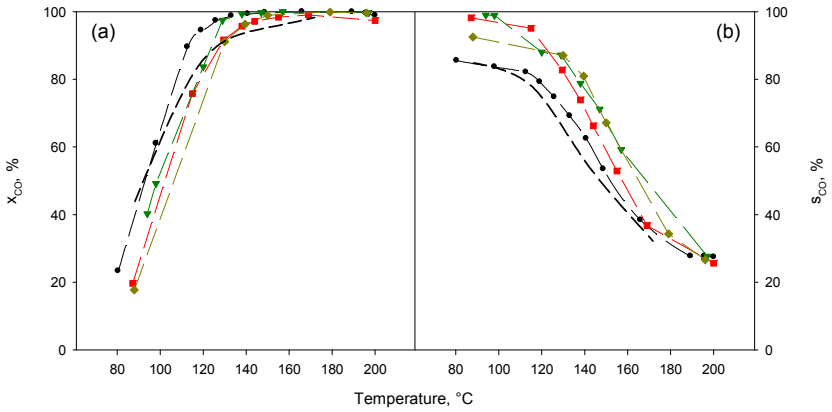

Fig. 1. CO conversion (a) and selectivity (b) as a function of the reaction temperature for monoliths: S1-400 (°); S2-400 (□); S3-400 (▼); S4-400 (□). Powder catalyst (short dashed line). $CO/H_2/O_2$=0.5/50/0.9; N_2 as balance.

4 Conclusions

CuO/CeO_2 monoliths were successfully prepared and tested in CO-PROX reaction. At high conversion (i.e. under the most interesting reaction conditions) monoliths show improved performance with respect to powder catalyst, providing higher catalyst efficiency. Slurry composition affects structural features of the washcoat and, consequently, catalytic layer adhesion and activity towards CO-PROX. The monolith performance can be optimized by engineering the catalytic systems and, in particular, by increasing the cell density and thermal conductivity of the substrate.

Kinetic Analysis of Decomposition of Ammonia over Nickel and Ruthenium Catalysts

Takahashi A.*, Fujitani T.

Research Institute for Innovation in Sustainable Chemistry, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

* at-takahashi@aist.go.jp

Keywords: ammonia, decomposition, hydrogen, production, kinetic model, catalysis, reaction, kinetics

1 Introduction

Hydrogen (H_2) is a promising energy resource and can be utilized in high-efficiency power generation systems such as fuel cells. However, the transport and storage of H_2 are obstacles for its practical use. Ammonia (NH_3) is a good candidate as an alternative H_2 carrier because of its high H_2 storage capacity and facile liquefaction under mild conditions [1]. Because high-purity H_2 is required to generate electricity with a fuel cell, a high-performance catalyst for producing H_2 from decomposition of NH_3 is needed when NH_3 is used as a H_2 carrier.

Previous studies indicated that Ru catalysts have the highest catalytic activity [1,2]. However, because precious metals are very expensive, alternative inexpensive Ni-based catalysts for decomposition of NH_3 have been widely investigated [3,4]. Nevertheless, the catalytic activity of Ni does not reach that of the Ru catalyst. Furthermore, it is unclear why there is a difference between the catalytic activities of the Ru and Ni catalysts.

In this study, the decomposition of NH_3 over Ni and Ru catalysts was investigated by using a kinetic model based on a reaction mechanism consisting of kinetically important elementary steps. The origin of the difference between the catalytic activities of the Ni and Ru catalysts was clarified.

2 Experimental

MgO-supported Ni and Ru catalysts were prepared by an impregnation method using aqueous solutions of $Ni(NO_3)_2$ and $RuCl_3$, respectively, followed by drying and calcination. The loading of metals was set at 30 wt % for Ni and 5 wt % for Ru.

The NH_3 decomposition reaction was carried out in a continuous-flow fixed-bed quartz tubular reactor at atmospheric pressure. The reaction products were analyzed by means of an on-line gas chromatograph equipped with a thermal conductivity detector and a Shincarbon ST column (Shinwa Chemical Industries Ltd., Kyoto, Japan) for N_2 and H_2. The NH_3 conversion was calculated on the basis of the production of H_2.

3 Results and discussion

A kinetic model for decomposition of NH_3 was constructed on the basis of the reaction mechanism including the following elementary steps: NH_3 adsorption⇆desorption (Eq. (1)), dehydrogenation of adsorbed NH_3 (Eq. (2)), recombinative N_2 desorption (Eq. (3)), and recombinative H_2 desorption⇆adsorption of gas-phase H_2 (Eq. (4)).

$$NH_3(g) + s \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} NH_3(a) \quad (1)$$

$$NH_3(a) + 3s \xrightarrow{k_2} N(a) + 3H(a) \quad (2)$$

$$2N(a) \xrightarrow{k_3} N_2(g) + 2s \quad (3)$$

$$2H(a) \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} H_2(g) + 2s \quad (4)$$

The 6 unknown constants were estimated by fitting the model equations with the experimental results. The fitted results were in good agreement with the experimental data. Estimated values of the constants are listed in Table 1. Recombinative N_2 desorption (Eq. (3)) has been suggested to be the rate-determining step in the decomposition of NH_3 over most catalysts [1], and several research groups have reported values of the activation energy for recombinative N_2 dissociation. The estimated activation energy for recombinative N_2 dissociation, k_3, on the Ni and Ru catalyst are in agreement with these reported values.

Table 1 Estimated values of constants in the model

Constant	Ni catalyst		Ru catalyst	
	Pre-exponential factor, A	Activation energy, E_a / kJ·mol^{-1}	Pre-exponential factor, A	Activation energy, E_a / kJ·mol^{-1}
k_1 [mol·s^{-1}]	7.55×10^{1}	0	8.36×10^{1}	0
k_2 [mol·s^{-1}]	7.54×10^{15}	144.0	1.34×10^{14}	105.8
k_3 [mol·s^{-1}]	3.12×10^{6}	127.8	6.26×10^{5}	123.5
k_4 [mol·s^{-1}]	3.92×10^{4}	109.0	7.18×10^{2}	67.8
K_1 [–]	2.26×10^{-14}	-79.4	3.49×10^{-13}	-64.0
K_4 [–]	4.13×10^{6}	109.0	1.51×10^{4}	67.8

Furthermore, the experimental results in the high-conversion region (20–100% conversion of NH_3) at various NH_3 partial pressures and space velocities (SVs) under high-temperature conditions were compared with simulated results. The simulated lines were in good agreement with the experimental results over a wide range of reaction temperatures, NH_3 partial pressures, and space velocities (SVs). Thus, the proposed model can predict the catalytic activities of both the Ni and the Ru catalysts under a remarkably wide range of reaction conditions.

4 Conclusions

Using the minimum numbers of elementary steps necessary to understand the chemistry on the catalyst surface, the kinetic analysis presented herein has clarified the true reaction step governing the decomposition of NH_3 on Ni and Ru catalysts. Thus, the kinetic approach described herein should be a useful tool for designing new high-performance catalysts.

* d.antonov@ips.ac.ru

Keywords: porous ceramic converter, Pd-containing membrane, reforming, hydrogen, syngas

1 Introduction

Original hybrid reactor consisted of Ni-Co-containing converter with integrated Pd-alloy membrane was developed. The construction allowed to carry out simultaneous processes of highly efficient dry reforming of methane (DRM) and ethanol (DRE) into syngas and in situ hydrogen separation. Removal of hydrogen decreased reaction temperature and shifted equilibrium of process.

2 Experimental/methodology

Porous ceramic membrane-catalytic converters (PCMCC) produced by self-propagating high-temperature synthesis were used for investigation. The precursors included a Ni metal powder containing 5 mass % of aluminum and a cobalt oxide (II, III) powder. The ready PCMCC contained of the Ni(Al) and Co_3O_4 active components in the ratios (mass %) 80 : 20. The PCMCC material also contained traces of carbon of the graphite press mold in which the PCMCC sintering took place. The PCMCC were porous gas permeable tubes with one end being sealed off and the other end having a round cap of larger diameter for being mounted inside the reactor. The length of the work area (tube) of the PCMCC was 160 mm, the outer diameter was 22 mm, the wall thickness was 4 mm, the average pore diameter determined by mercury porosimetry method and the bubble point method was 1–3 μm, and the material porosity was 40–60%.

Pd-containing membrane was made as a hollow fiber and was fixed in a PCMCC outlet channel. Carrier gas Ar was used for removal hydrogen from inner side of the catalytic converter.

The dry reforming of methane was carried out under the following conditions: $CH_4 : CO_2 = 1 : 1$, T = 550°C, W = 5–10 L/h, P_{inlet} = 1.1 atm, P_{outlet} = 1 atm.
The dry reforming of ethanol was conducted under the following conditions: $EtOH/CO_2$=1:5, T=200-600°C, W = 30 l/h, P_{in}=1.1 atm., P_{out} = 1 atm.

The compositions of the initial gas mixture and the reaction products were determined on-line by gas chromatography on a CHROM5 chromatograph with a thermal conductivity detector, high purity argon as the carrier gas (99.998 vol %, flow rate of 30 mL/min), and two chromatographic columns packed by SKT activated carbon. The gas concentrations were determined using Ecochrom software.Results and discussion

It was demonstrated that in DRM selective hydrogen removal from reaction zone using Pd-alloy membrane allowed to increase methane conversion up to 15% in comparison with equilibrium value. Feeding the substrate at a rate of 9 L/h and T=550°C hydrogen productivity was 3.7 L/h, including 50% of ultrapure hydrogen.

It was found that in DRE selective removal of ultrapure hydrogen decreased methane

containing in products and increased the total yield of hydrogen. It was determined that feeding the substrate at a rate of 30 L/h and T=600°C hydrogen productivity was 9 L/h, including 1.6 L/h of ultrapure hydrogen.

3 Conclusions

It was demonstrated a principal possibility of simultaneous processes of highly efficient production of syngas and ultrapure hydrogen with high performance and rate of extraction up to 50% in dry reforming of methane and ethanol using hybrid reactor.

Solution Combustion Synthesis of Noble Metal-Loaded Ceria Catalysts and Application to Hydrogen Production and Purification for Fuel Cells

Nguyen T.S., Postole G., Morfin F., Piccolo L.*

Institut de recherches sur la catalyse et l'environnement de Lyon (IRCELYON), UMR 5256 CNRS & Université Claude Bernard - Lyon 1, Villeurbanne, France

* laurent.piccolo@ircelyon.univ-lyon1.fr

Keywords: solution combustion synthesis, ceria, Pt-group, metals, SRM, PROX

1 Introduction

Due to its excellent redox properties, ceria is extensively used in heterogeneous catalysis, where it can act as an oxygen buffer in oxidation reactions or prevent coking of metal phases in reforming reactions. Solution combustion synthesis is a simple and inexpensive method for preparing reducible oxides possibly loaded with noble metals in a single step [1, 2] (Fig. 1).

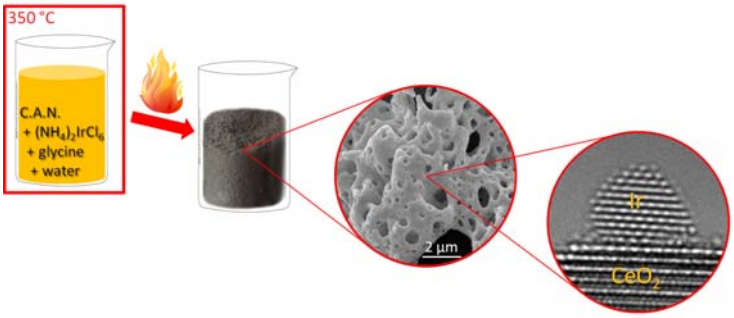

Fig. 1. Illustration of the Ir-CeO_2 catalyst preparation by SCS.

2 Experimental/methodology

Mesoporous ceria powders doped with up to 2 wt% platinum-group metals (PGMs: Pt, Pd, Ir, Rh, Ru) were synthesized by the ambient air combustion of an aqueous solution of ceric ammonium nitrate (CAN), chloride or nitrate metal precursor, and glycine or oxalyl dihydrazide used as fuels (Fig. 1). The structural properties of the powders, and the influence of such parameters as metal loading and thermochemical post-treatments, were investigated combining N_2 volumetry, aberration-corrected HRTEM, SEM, *in situ* XRD, XPS, DRIFTS, and Raman spectroscopy. The powders were employed as catalysts for the the steam reforming of methane (SRM) in water-deficient conditions (CH_4/H_2O = 10, 1 atm, 750 °C), and for the CO oxidation and preferential oxidation of CO (PROX) in H_2 excess ($H_2/CO = H_2/O_2$ = 24, 1 atm, 20-400 °C).

3 Results and discussion

The materials, whose texture appeared spongy at the micrometer scale and depended on the fuel nature, exhibited *ca.* 30 nm-sized ceria crystallites with a layered structure at the nanoscale. Comparisons with pure ceria showed that the metal inhibited ceria grain coarsening.

For SRM, 0.1 wt% Ir-CeO_2 exhibited the best performances. Due to its higher Ir dispersion and stronger Ir-CeO_2 interaction, the combustion-synthesized material was more active and stable than its conventionally prepared counterpart [3, 4]. Moreover, it was not permanently

deactivated by the introduction of H_2S in the reactant feed [4]. After reducing treatments, Ir nanoparticles anchored at the surface of ceria grains were imaged (Fig. 1), and their size (*ca.* 2 nm) and morphology did not evolve upon further heating at up to 900 °C. A complete picture of the Ir-CeO_2 interface could be established, with the presence of Ir^{x+}-O^{2-}-Ce^{3+} entities along with oxygen vacancies [3].

For CO oxidation and PROX, systematic comparisons between the samples, which exhibited similar metal nanoparticle sizes, allowed us to rank the Pt-group metals for the first time in the same conditions (Fig. 2) [5]. Rh-CeO_2 appeared as the most active system in H_2-free CO oxidation. The presence of H_2 boosted the CO oxidation activity of all the catalysts, except that of Rh-CeO_2, which promoted the decomposition of CO and the subsequent formation of methane. Pt-CeO_2, which was the most active and selective PROX catalyst, was further investigated by changing the nature of the fuel and the metal precursor. Although the catalyst activities were influenced by such parameters, the selectivities were strikingly unaffected.

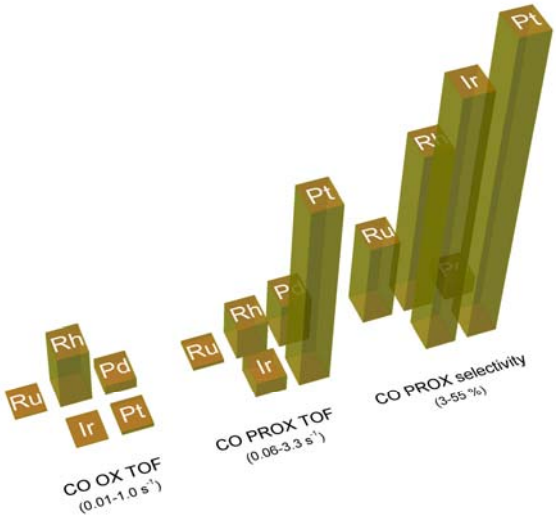

Fig. 2. Comparison of the Pt-group metals' CO oxidation and PROX performances at 140 °C.

4 Conclusions

The SCS method allowed us to prepare a series of PGM-CeO2 catalysts with high activity and high thermal stability in SRM and CO oxidation/PROX. For SRM, Ir-doped CeO2, which was synthesized for the first time by this method, is promising as catalytic layer for gradual internal reforming in solid oxide fuel cells fed with natural gas or biogas for the production of hydrogen [3, 4]. In the case of PROX, the comparison of our results with trends established from DFT calculations provides useful mechanistic insights relevant to hydrogen purification for proton-exchange membrane fuel cells [5].

Syngas Production via Combined H_2O and CO_2 Reforming of Coke Oven Gas over La-Promoted $Ni/MgAl_2O_4$ Catalyst

Koo K.Y., Park J.E., Jung U.H., Yoon W.L.*

Yonsei University, Department of Environmental Engineering, Wonju, Republic of Korea

* wlyoon@kier.re.kr

Keywords: coke oven gas, combined H_2O and CO_2 reforming, syngas, sinter-stability, Ni-La/Mg Al_2O_4

1 Introduction

Coke oven gas (COG) composed of H_2 (55-60%), CH_4 (23-27%), CO (5-8%), N_2 (3-6%), and CO_2 (<2%) is a by-product of the coking process in steel industry [1]. Recently, direct reduction iron (DRI) production technology has been developed using syngas as a reducing agent in place of coke [2]. When syngas can be produced through the reforming of COG for use as a reducing gas in DRI, CO_2 emissions are reduced as the amount of coke used is minimized. In this study, syngas has been produced by combined H_2O and CO_2 reforming (CSCR) of COG. Different H_2/CO ratios can be obtained by controlling the feed ratio of H_2O and CO_2 in CSCR. CSCR is an economical and energy efficient process to supply reducing gas (H_2+CO) of DRI without an additional H_2/CO adjustment unit [3]. In general, Ni-based reforming catalysts are extensively used in commercial reforming processes because of their high activity and relatively low cost in comparison with noble metal catalysts. Ni-based catalysts often suffer from deactivation due to coke deposition and particle sintering at high reaction temperatures. However, in the reforming of COG, very little coke is formed because of coke hydrogenation by the excess hydrogen present in COG. Therefore, the development of catalysts that have high activity and good sinter-stability is a top priority in CSCR of COG. We have investigated the La promotion effect on the activity and sinter-stability of $Ni/MgAl_2O_4$ catalyst in CSCR of COG for syngas production.

2 Experimental/methodology

Ni-xLa/$MgAl_2O_4$ catalysts were prepared by a co-impregnation method using the mixture solution of $Ni(NO_3)_2{\cdot}6H_2O$ and $La(NO_3)_3{\cdot}6H_2O$. MgO-Al_2O_3 mixed oxide (MgO=30%, SASOL) was employed as a precursor of support after the pre-calcination at 800 °C for 6h in air. And then, an as-prepared catalysts were calcined at 800 °C for 6h in air. The Ni content of catalysts was fixed at 10 wt% and the La content was varied from 0 to 5 wt%. To compare the sinter-stability of Ni-xLa/$MgAl_2O_4$ catalysts, the aging treatment was carried out at 900 °C for 50 h in $H_2/H_2O/N_2$ (=20/200/25 ml/min) flow. The characterization as to surface area, metal dispersion, Ni crystallite size and reduction temperature of prepared catalysts was analysed by BET, H_2-chemisorption, XRD and TPR. The CSCR of COG was carried out at 900 °C under 5 atm for 40 h. The feed ratio was CH_4 : H_2O : CO_2 : CO : N_2 = 1 : 1.2 : 0.4 : 0.3 : 0.3 and the space velocity(SV) was fixed at 4,680,000 ml/g_{cat}·h. Before the reaction, the catalysts were reduced in 50% H_2/N_2 flow at 900 °C for 1.5 h under 5 atm. The effluent was analysed with an on-line micro gas chromatograph (Agilent 3000) equipped with TCD detector. The morphology and elemental mapping images of used catalyst were observed by TEM analysis.

3 Results and discussion

Table 1 summarizes the BET surface area, Ni dispersion, and Ni surface area of La-

promoted Ni/$MgAl_2O_4$ catalysts. For the fresh catalysts, BET surface area was gradually decreased with increasing La content. The Ni dispersion and Ni surface area were similar each other in La content of 0-2.5 wt%. However, it is noteworthy that La-promoted catalysts showed higher surface area, Ni dispersion, and Ni surface area than Ni/$MgAl_2O_4$ catalyst after aging treatment at 900°C for 50 h in $H_2/H_2O/N_2$ flow. These results demonstrate that La promotion prevents the sintering of Ni particles during the aging treatment.

CSCR of COG was conducted to examine the performance and stability of the aged catalysts. The Ni-xLa/$MgAl_2O_4$ catalysts exhibited better catalytic activity than Ni/$MgAl_2O_4$ catalyst with time on stream (data not shown here). This is in agreement with Ni dispersion and Ni surface area of the catalysts after the aging treatment. In particular, Ni-2.5La/$MgAl_2O_4$ catalyst showed the highest catalyst activity and stability for 40 h in CSCR of COG due to high Ni dispersion and surface area. TEM analysis showed that the Ni-2.5La/$MgAl_2O_4$ catalyst exhibited highly uniform dispersion of small Ni particle compared with Ni/$MgAl_2O_4$ catalyst in Fig. 1.

Table 1. Characteristics of La-promoted Ni/$MgAl_2O_4$ catalysts.

La content (%)	BET surface area (m^2/g)		Ni dispersion (%)		Ni surface area (m^2/g)	
	Fresh	Aged	Fresh	Aged	Fresh	Aged
0.0	94.3	8.8	5.2	0.28	3.5	0.18
1.0	90.3	17.0	5.4	0.28	3.6	0.18
2.5	89.0	20.0	5.3	0.36	3.5	0.22
5.0	85.0	16.6	4.2	0.30	2.8	0.20

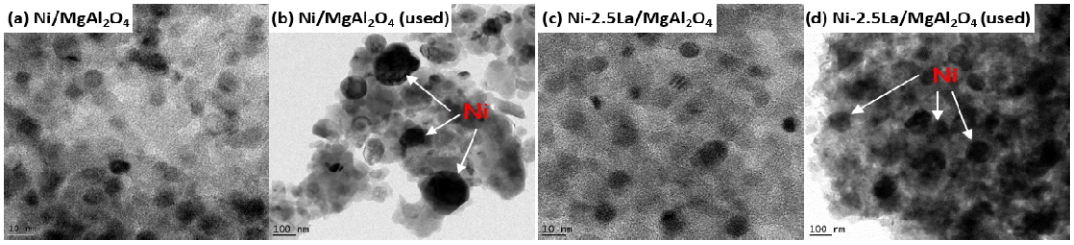

Fig. 1. TEM images of reduced and used catalysts; (a, b) Ni/$MgAl_2O_4$, (c, d) Ni-2.5La/$MgAl_2O_4$.

4 Conclusions

The La promotion to Ni/$MgAl_2O_4$ catalyst has significant effect on the Ni dispersion and surface area after the aging treatment. La-promoted catalysts had higher Ni dispersion and Ni surface area due to the enhancement of metal dispersion and SMSI. The catalyst with 2.5 wt% La, which is optimum to achieve highly dispersed Ni particles, showed the best catalytic activity and stability in CSCR of COG.

Hybrid DFT Study of Fe:NiOOH O_2 Electroevolution Catalyst

Conesa J.C.*

Instituto de Catálisis y Petroleoquímica, CSIC, Madrid, Spain

* jcconesa@icp.csic.es

Keywords: solar fuels, photocatalysis, water splitting, electronic structure, electrocatalysis, nickel hydroxide

1 Introduction

The layered compound NiOOH, especially when Fe-doped, is one of the best catalysts for evolution of O_2 in photo/ electrocatalytic water splitting, the mechanism involving probably Fe^{4+} or Ni^{4+} species [1]. That compound is however not well understood, as the protons in it are disordered and its electronic structure is not well clarified. The only DFT studies made, at the GGA+U level [2], assume that all OH groups are at the same side in each layer and propose a location of Fe for the most active site. Here the electronic structure of the bulk system, Fe-doped or not, is modelled with a hybrid DFT method of PBE0 type, but with the fraction α of Fock exchange taken, on the basis of GW theory concepts, as the inverse of the optical dielectric constant ε_∞, determined self-consistently by the same method. This method (named here PBE0α) gives accurate bandgap values for very different semiconductors [3].

2 Models and methodology

Several models with different stackings of the NiOOH layers were studied. Since the simple 1H stacking of $Ni(OH)_2$ is known to be changed upon oxidation to NiOOH, those of type 2H, 3H or that reported in [4], here called 2M, are tested, in all cases having 50% of protons at each layer side to avoid unphysical effects on the ε_∞ result. Calculations (spin-polarized) use periodic code VASP. First the NiOOH lattices were relaxed with a GGA+U+vdW functional; then the thus relaxed structures were used, with atoms fixed, to obtain the electronic structure data with method PBE0α. With the structures giving lowest energies supercells were constructed with 8 formula units/cell; one Ni atom in them was substituted by Fe, a new GGA+U+vdW relaxation was carried out and in the resulting configuration the electronic structure was computed with fixed geometry with the same PBE0α method as in the undoped system.

3 Results and discussion

After relaxation all Ni ions appear with distorted octahedron coordination, with 2 longer Ni-O bonds in *trans* position. Ni^{3+} ions (low spin) show ferromagnetic order, the antiferromagnetic one having slightly higher energy. For all three stackings considered (which gave similar energies, explaining the high stacking disorder experimentally observed) the preferred OH situation has a mixture of Ni atoms having $O_4(OH)_2$ and $O_2(OH)_4$ coordinations of centrosymmetric type, rather than the average $O_3(OH)_3$ one (which is anyway not far in energy). The bandgap obtained with the PBE0α method varies somewhat depending on the stacking, going from ~0.95 eV to 1.45 eV; a value of 1.28 eV is found for a 3R-type stacking presenting the mentioned *trans* $NiO_2(OH)_4$ and $NiO_4(OH)_2$ coordinations (which gives the lowest energy; Fig. 1). These gap values are much larger than predicted with the GGA+U

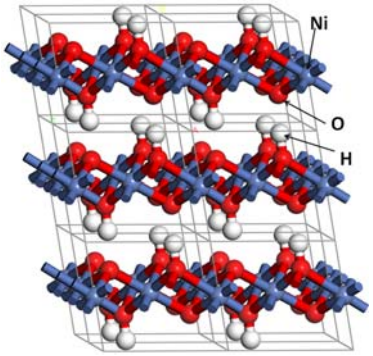

Fig. 1. Relaxed 3R-type NiOOH structure

DFT method, but are not unreasonable given the jump feature observed at 1.45 eV in the UV-Vis-NIR absorption spectrum [5]. The DOS curves (see e.g. Fig. 2a) show that the gap edges are formed by Ni 3d (e_g) states.

Substitution of Ni by Fe may give Fe^{3+} with some filled 3d states close to the valence band edge (Fig. 2b), but in some cases produces an electron transfer such as

$Ni^{3+} + Fe^{3+} \rightarrow Ni^{2+} + Fe^{4+}$

which explains some EXAFS observations of Fe^{4+} [6]; this is reflected in the DOS curves (Fig. 2c) where the Fe states at the valence band edge are replaced by Ni states. Jump of protons from the O atoms of the Fe coordination sphere to other O atoms around Ni can then be observed. Both effects indicate an easy mobility of electrons and protons between Ni and Fe species, in agreement with the conductivity increase observed upon Fe doping [1].

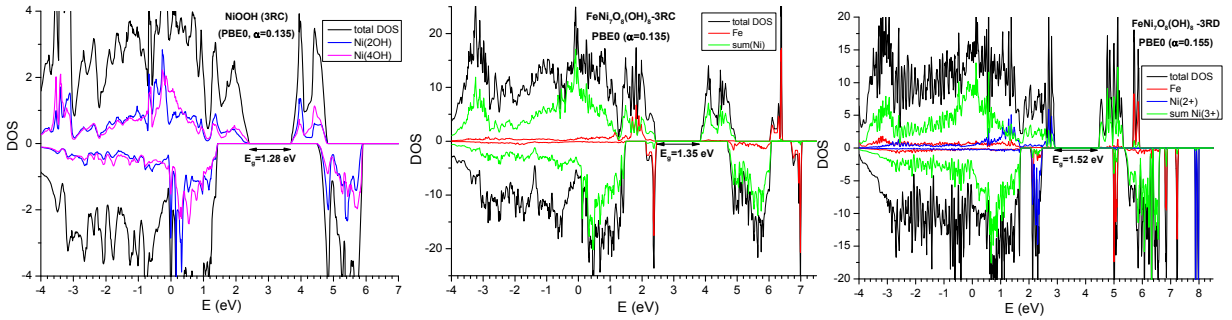

Fig. 2. DOS curves (incl. cation projections) given by PBE0α functional for a) NiOOH configuration with lowest energy (stacking 3R); b) Fe-doped NiOOH (with Fe as Fe^{3+}, coordinated to 4 OH groups); c) Fe-doped NiOOH in which electron transfer producing Fe^{4+} and Ni^{2+} has occurred.

4 Conclusions

DFT results justify the disordered character of NiOOH and predict for it a gap somewhat above 1 eV. Insertion of Fe in it gives a similar gap but facilitates proton and electron transfer in the bulk, which may explain the good electrocatalytic activity of the material.

Keywords: heterogeneous, photocatalysis, solar fuel, hydrogen, evolution, TiO_2, POMs

1 Introduction

In order to respond to the rising energy demand and the fossil fuels limitation, the interest in developing new ways of supplying solar fuel is growing [1]. The discovery of the *Honda-Fujishima effect* proved that water can be split photochemically [2]. Due to the advantages of heterogeneous catalysis during the conversion of harvested light energy into utilizable fuels, focus is placed on the identification of new materials, composites and reaction pathways [3]. Nevertheless, suspended catalysts compared to photo-electrochemical cells have the advantage of a larger density of active sites and shorter diffusion lengths for charge carriers. Unfortunately, most of the suspended photocatalysts need a chemical bias in order to evolve H_2 *or* O_2 [4]. For a functional catalyst, light harvesting semiconductors and composites as well as promoters for H_2 *and/or* O_2 evolution will have to be developed [5].

2 Methodology

In order to overcome the shortcomings in the photocatalytic H_2 evolution from water, it was investigated how solid solutions of polyoxometalates (POM) in the semiconductor TiO_2 can enhance the catalytic activity of TiO_2. Hence, several synthesis routes were followed to incorporate $H_3PW_{12}O_{40}$ into the framework of TiO_2 without destroying the Keggin-structure of the POM.

I. Synthesis. The incorporation of POM into the TiO_2 was achieved by different synthesis strategies, i.e.,sol-gel method with and without a template (Pluronic P123) and hydrothermal approaches using conventional and microwave-assisted synthesis.

II. Material Characterization. The resulting materials were thoroughly characterized with N_2-sorption, elemental analysis, diffuse reflectance UV/Vis, XRD, photoluminescence, TGA, TPD and solid state MAS NMR. Thus, detailed information about the kind of incorporation of the POM was obtained for interpretation of the photocatalytic activity.

III. Catalytic Testing. A 150 W Hg-medium-pressure lamp was used to irradiate a 380 ml aqueous suspension of 100 mg catalyst (incl. 0.5wt.-% Pt^0) in 10 vol-% MeOH. The resulting gases were analyzed every 2.5 min by gas chromatography to monitor the hydrogen evolution over time.

3 Results and discussion

So far, there were no reports of a possible application of POM/TiO_2 composited for photocatalytic H_2 generation. The incorporation of intact Keggin-$PW_{12}O_{40}^{3-}$-clusters into a TiO_2 material was successful via a conventional and a microwave-assisted hydrothermal synthesis as

proven by ^{31}P-MAS NMR analysis. The materials prepared via a sol-gel method revealed the decomposition of the Keggin-cluster during preparation. No XRD reflexes were found for the Keggin structure, but both strategies prove the successful synthesis of rutile or anatase.

The left side of Figure 1 shows photoluminescence spectra of pure TiO_2 from a sol-gel synthesis as a reference material and a hydrothermally synthesized POM/TiO_2 (HT-20%PW_{12}/TiO_2) composite. Obviously, the luminescence of the reference material is magnitudes higher than that of the composite. This behavior indicates that the rate of the electron-hole recombination is lower in the composite material.

This might explain the results which are depicted in the right side of Figure 1 which shows the hydrogen evolution over time. Thus, the composites have a higher photocatalytic activity compared to the pure TiO_2 which was prepared by the same route. Hence, the incorporation of POMs into TiO_2 enhances the photocatalytic activity; most probably by altering the charge carrier recombination.

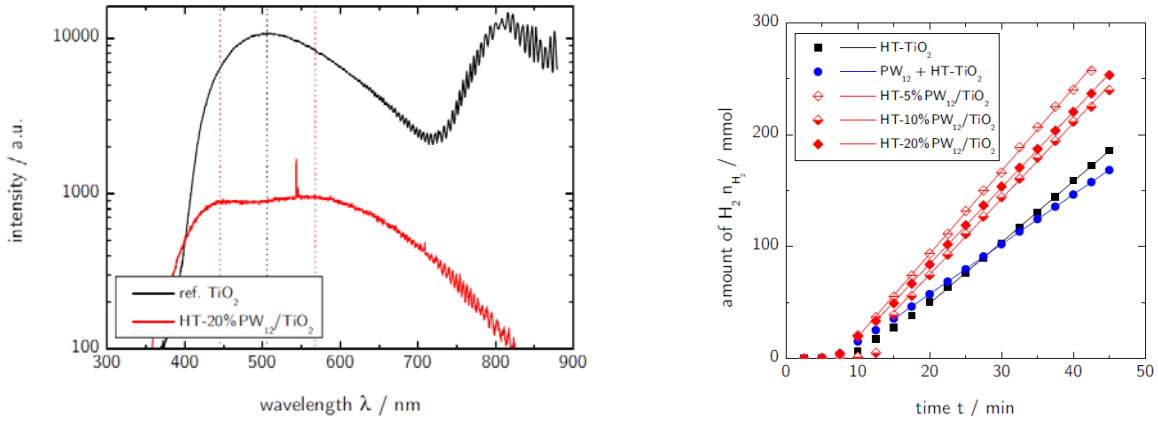

Fig. 1. Left: Photoluminescence spectra of HT-20%PW_{12}/TiO_2 and a TiO2 reference (synthesized by a sol-gel method), the dotted lines mark the maximum of the corresponding luminescence bands. Right: Amount of H_2 formed during UV irradiation of TiO_2 over time – TiO_2 samples are modified and unmodified with different amounts $H_3PW_{12}O_{40}$ (in wt.-%).

4 Conclusions

Composites of polyoxometalates $H_3PW_{12}O_{40}$ and TiO_2 exhibit a higher photocatalytic activity for hydrogen evolution in water than TiO_2 alone. Using solid state ^{31}P-MAS NMR it was proven that the Keggin structure was incorporated into TiO_2. A composite-strategy can improve the photocatalytic activity of semiconductors. Apparently, a composite strategy based on solid solutions might lead to higher photocatalytic activities due to a charge separating effect.

Keywords: electrical, conductivity, $Pr_{1,85}Sr_{0,15}Ni_{1-X}Cu_xO_4$

1 Introduction

Currently, studies are being conducted on materials with mixed-conductivity Ln_2NiO_4(Ln=La,Pr)[1-2], which can be used to mean-temperature electrochemical devices as cathodes.

This paper presents the results of researches, coefficients of thermal expansion, conductivity $Pr_{1,85}Sr_{0,15}Ni_{1-X}Cu_xO_4$(X=0.0;0.1;0.5;0,9 and 1.0), Pr_2NiO_4 and Pr_2CuO_4 in the interval 293-1273K in air

2 Experimental

Samples were prepared by solid phase synthesis. The starting materials served as $Pr(OH)_3$,PrO_2,Cu_2,NiO and $SrCO_3$. Mixture of oxides and carbonic strontium mixed in alcohol medium a mortar during 1 hours were pressed pills under the pressure 67 Mpa.

The compositions were synthesized in the air during 1-11 hours at temperature 1373-1473K.

Roentgen phase analyses was performed on a Rigaku D_{max}-2200, in the copper Kα-radiation. Synthesized samples had the structure of Layered Perovskite A_2BO_4 except for composition Pr_2NiO_4, $Pr_{1,85}Sr_{0,15}NiO_4$ and $Pr_{1,85}Sr_{0,15}Ni_{0,9}Cu_{0,1}O_4$. That had impurity phase $Pr_{11}O_6$,$Pr_{11}O_6$ and PrO_2, respectively.. The thermal coefficient of linear expansion of samples was measured with quartz dilotometer. The electrical conductivity was measured by DC four probe method with Platinum electrodes. Thermal coefficient of linear expansition of $Pr_{2-Y}Sr_YNi_{1-X}Cu_XO_4$ is in the range (11.2-16,6)$\times 10^{-6}deg^{-1}$and (11.6-16,3)$\times 10^{-6}deg^{-1}$ for temperature intervals 298-973K 298-1173K,respectively.

3 Results and discussion

The total electrical conductivity of Pr_2CuO_4 is higher the electrical conductivity of Pr_2NiO_4 and $Pr_{1,85}Sr_{0,15}NiO_4$ in air at temperature above 603K(fig.1).

Praseodymium in Pr_2NiO_4 replacement for strontium leads to an increase in conductivity. Electrical conductivity of Pr_2CuO_4 has a large activation energy than σ(Pr_2NiO_4)and σ($Pr_{1,85}Sr_{0,15}NiO_4$). At temperature above 623K maximum conductivity has the $Pr_{1,85}Sr_{0,15}Ni_{0,1}Cu_{0,9}O_4$(fig.2). At temperature above 833K the conductivity of $Pr_{1,85}Sr_{0,15}CuO_4$ is higher the electrical conductivity of $Pr_{1,85}Sr_{0,15}NiO_4$, $Pr_{1,85}Sr_{0,15}Ni_{0,9}Cu_{0,1}O_4$ and $Pr_{1,85}Sr_{0,15}Ni_{0,5}Cu_{0,5}O_4$

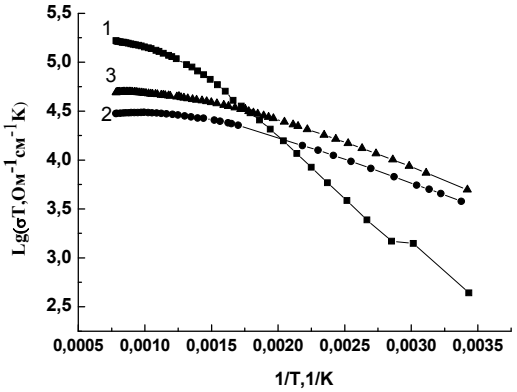

Fig.1 Temperature dependence of electrical conductivity of Pr_2CuO_4(1), Pr_2NiO_4(2) and $Pr_{1,85}Sr_{0,15}NiO_4$(3) in the air.

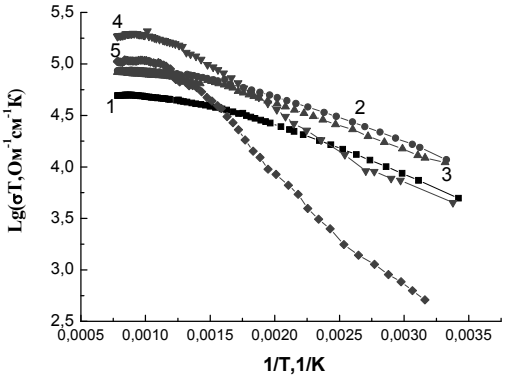

Fig.2 Temperature electrical conductivity of the samples $Pr_{1,85}Sr_{0,15}Ni_{1-X}Cu_xO_4$ in the air.1-X=0,0;2-0,1;3-0,5;4-0,9and 5-1,0.

4 Conclusions

Calculation of the activation energy of electrical conductivity in terms of the $\sigma_T = \frac{\sigma_0}{T}\exp(-\frac{E_a}{RT})$ showed that the compositions Pr_2CuO_4, $Pr_{1,85}Sr_{0,15}CuO_4$ and $Pr_{1,85}Sr_{0,15}Ni_{0,1}Cu_{0,9}O_4$ have a large activation energy of conductivity in comparison with compositions Pr_2NiO_4, $Pr_{1,85}Sr_{0,15}NiO_4$, $Pr_{1,85}Sr_{0,15}Ni_{0,9}Cu_{0,1}O_4$ and $Pr_{1,85}Sr_{0,15}Ni_{0,5}Cu_{0,5}O_4$.. The activation energy is small and is in the range (E_a=0,01—0,23 eV). This is typical of hopping conduction mechanism. Because the activation energy of σ(Pr_2NiO_4) less Ea σ (Pr_2CuO_4) it should be that the jup of e-holes is easier for nickel than for copper.

Keywords: hydrogen, flux, palladium alloy, foil, hydrogen separation, CO negative effect, carbon, deposits

1 Introduction

Demand in high-purity (99.9999 vol.%) hydrogen is being increased sharply due to the fast development of hydrogen power engineering. Among existing methods for hydrogen purification, membrane processes are characterized by lowest operating and capital outlays. The most promising membrane materials are palladium alloys. It is important to develop palladium alloys with high parameters of strength, plasticity, and hydrogen permeance; low thermoconcentration dilation for the operation in hydrogen; and high corrosion resistance to aggressive components of gas mixtures, because the composition of the mixtures substantially affects the productivity of the membrane and service resource. This paper presents the technological characteristics of Pd-6 wt.% In -0.5 wt% Ru alloy and the results of the study the specific permeability and the separation performance of a membrane unit based on a foil 28 μm thick from the specified alloy.

2 Experimental/methodology

The alloy composition is optimal, where a Pd–6 wt.% In solid solution corresponds to the maximum hydrogen permeability, and the addition of 0.5 wt.% Ru to Pd-In matrix increases the strength of the alloy and its operation in a hydrogen-containing atmosphere without any changes to the composition of its surface, which were observed in the Pd-6 wt.% In alloy. To exclude the formation of impurity inclusions and defects, the purity of the used materials was not lower than 99.95 wt.%. The alloy was melted in a protective atmosphere in an electric-arc furnace. The foil of the indicated alloy was prepared by cold rolling on a four-high rolling mill with intermediate vacuum annealings. The obtained foil did not require additional purification prior to experiments.

The H_2 flux through the membrane was studied in membrane unit (MU) based on a foil 28 μm thick of the Pd–In–Ru alloy. The main part of the MU is a hydrogen-permeated disc 58 mm in diameter placed between two stainless steel grids, which have 130 μm thickness and average pore radius of 2.0 μm, that provided its high mechanical strength. Graflex was used as a material for unit sealing. Filtering characteristics were studed at the temperature range of 573 to 823 K.

3 Results and discussion

The alloy Pd–6 wt.% In–0.5 wt.% Ru possesses an optimum complex of the properties. The alloy has high strength and high ductivity (H_v = 114 kg/mm^2, σ_B = 48 kg/mm^2, $\delta \approx 26\%$ (annealed)), sufficient specific hydrogen permeance, egual at 873 K to 2.2 m^3·mm/(m^2·h·MPa$^{0.5}$), and high corrosion resistance in hydrogen-containing gas mixtures obtained by hydrocarbon fuel conversion [1]. The ternary alloy withstands prolonged operation

in a hydrogen atmosphere and is stable during thermal cycling and in corrosive media (methane, CO_2, H_2S (up to 1.5 vol.%)). The technology was developed for the preparation of a membrane module based on the PdInRu foil (membrane diameter 50 mm, thickness 30 μm). The productivity of the membrane module for H_2 separation from the mixture, whose composition is identical to that of the products of natural gas conversion, is 0.3 Nm^3/h at the following parameters of the process: $P_{inlet\ mixture}$ = 2 MPa, P_{outlet} = 0.15 MPa, T = 873 K, and degree of hydrogen separation η = 0.8 [2].

The hydrogen flux through the foil (thickness 28 μm) with the composition Pd–6 wt.% In–0.5 wt.% Ru is more than twice as large as that through the foil of the Pd–23 wt.% Ag alloy. The membrane has high parameters of thermal stability and mechanical strength. The study of the dependence of the H_2 flux on the difference of the partial hydrogen pressures in the gas phase from the retentate and permeate sides of the membrane unit indicates that the permeation of hydrogen in the Pd–In–Ru foil is controlled by the diffusion of atomic hydrogen in the membrane bulk. The apparent activation energy of the hydrogen permeance is 18.7 kJ/mol. The influence of impurities (CO, N_2, Ar) on the hydrogen flux is studied using both a sweep gas (N_2) and transmembrane pressure. No negative effect of CO is observed in experiments using a sweep gas. The decrease in the H_2 flux with an increase in the impurity content in the hydrogen is due to the dilution of the mixture only. When the transmembrane pressure is used, CO exerts a negative effect on the H_2 flux, and this influence decreases with increasing temperature from 573 to 773 K. Contact of the foil with pure CO at 673 and 773 K results in an insignificant formation of carbon deposits on the membrane surface, which exerts almost no effect on the H_2 flux. No carbon deposits are formed on contact of the foil with the mixture H_2-22.5 % CO at 773 K due to CO methanation with the formation of CH_4 and H_2O.

4 Conclusions

The results of the present study show that palladium–6 wt.% indium–0.5 wt. % ruthenium alloy possesses an optimum complex of high technology characteristics. The foil of the ternary alloy is a good material for membrane technology of preparing high-purity hydrogen. The H_2 flux more than 2 times exceeds the corresponding parameter for the traditionally used foil of the Pd–23 wt.% Ag alloy. The membrane has high parameters of thermal stability and mechanical strength. The optimal temperature for H_2 separation from CO-containing mixtures is 773 K, since the inhibition of the separation process because of the reversible adsorption of CO molecules becomes lower, and the efficiency of the catalytic reaction on the membrane surface resulting in carbon deposits formation is insignificant.

1 Introduction

The technology for producing high-quality synthetic oil and fuels from carbon-containing feedstock — the so-called XTL (X-to-liquids) technology — is attracting increasing attention as an alternative to the use of dwindling oil reserves. Fischer–Tropsch synthesis (FTS) is the main stage of XTL technology, which allows converting natural gas, shale gas, coal and biomass and even helps solving ecological problems such as associated gas utilization [1, 2].

Cobalt FTS catalysts convert synthesis gas into clean sulfur-free synthetic liquid hydrocarbons, mostly linear paraffins, although both branched and unsaturated hydrocarbons may also occur [2, 3]. The product does not contain undesirable aromatics nor oxygenates and satisfies petrochemical quality requirements.

Since the contemporary XTL technology is rather expensive, the prospects of its widespread industrial adoption are related with improvement of all the technological stages of the process, especially with the performance of FTS catalyst. The combination of FTS catalyst with zeolite in a composite material leads to formation of bifunctional catalyst producing high-quality synthetic oil in one step by eliminating the hydrotreating stage [4]. The main role of zeolite is the decrease in average molecular weight of produced hydrocarbons by cracking on acid sites.

The use of metallic additives in the composition of FTS catalyst provides such advantage as intensified heat conductivity, which is particularly important for FTS due to strong exothermal nature of Fischer–Tropsch reaction [2]. Catalysts of low thermal conductivity tend to get overheated during the synthesis, which may cause enlargement of the active component crystallites and decrease theproductivity and selectivity of the process.

The purpose of this work was to study the effect of heat-conductive additives (aluminum, copper or zinc metal powder) introduction to cobalt-based catalyst.

2 Experimental/methodology

The investigated catalysts were produced by the extrusion of pastes. Pastes were prepared by the techniques described elsewhere [5, 6]. All the paste samples contained 50 wt.% of heat-conductive component (Al flakes, Al spheres, Cu or Zn metal powder — HB-Al1, HB-Al2, HB-Cu and HB-Zn samples, respectively), 20–35 wt.% of binder (boehmite) and 15–30 wt.% of zeolite Beta in H-form. One sample was prepared as a reference and did not contain heat-conductive component (HB sample).Cobalt was used as an active component. The introduction of the active component into the samples was conducted by two-step impregnation with a $Co(NO_3)_2 \cdot 6H_2O$ aqueous solution.

The catalyst was activated in pure hydrogen (3000 h^{-1}) at 400˚C and 0.1 MPa for 1 hr.After activation the catalyst was heated in a synthesis gas stream at 2 MPa, raising the temperature from 170 to 230˚C. Synthesis gas (molar ratio of $H_2/CO=2$ with 5 vol.% of N_2 as balance and internal reference) was supplied at gas-hour space velocity (GHSV) of 1000 h^{-1} while the temperature was raised and optimized and then GHSV was increased stepwise up to 6000 h^{-1}. Temperature was

optimized for every GHSV so that the productivity was maximum possible.

3 Results and discussion

The introduction of different heat-conductive components into cobalt-based catalyst influenced the main catalytic properties such as CO conversion, selectivity of C_{5+} hydrocarbons formation and productivity (Fig. 1): the GHSV increase resulted in appearance of strong differences in catalysts behaviour.

The introduction of dispersed aluminum (both flakes and spheres) influenced positively the main catalytic properties and led to increase in CO conversion — by 17–25%, C_{5+} selectivity — by 7–10% and productivity — 1.1–2.7 times, compared to the reference sample. The introduction of copper powder had almost no effect on CO conversion, but resulted in C_{5+} selectivity drop to about 20% and productivity decrease in 2.4 times. The introduction of zinc was not effective as well: CO conversion did not differ much from the reference sample, but C_{5+} selectivity and productivity were noticeably lower.

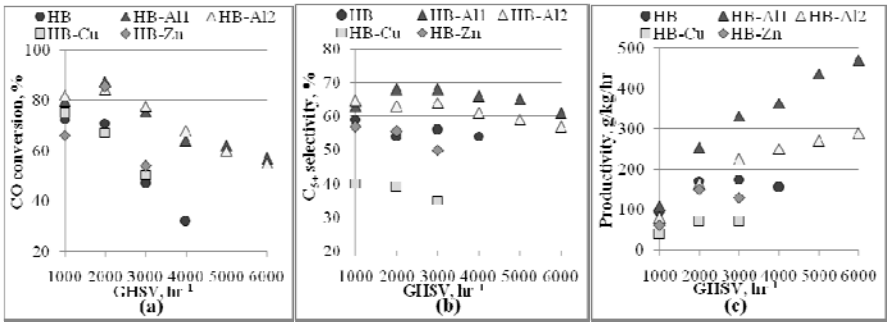

Fig. 1. The influence of GHSV on the main catalytic properties: (a) CO conversion, (b) selectivity of C_{5+} hydrocarbons formation and (c) productivity

Product composition and chain growth probability depend on heat-conductive component and on its catalytic activity (Table 1).The composition of product obtained in the presence of catalysts containing Al is the closest to those obtained in the presence of reference sample. So we suggest that Al provides heat transfer while manifesting no own catalytic activity in FTS condition. The introduction of Cu or Zn leads to drastic change in the product composition, which indicates that these metals are catalytically active in FTS conditions.

Table 1. The influence of catalyst composition on C_{5+} hydrocarbons composition (GHSV 3000 h^{-1})

Sample	C_{5+} hydrocarbons composition, wt.%			Chain growth probability (α)
	Olefins	N-paraffins	Iso-paraffins	
HB	29	32	39	0.74
HB-Al1	32	38	30	0.69
HB-Al2	31	39	30	0.72
HB-Cu	19	31	50	0.54
HB-Zn	8	77	15	0.80

4 Conclusions

Aluminum is the most promising metal for heat transfer intensification and provides significant improvement of main catalytic properties. The introduction of copper or zinc to these catalysts does not result in heat transfer intensification; moreover these metals influence the FTS parameters and thus change the group composition of the product.

Keywords: gold catalysts, Y-modified ceria, WGSR, PROX

1 Introduction

Hydrogen has a great potential as clean and high efficient energy carrier. After the conversion via steam reforming of hydrocarbons (from natural or renewable materials) into ‘‘syn gas’’, the mixture contains CO with concentration of about 10 vol%. The preferred process for increasing the H_2 amount is the water gas shift reaction (WGSR), lowering the CO concentration to about 0.5–1 vol%. However, for the development of fuel cell technology, the concentration of CO should be below 10 ppm because of the high sensitivity of the Pt anode towards CO in polymer electrolyte membrane fuel cells. The catalytic oxidation of CO in hydrogen-rich gas streams (PROX) appears to be the simplest and the most cost effective for this purpose. Nano-gold catalysts have been proven very efficient both for WGSR at low temperatures (200–300 ^{o}C) and PROX at the fuel cell operating temperatures (80–120 °C). Beside the gold dispersion the support plays a decisive role for a good performance. Doping of ceria by metals of lower valence (< 4+) causes oxygen vacancies formation and thus increases the oxygen capacity of the ceria-based catalysts. The aim of the present study was to compare the effect of different preparation methods and the amount of Y as dopant on the WGS and PROX activity of Au/CeO_2 catalysts.

2 Experimental

Two different synthesis routes: impregnation (IM) and co-precipitation (CP) were used for preparation of Y-modified ceria supports (1, 2.5, 5 and 7.5 wt% Y_2O_3). Gold catalysts (3 wt% Au) were prepared by deposition-precipitation method. The samples were characterised by means of BET, XRD, HRTEM/HAADF, XPS, H_2-TPR and Raman spectroscopy. The WGS activity was evaluated under the following conditions: gas mixture of 4.5 vol% CO in Ar + 25 vol. % H_2O, catalyst bed volume=0.5 cm^3, space velocity (GHSV)=4000 h^{-1}. The measurements of the PROX activity, expressed as the degree of CO conversion and selectivity toward CO_2, were carried out using 60% H_2 + 1% CO + 1% O_2 and He as balance (WHSV of 60 000 mL g^{-1} h^{-1}). Tests with CO_2 and water addition to the gas feed were carried out over selected samples. For both reactions the effect of pre-treatment (reductive or oxidative conditions) and stability of the best performing catalysts was also studied.

3 Results and discussion

The catalytic tests showed better WGS performance after pretreatment in air at 350 ^{o}C than at 200 ^{o}C. In Fig. 1 (A and B) the obtained results after pretreatment at 350 ^{o}C are compared. The results revealed very high activity of all catalysts. The samples on IM supports exhibited

better performance as compared to those on CP supports. A clear trend of decreased WGS

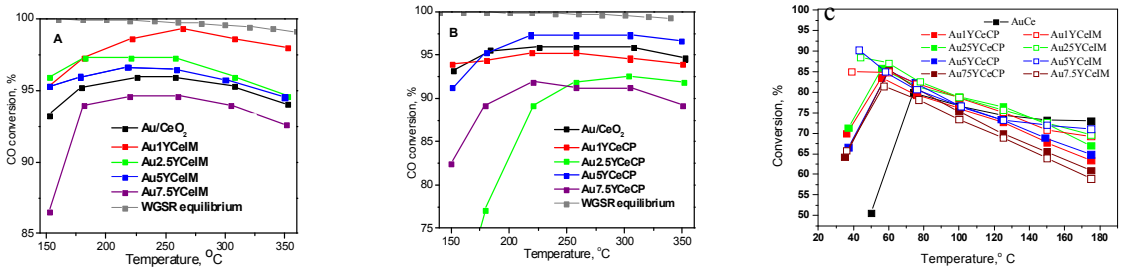

Fig. 1. WGS activity of Au samples supported on Y-doped CeO_2 prepared by IM (A) and CP (B); PROX activity of the studied gold catalysts (C)

activity with increased Y content was registered for IM samples. The best CO conversion exhibited Au1YCeIM (>98% in the range 275-300°C). The activity in PROX (higher using reductive pretreatment) is illustrated in Fig. 1 (C). At room temperature the CO conversion was significantly higher over the catalysts on IM supports as compared to those on CP ones and bare ceria. However, in the interval 80-120 °C the activity and the selectivity to CO_2 (not shown) are relatively high and they did not differ substantially, regardless the synthesis procedure and Y-amount. Slightly higher activity exhibited Au2.5YCeIM (relatively good selectivity of about 40%). The drop in activity and selectivity after CO_2 and water addition to the feed over this catalyst was not very significant, in contrast to the substantial deactivation over Au2.5YCeCP sample. The better resistance toward CO_2 deactivation using IM method could be due to the separate Y_2O_3 phase on ceria grains (confirmed by HRTEM) leading to decreased surface basicity. The differences in the catalytic behaviour was not connected to gold dispersion but it was likely related to support features. The size of gold particles seems to be independent of the synthesis procedure (XRD and HRTEM data). Y-doping of ceria by both preparation methods is favoring the high dispersion of gold particles and their stability during the catalytic operation in both reactions (HRTEM data of average size of gold particles 2.2 - 3.5 nm for all fresh and spent samples). Ceria particles were in the range of 4-8 nm (XRD data). Differences in the reducibility of ceria surface layers were visible in the TPR spectra of the initial supports. Gold causes a significant shift to lower temperature of the TPR peaks assigned to ceria surface reduction. The differences in the reducibility of all gold catalysts seems not so substantial. The relative amount of oxygen vacancies (Raman data) increased linearly with the Y-amount, to a large extent for the CP preparation. In the case of IM supports the relative concentration of oxygen vacancies is almost equal for all samples and it is significantly lower as compared to the corresponding CP supports. These results suggest that CP preparation method leads to in depth distortion of ceria structure, whereas the IM method causes predominantly surface ceria modification.

4 Conclusions

Adding yttrium to ceria had generally a positive effect on the WGS activity of the supported gold. Moreover, when yttrium was added by IM procedure the effect was inversely dependent on its amount and it was also larger than in the case of the CP procedure. At the temperature of interest for fuel cells application the catalytic activity in PROX did not differ significantly over all studied samples; the IM preparation method was beneficial for PROX at real conditions improving the resistance toward CO_2 deactivation. The comparison of present WGS and PROX results with our previous findings about the effect of different rare earths as dopants of ceria used as support of gold catalysts reveal a promising role of Y-doping.

Gallium-Promoted Nickel/Cerium Catalysts for Hydrogen Production from Steam Reforming of Acetic Acid as a Model Compound of Bio-Oil

Nogueira F.G.E., Assaf P.G.M., Tremiliosi Filho G., Assaf E.M.*

São Paulo University, São Paulo, Brazil

* eassaf@iqsc.usp.br

Keywords: hydrogen, bio-oil, acetic acid, gallium, cerium, nickel

1 Introduction

A renewable biomass may be use as an alternative energy source, due to the large variety of feedstock available, such as sugar cane residues (tops, leaves and bagasse), grass, straw, sludge, organic domestic waste and industrial wood waste. The use of biomass reduces CO_2 emissions compared to using fossil fuels because it is a CO_2 neutral energy source besides reducing emissions of NOx and SO_X [1-2].

Hydrogen can be produced from biomass via thermochemical processes, such as flash pyrolysis, which produces mainly liquids (bio-oils), and then the bio-oils can be converted to hydrogen by catalytic steam reforming . Nevertheless, bio-oil is a very complex organic mixture like acids, ketones, alcohols, phenols and guaiacols [3-4].

Therefore, designing efficient catalyst requires the use of model oxygenated components for preliminary tests. Acetic acid (HAc), which is soluble in water, is chosen as a model compound because it is one of the most representative constituents of bio-oil. Thus, the aim of this work was to study the performance of nickel catalysts promoted with gallium (Ga) supported on CeO_2 to convert acetic acid into hydrogen.

2 Experimental/methodology

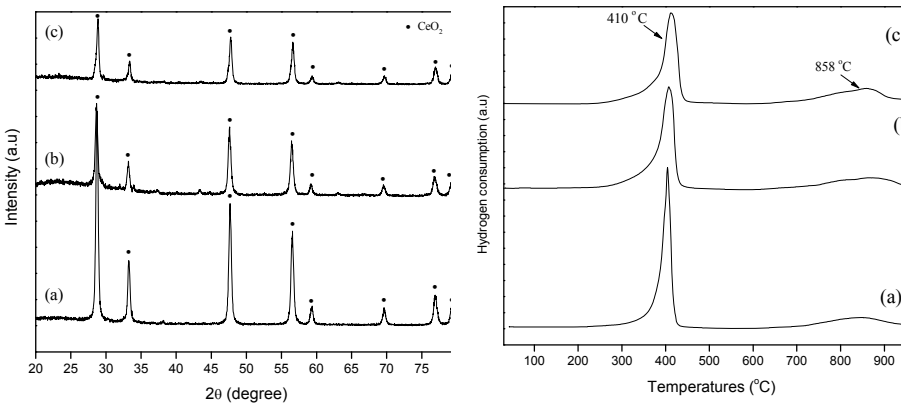
Ni catalysts supported on CeO_2 and promoted with Ga were prepared by the impregnation method. First, the Ga-CeO_2 supports were synthesized using the coprecipitation method with loadings of 1 and 3 wt. % of Ga. Ga/CeO_2 supports were then impregnated with the solution of $Ni(NO_3)_2.6H_2O$ under stirring at 70 ^oC and then dried overnight in air at 110 ^oC. The dried powder was finally calcined at 650 ^oC for 3h to obtain the NiO/Ga-CeO_2. All the nickel catalysts were prepared with a load of 5 wt.% Ni. The samples were characterized by X-ray diffraction (XRD), temperature-programmed reduction (TPR) and thermogravimetric analysis (TGA). The catalysts were named 5Ni1Ga/CeO_2 and 5Ni3Ga/CeO_2. The unpromoted catalyst, 5%Ni/CeO_2 was also prepared for comparison and was named 15Ni/Ce.

The catalytic tests for the acetic acid steam reforming were carried out using a tubular quartz reactor, containing 100 mg of catalyst. Before the reactions, the catalysts were reduced with hydrogen (30 mL min^{-1}) at 750 ^oC for 1h, to activate the catalyst. Aqueous solution of acetic acid 2:1 (H_2O: CH_3COOH) molar ratio was fed by a piston pump resulting in a flow of 2.5 $mL.h^{-1}$. The reactions were carried out at temperatures of 600 °C. The product composition was recorded over 6h of reaction.

3 Results and discussion

Figure 1A shows a XRD of 5Ni/CeO_2, 5Ni1Ga/CeO_2 and 5Ni3Ga/CeO_2 catalysts. The main phase observed in the diffraction patterns was CeO_2 with a fluorite structure (ICDD 34-0394). Diffraction peaks related to the Ga_2O_3 and NiO crystallites were not observed in the

XRD patterns of these samples. Figure 1(B) shows the H_2-TPR curves of catalysts. The catalysts present two redox peaks between t 410 ^oC and 858 ^oC which correspond to the reduction of NiO and CeO_2.



(A) (B)

Fig.1 (A) DRX of (a) 5Ni/CeO2 (b) 5Ni1Ga/CeO2 and (c) 5Ni3Ga/CeO2 catalysts and (B) H2 - TPR profiles of catalysts (a) 5Ni/CeO2 (b)5Ni1Ga/CeO2 and (c) 5Ni3Ga/CeO2

All catalysts showed conversion above 90% for acetic acid at 600 ^oC. It is noteworthy that the addition of Ga as promoter did not affect the conversion of acetic acid. The selectivity for H_2 for $5Ni/CeO_2$, $5Ni1Ga/CeO_2$ and $5Ni3Ga/CeO_2$ catalysts was ~3.5 mol H_2/mol $CH3COOH_{conv.}$ at 600 ^oC for all catalysts. However, with addition of 3% Ga the rate of coke was 0,0098 g_c $gcat^{-1}h^{-1}$, while the rate of coke formation for $5Ni/CeO_2$ and $5Ni1Ga/CeO_2$ catalysts was 0,0295 and 0,0179 g_c $gcat^{-1}h^{-1}$, respectively. This shows that addition of Ga prevents the formation of coke on the catalyst surface.

4 Conclusion

The present study demonstrates that the catalysts containing $5Ni3Ga/CeO_2$, showed the lower rate of coke formation when compared with catalysts $5Ni/CeO_2$ and $5Ni1Ga/CeO_2$.

Effects of Mg Content on Ni/MgO-SiO_2 Catalyst for Ethanol Steam Reforming

Thyssen V.V., Georgetti F., Assaf E.M.*

São Paulo University, São Paulo, Brazil

* eassaf@iqsc.usp.br

Keywords: ethanol steam reforming, H_2, production, nickel, catalyst, magnesia, silica

1 Introduction

Industrially, the metal of choice for catalysts applied in several types of reactions is Ni, due to its high availability and lower cost compared to noble metals. [1,2]

Commercial silica is often used as a support due to its high specific area, which provides the reaction environment a greater contact area and possibly a greater number of active sites for the tested reaction to take place. [2]

MgO is known by the possibility of solid solution formation with the NiO. NiO-MgO is an interesting system of solid solution; they form the "ideal" model of solid solution - in which the NiO becomes part of the mesh of the support with a strong interaction with MgO - and exhibit unique catalytic properties for many reactions. [3]

Thus, the aim of this study was to prepare, characterize and tested Ni catalysts supported on MgO-SiO_2 matrices in ethanol steam reforming, and observe the influence of the Mg content on the structural and physic-chemical properties of the catalysts.

2 Experimental/methodology

Catalysts were prepared by impregnation method [2] using 10wt% of Ni supported on SiO_2, MgO and MgO-SiO_2 (10, 30 and 50wt%Mg) and named: NS, NM, N10MS, N30MS and N50MS.

The samples were characterized by EDS, surface area (BET), XRD, TGA, and H_2-TPR.

The catalysts were tested in ethanol steam reforming for initial results, using a mixture of ethanol:H_2O with feed molar ratio of 1:6 flowing at 2.5mlh^{-1}, in a period of 5h at 600^{o}C.

3 Results and discussion

The compositions obtained by EDS for Mg and Ni were close to nominal values (10, 30 and 50wt% of Mg; and 10wt% of Ni): 11, 29 and 48 wt% Mg for mixed supports (10MS, 30MS and 50MS, respectively); 11, 13, 12, 12 and 11 wt% Ni for catalysts (NS, N10MS, N30MS, N50MS and NM, respectively).

The specific surface areas showed that the addition of Mg or Ni on the S-support caused a decrease in its area: 324, 129, 56, 40 and 212 m^2g^{-1} for S-support, 10MS, 30MS, 50MS and NS, respectively. However, the addition of Ni over the M and MS-supports caused an increase in them areas: 13 m^2g^{-1} for M-support; 206, 170, 64 and 41 m^2g^{-1} for N10MS, N30MS, N50MS and NM, respectively.

XRD (Figure 1a) analysis of the supports presented diffraction peaks of amorphous SiO_2, MgO, $Mg(OH)_2$ and magnesium silicate hydrate (MSH). The catalysts showed, besides the peaks found in the supports, peaks related to NiO and $MgNiO_2$ (solid solution). [4,5]

TGA experiments (not shown here) were carried out to observe the weight loss of the 30MS and 50MS supports, and confirm the presence of MSH and $Mg(OH)_2$ on these samples. The MSH loses molecular water at 80-200^{o}C, and both supports presented a peak at this temperature range. Weight loss due to $Mg(OH)_2$ decomposition appears around 450^{o}C and was

more evident on 50MS support.[4]

Literature reports that the MgO samples hydrate to some extent by exposure to the air forming $Mg(OH)_2$ species, and when MgO or $Mg(OH)_2$ is in contact with amorphous silica and water (air) the MSH is formed in a relatively short period at room temperature.[4,5]

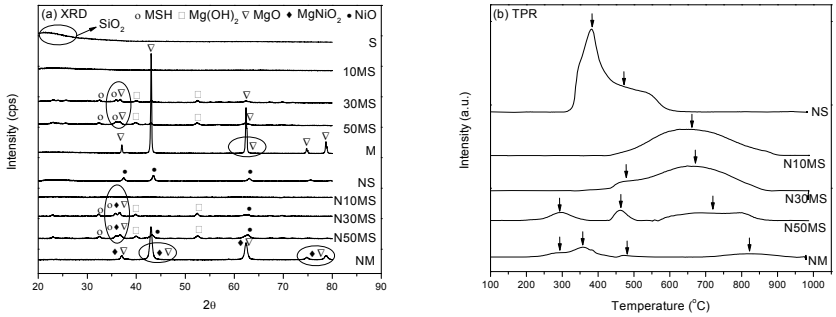

Figure 1. (a) XRD and (b) H_2-TPR.

Since the supports present no reduction, the peaks showed in TPR (Figure 1b) profiles were assigned to the reduction of NiO species present on the catalysts surface. The reduction profiles could be deconvoluted into several contributions, corresponding to different intensity of metal-support interaction: at 250-300°C signal can be attributed to the reduction of isolated NiO; the signals at 350-550°C were assigned to NiO with weak interaction with the support. It is possible to distinguish that the temperature at the maximum of the reduction peak, which was related to the NiO with moderate interaction with the support, increased from 660 to 720°C as Mg content increases between 10 and 50wt%. It would be possible to attribute the increment in the reduction temperature as Mg content increases to a greater interaction between NiO and MgO. The peak of reduction that appears at 820°C can be related to the NiO species with strongly interaction with the support.[6]

The catalysts were tested in ethanol steam reforming, and they presented activity and selectivity to gaseous products (H_2, CO, CO_2 and CH_4). All the catalysts showed total conversion of ethanol and it was observed that with the increase of Mg content on the support, the carbon deposition decreases. N30MS and N50MS catalysts showed the best H_2 selectivity.

4 Conclusions

It can be concluded that the Mg content influences the catalytic properties; it was observed that the catalysts presented different species of Mg and Ni in them surfaces: MgO, $Mg(OH)_2$, MSH, NiO and $MgNiO_2$. The catalytic tests showed that with the increase of Mg content on the support, the carbon deposition decreases.

Ni/ZrO-ZnO Catalysts Applied in Ethanol Steam Reforming for H_2 Production

Elias K.F.M., Assaf E.M.*

São Paulo University, São Paulo, Brazil

* eassaf@iqsc.usp.br

Keywords: ethanol steam reforming, hydrogen, nickel catalyst, ZnO, ZrO_2

1 Introduction

Ethanol is a product derived from biomass and it can be transformed by steam reforming (ESR) in products with higher added value, as hydrogen fuel, it can be used in electrochemical cells that generate electricity [1]. The conversion of ethanol and products distribution are related to the composition of the catalyst and the reaction conditions. Nickel-based catalysts have been more extensively studied due to high activity and low cost. It was found that ZnO supported catalysts showed good performance because its redox and basic properties [2]. ZrO_2 is a good catalyst support for methane and methanol reforming, and it is also a good promoter for ZnO-supported catalysts in the steam reforming of methanol, but to the best of our knowledge, there has been no previous report concerning the simultaneous use of ZnO and ZrO_2 in a catalyst for ESR. The goal of this study was to evaluate the effect of adding ZrO_2 in NiZnO catalysts applied to ESR in order to produce hydrogen.

2 Experimental/methodology

NiZrOZnO catalysts containing 10wt% of Ni and 0%, 10%, 20% and 30% of ZrO2 were prepared by coprecipitation of the respective nitrates and tested in ethanol steam reforming. All samples were calcined at 700°C / 2h. The materials were characterized by temperature programmed reduction (TPR), specific surface area by the BET method and energy dispersive X-ray spectroscopy (EDX). The catalytic tests (ESR) were carried out using 150 mg of catalyst and with molar ratio ethanol: water 1:6, and total feed flow of 2.5 ml h^{-1} at 600 °C. Before the tests, the catalysts were reduced in situ with H_2 (30 mL min^{-1}).

3 Results and discussion

According to Table 1 a low surface area was observed for the 10NiZnO catalyst, as previously literature reports [3]. The addition of ZrO2 to the system favoring an increase in the area of the catalysts, however, with a high content (30%) the area returns to decrease. It is observed that there was a difference between the calculated values and real values found by EDX. This is related to small errors in handling the reagents at the time of synthesis. Table 2 shows the reactions results. A high conversion was observed for all the catalysts and it occurred because temperatures above 500 °C and high ratio water:ethanol promote high conversion. It was observed that the ethanol steam reforming was the predominant reaction, and the CO and CH_4 contents were minimized [4]. Furthermore, it was noted that increasing of ZrO_2 content, the H_2 selectivity improved, from 2.3 moles of H_2 in the catalyst 10NiZnO up to 4.4 moles of H_2 in the catalyst 10Ni30ZrZn. This effect of the ZrO_2 is according to literature, where is observed that the surface hydroxyl groups contribute significantly to the steam reforming and improving the thermal resistance of the material [5]. Moreover, it was observed by TPR analysis, which are not shown here, that increasing the ZrO2 content, there was a higher nickel-support interaction, displacing the main reduction peak of nickel to higher temperatures, an important feature for

that there is no sintering of the metal phase.

Table 1. Surface area and composition by EDX

Catalyst	Surface Area (m2 g-1)	%Ni calculated	%Ni Real*	%Zr calculated	%Zr Real*
ZrO_2	25	----	----	----	----
10Ni/ZnO	13	10	10.3	----	----
10Ni/10ZrZnO	27	10	9.6	10	7.9
10Ni/20ZrZnO	23	10	9.6	20	16.3
10Ni/30ZrZnO	12	10	9.2	30	23.8

Table 2. Conversion (%) and selectivity (mol produced/ mol of ethanol converted)

Catalyst	Conv.	H_2	CH_4	CO	CO_2
10Ni/ZnO	99	2.35	0.09	0.19	0.56
10Ni/10ZrZnO	99	3.60	0.12	0.38	0.94
10Ni/20ZrZnO	99	3.09	0.16	0.32	0.79
10Ni/30ZrZnO	99	4.42	0.23	0.46	1.23

4 Conclusions

The catalyst with 30wt% ZrO_2 exhibits superior H_2 selectivity compared to others catalysts for ESR at 600 ^oC. Therefore, the NiO/ZrO2/ ZnO catalyst is promising and could be a good choice for application in ethanol steam reforming.

Co Catalysts for the Dry Reforming of Methane: Effect of Support

San Jose-Alonso D., Roman-Martinez M.C.*, Illan-Gomez M.J.

Department of Inorganic Chemistry, University of Alicante, Alicante, Spain

* mcroman@ua.es

Keywords: Co catalysts, dry reforming, alumina, spinel, carbon nanotubes, magnesium, titanate

1 Introduction

The dry reforming of methane (DRM) is nowadays an attractive reaction to obtain synthesis gas with a H_2/CO ratio close to 1(very suitable to obtain different valuable products) which implies the consumption of two greenhouse gases (CO_2 and CH_4) and allows the use of biogas [1-3]. All metals from 8, 9 and 10groups (excepting Os) are able to catalyse the DRM reaction but, for industrial application, only Co and Ni are convenient from an economical point of view. The main drawback of these two metals is the high carbon deposition during reaction. Several variables have been investigated with the purpose of diminishing carbon deposition. In this work, the effect of the support in the DRM performance (activity and carbon generation) of a series of cobalt catalysts has been analyzed.

2 Experimental

Five catalysts, with a 9 wt.% nominal Co content have been prepared by excess solution impregnation using the following supports: Al_2O_3, $MgAl_2O_4$, Mg-Al_2O_3 (Mg impregnated alumina), carbon nanotubes (C) and $MgTiO_3$. After impregnation, the catalysts were dried at 100 ºC for 12 h.

Catalysts characterization was done with the following techniques: i) ICP-OES, to determine metal content, ii) TEM to study particles size distribution and the morphology of deposited carbon, iii) H_2–TPR, to analyze the catalysts reducibility and iv) OTP, to determine the amount of deposited carbon.

Prior to the catalytic activity tests, the catalysts were activated in situ by treatment with H_2 (60ml/min) at 500ºC for 90 minutes. DRM experiments were carried out in a fixed-bed quartz reactor at 700 ºC for 6 h with a 50:50 CH_4:CO_2 gas mixture (60ml/min) and 0.18 g of catalyst (20.000 h^{-1} space velocity). A gas chromatograph (HP 5890 series II with two packed columns Porapak Q and MolSieve 13X) was used for analysis.

3 Results and discussion

Table 1 shows the CH_4 and CO_2 conversion data (at ½ h and 6 h), the deactivation percentage and the amount of deposited carbon, expressed as molar percentage (moles of deposited carbon respect to the total converted carbon) and as mg of deposited carbon per g of catalyst. It is observed that the support determines the initial activity, the stability and also, the amount of deposited carbon. The catalyst supported on $MgTiO_3$ features the lowest initial conversion of methane and the lowest stability as it loses its activity after 90 minutes.The catalyst supported on carbon nanotubes and on Mg-Al_2O_3 show intermediate values of methane conversion, a constant deactivation during 6 h reaction and, the amount of deposited carbon is high. Finally, the catalysts supported on $MgAl_2O_4$ and on Al_2O_3 present high methane conversion values during the 6 h reaction, being Co/$MgAl_2O_4$ the one which shows the lowest amount of deposited carbon.

Table 1. Activity data for Co catalysts during DRM reaction at 700ºC.

	Conversion (%)				Deposited Carbon (6h)	
	CH_4, at ½ h	CH_4 at 6 h	CO_2 at 6 h	Deactivation[a] (%)	%molar[b]	mg/g[c]
Co/Al_2O_3	73	72	81	1	0.57	290
$Co/MgAl_2O_4$	63	64	74	-1	0.25	135
$Co/Mg\text{-}Al_2O_3$	51	41	52	20	0.42	230
Co/C	37	27	38	27	0.80	440
$Co/MgTiO_3$	30	0	0	100	0.04	20

[a] Deactivation, calculated as the difference between conversion at 30 minutes and 6h divided by conversion at 30 minutes and multiplied by 100.
[b] (mol of deposited carbon/mol of converted carbon)*100 (at t=6h)
[c] mg of carbon deposited per gram of catalyst

To explain the observed differences, the used (after DRM reaction) catalysts were characterized by TEM. The average size of Co particles is 14.1, 7.8, 10.2, 15.7 and 22.2 nm in catalysts supported on Al_2O_3, $MgAl_2O_4$, $Mg\text{-}Al_2O_3$, carbon nanotubes and $MgTiO_3$, respectively. This indicates that the support has a clear influence on the particle size and as a consequence on the initial catalytic activity. Thus, excepting catalyst Co/Al_2O_3, methane conversion increases as the average size of cobalt particles decreases, that is as the metal dispersion increases. The higher acidity of Al_2O_3 favors the fragmentation of methane (rate limiting step) and this could explain the higher activity of the Co/Al_2O_3 catalyst. On the other hand, the lower amount of carbon deposited on $Co/MgAl_2O_4$ respect to Co/Al_2O_3 seems to be related, also, with the lowest acidity of the $MgAl_2O_4$ support, which determines the decomposition of methane that mainly causes the carbon deposition.

4 Conclusions

The support strongly influences the catalysts activity of Co catalysts (9 wt%) in DRM. It affects the size of the loaded Co particles and, as consequence, the number of active sites on the catalyst surface. The acid/basic properties of the Al_2O_3 and $MgAl_2O_4$ supports justifies the high activity of the former and the low amount of deposited carbon of the latest catalyst, respectively.

Iron Based Catalysts Supported on KL Zeolite for Fischer-Tropsch Synthesis

Silva J.F.[1], Bragança L.F.F.P.G.[2], Pais Da Silva M.I.[1*]

1 - Pontificia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil
2 - Universidade Federal Fluminense, Niteroi, Brazil

* isapais@puc-rio.br

Keywords: KL zeolite, Fischer-Tropsch synthesis, iron catalysts

1 Introduction

Fischer-Tropsch synthesis (FTS) produces clean fuels and chemicals from syngas generated from natural gas. Iron and cobalt metals have been found to be suited for FTS. Also, it has been reported that iron based catalysts generate more oxygenates and high olefin selectivity [1]. Here, we propose studying the catalytic behaviors on FTS of iron based catalysts supported on KL zeolite with different metal content (1 and 5 wt %).

2 Experimental/methodology

The KL zeolite was obtained from Toyo Soda. The catalysts were synthesized by the incipient wetness impregnation method using an aqueous solution of iron nitrate so as to prepare catalysts containing 1 and 5 wt % of Fe metal on KL zeolite support. Following impregnation, the catalysts were dried for 24 h at 353 K and calcined at 723 k in air (30 mL/min) for 4 h. The amount of incorpored metal was analyzed by Atomic Absorption Sprectroscopy (AAS). Nitrogen isotherms at 77 K were measured using a Micromeritics ASAP2010 apparatus. The X-ray diffraction (XRD) measurements were performed in a X'Pert PHILIPS equipment with Cu Kα radiation (40 kV, 30 mA) in the 2Θ range of 5°-80°. The catalytic performance in FTS was evaluated in a fixed bed microreactor under controlled conditions (543 K and 20 bar).

3 Results and discussion

The chemical composition and the textural properties of KL support and calcined supported catalysts are listed in Table 1. The results indicated that the measured metal contents approach the nominal values expected from catalysts preparation. The structural properties showed a higher total pore volume for 1 wt % Fe/KL sample and similar values for specific surface area for both catalysts. The BET area decreased after introduction of iron to KL support about 16% for both samples probably due to blocking of some zeolite pores. The XRD patterns of the KL zeolite support and catalysts are shown in figure 1. It is possible to verify that the KL zeolite structure was maintained after iron impregnation for both samples. The performances of the catalysts in FTS are presented in Table 1. According to the data obtained a higher conversion of CO was observed for 5 wt % Fe/KL. It could be attributed to the amount of iron in the support. The majority of CO was converted to C_2-C_4 and C_{5+} products for 1 and 5 wt % Fe/KL. A low content of heaviest fraction C_{19+} was observed for both catalysts showing a narrow hydrocarbons distribution from C_2 to C_{19}.

Table 1. Chemical composition, textural properties and FTS results for Fe/KL catalysts.

Samples	Metal (wt. %)	BET area (m2/g)	TPV (cm3/g)	CO conversion (%)	CH_4	C_2-C_4	C_{5+}	C_{19+}
KL	-	346	0.22	-	-	-	-	-
1wt % Fe/KL	1.1	292	0.22	19	16.5	28.8	54.8	5.7
5wt % Fe/KL	4.1	293	0.18	32	18.2	34.9	46.9	12.3

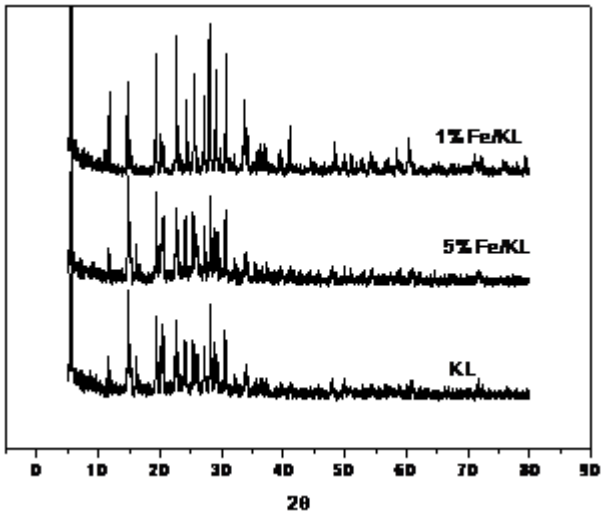

Fig. 1. XRD patterns

4 Conclusions

The characteristic pattern of the KL zeolite structure was retained after addition of metallic iron. However, the introduction of iron in the KL zeolite decreased the specific superficial area for both catalysts.

The increase of total metal content from 1 to 5 wt % indicated an increasing in CO conversion and CH_4 production.

A high (C_2-C_4) hydrocarbons distribution was observed proving that iron catalysts favour the light hydrocarbons formation.

The heaviest fraction was low for Fe catalysts indicating mainly the formation of lighter liquid hydrocarbons fractions (gasoline and diesel).

Highly Dispersed Ni Catalysts over Cerium Modified Mesoporous MCM-41 for Hydrogen Production by Ethanol Steam Reforming

Tovar Rodríguez J.[1,2*], Ramírez Hernández G.Y.[1], Galindo Esquivel I.R.[1], Fratini E.[2], De Los Reyes Heredia J.A.[3]

1 - Universidad de Guanajuato, División de Ciencias Naturales y Exactas, Guanajuato, México

3 - Universidad Autónoma Metropolitana, División de Ciencias Básicas e Ingeniería, México, México

* tovar@csgi.unifi.it

Keywords: nickel catalyst, hydrogen, ethanol reforming, MCM-41

1 Introduction

Hydrogen has attracted much attention as an alternative energy carrier due to its non-polluting nature. Nevertheless, the current main sources of hydrogen are still oil-based hydrocarbons, since most of the hydrogen on Earth is found as constitutive part of larger molecules [1]. In this sense, the Ethanol Steam Reforming reaction (ESR) could be a very promising production route [2], particularly when ethanol is obtained from renewable sources. Although the use of mesoporous materials can find a versatile and broad range of applications, they still seem to be a preferred and unique source of catalytic supports for various active phases and their application shifts towards the catalysis of more selective reactions. For this purpose, Ce modified mesoporous MCM-41 could provide a better catalytic support for a Ni active phase in the ethanol steam reforming reaction to produce H_2.

2 Experimental

Cerium modified mesoporous silica MCM-41 was prepared in a hydrothermal direct synthesis approach (100ºC, 24h, following calcination at 550ºC) using 0.02, 0.04, 0.06 and 0.08 as Ce/Si molar ratios. Hexadecyltrimethylammonium bromide was used as structure directing agent; Ammonium hydroxide was used as mineralizing agent; Cerium nitrate was used as cerium precursor and Tetraethyl orthosilicate as Si source. Ni catalysts were prepared by dry impregnation method with loadings of 10% wt of Ni, using a solution of $Ni(NO_3)_2 \bullet 6H_2O$. The resulting solids were dried at room temperature for 24h and calcined at 550°C for 2h. All materials were characterized by means of Small Angle X-Ray Scattering, N_2 physisorption, Scanning Electron Microscopy and MAS Nuclear Magnetic Resonance. The ESR reaction was performed in a micro-reactor with 10mm of internal diameter and a length of 50cm at 500ºC, atmospheric pressure, a weight hourly space velocity of 0.192 cm^3/g_{cat}*min and molar ratio water/ethanol = 3. The catalysts were reduced in-situ at 546ºC for 2h with a H_2 flow of 50cm^3/min. The composition of the reactor effluent was analyzed by two gas chromatographs Clarus 580 Perkin Elmer equipped with a capillary column, one with an FID detector and the other with a TCD detector.

3 Results and discussion

The use of ultrasound irradiation in the stage preceding the hydrothermal treatment resulted in a successful incorporation of Cerium in the mesoporous structure. The hexagonal arrangement of the materials is decreased as a consequence of isomorphic Cerium substitution, with an interplanar distance ranging from 4.59 to 5.11nm. Surface area decreases from 828 to

546m^2/gr and the pore sizes enlarges from 3.56 to 4.39nm. The proportion of isolated silanol (Q_3) and total silanol groups (Q_3+Q_2) decreases at higher Ce/Si molar ratios. Figure 1 shows the well-dispersed Ni species over the MCM-41 support. The presence of cerium promoted a reduced particle size, decreasing from an average of 18nm to smaller and better-dispersed particles with sizes of 5nm.

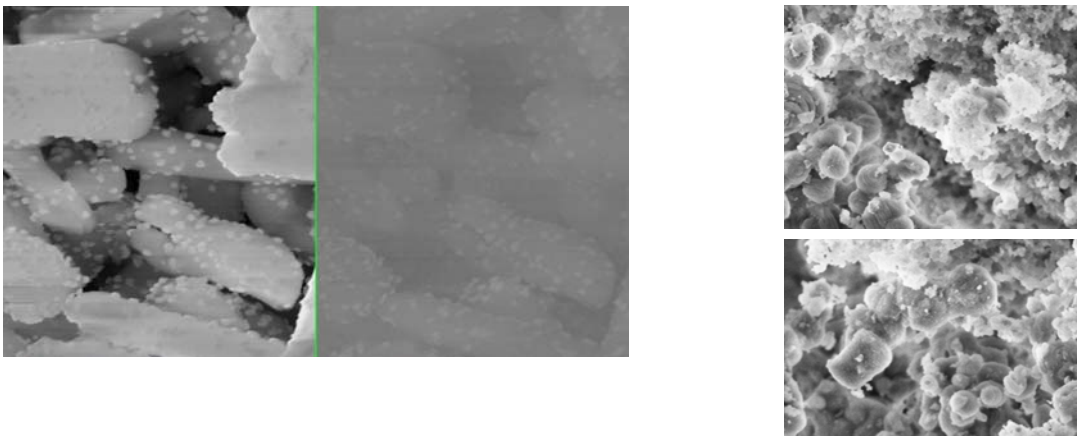

Figure 1 SEM Micrographs for 10%Ni/MCM-41: Left) Image obtained using the In-lens detector; Center) Z-contrast image acquired using the Backscattered Electron Diffraction; Right) 10%Ni/0.02CeMCM-41 catalyst (Bar length = 200nm, magnification 50kX)

When unmodified bare silica MCM-41 was used as catalytic support, the Ni/MCM-41 catalyst presented a markedly deactivation after 6h on stream, from 55% to a final value of 40% in ethanol conversion and correspondingly, hydrogen production dropped from 56% to 38%. While the composition values for CO, CH_4 and CO_2 (5, 2 and 15% respectively) remained constant, after 1.5h the Ni/MCM-41 catalyst presented formation of C_2H_4 and $C2H_4O$, which is associated to a decrease in H_2 production and coke formation by ethylene polymerization [3]. Although the production distribution was not dependant on Ce content, the CeMCM-41 proved to be a better support since the Ni/xCeMCM-41catalysts series are highly selective towards H_2, CO_2, CO and CH_4 as main gas products without ethylene formation. Complete conversion of ethanol was obtained for these catalysts during 6h on stream and no catalyst deactivation occurs.

4 Conclusions

Cerium modified mesoporous MCM-41 results in a better catalytic material for the ESR reaction compared to the support composed solely by silica since it promotes an enhanced dispersion and smaller particle size for a Ni active phase. Furthermore, the Cerium modified silica increases hydrogen production and constitutes a better catalytic support since no catalyst deactivation is evident after 6h on stream.

Keywords: membrane, hydrogen energy, palladium alloys, gas mixtures

1 Introduction

Due to the rapid progress of the hydrogen power engineering and a number of science intensive technologies, the demand for high-purity hydrogen (≥99.9999 vol %) is increased abruptly. Such high-purity hydrogen can be prepared only by its separation from hydrogen-containing gas mixtures via hydrogen diffusion through palladium-alloy membranes.

In the first place, the problem of production of commercial low-cost high-purity hydrogen requires the development of high-variety highly efficient membrane palladium-based alloys, which are intended for the preparation of efficient membrane elements for the separation of high-purity hydrogen from different hydrogen-containing gas mixtures.

Traditional palladium-silver membrane alloys cannot be used for the operation at high temperatures (773-973 K).

2 Experimental/methodology

The palladium alloys characterized by high strength, plasticity, and hydrogen permeability can be prepared via the alloying of palladium to form palladium-based solid solutions. The palladium-lead system is characterized by a wide palladium-based solid solution region (up to 20 wt % Pb). Palladium alloys with 5, 8, 12, 16, and 20 wt % Pd were prepared in the form of foils 50 μm thick by cold rolling with intermediate vacuum annealings, and their physical and mechanical properties and hydrogen permeability have been studied. Lead additions substantially strengthen palladium, whereas it plasticity decreases slightly. The hydrogen permeability was measured using an original technique, which is based on filling a calibrated volume with hydrogen, and a high-temperature cell. The Pd -8 wt % Pb alloy has the maximum specific hydrogen permeability among the Pd-Pb alloys. At 723 K, it is 2.6 $m^3 \cdot mm \cdot m^{-2} \cdot ч^{-1} \cdot MPa^{-0,5}$ and exceeds twice the hydrogen permeability of commercial B1 alloy (Pd-15 Ag-2,5 Au-0,7 Pt- 0,7 Ru-0,3 Al wt.%) at the same temperature [1].

The composition Pd - 8 wt.% Pb, which is characterized by the maximum hydrogen permeability and high strength characteristics, was selected for further studies.

Main problems of reliable operation of membranes for deep hydrogen purification and separation of gas mixtures are related to the corrosion resistance of membrane alloys, structural changes and degradation of their hydrogen permeability during operation in gas mixtures. The composition of gas mixtures affects both the possibility itself to separate high-purity hydrogen, performance, and life time.

Because of thermoconcentrational dilatation, the heating and cooling of membranes during their operation in gas mixtures are performed in vacuum or an inert atmosphere. We studied the effect of composition of synthetic gas for conversion of hydrocarbon fuels on the hydrogen permeability of Pd – 8 wt % Pb membrane, namely, on changes its hydrogen permeability during heating and cooling in one of components of conversion products, i.e., CO_2. The absence of structural changes and stable hydrogen permeability magnitudes show that the membrane can be heated to a temperature of ~300°C in the CO_2 atmosphere that subsequently changes to

operating gas mixture. This makes the membrane technology of high-purity hydrogen separation from gas mixtures of hydrocarbon fuel conversion simpler and cheaper.

3 Results and discussion

To efficiently apply the Pd-8 wt % Pb alloy in membrane elements, the alloy was evaluated for the most importance key parameter, namely, the corrosion resistance during operation in working mixture, which is identical to that of natural gas conversion, i.e., in the 60 vol % H_2 + 31 vol % CO_2 + 9 vol % CO gas mixture at temperatures of 573-773°K. It was showed that the hydrogen permeability of membrane remains unchanged, and the membrane is pressure-tight. To study the producing capacity of the Pd – 8wt%Pb membrane in the aforementioned mixture, membrane elements with membranes 50 mm in diameter and 50 μm thick have been prepared. The producing capacity (Q) of such a membrane element at $P_{input\ mix}$ = 2 MPa ($P_{H2\ part}$=1,5MPa), P_{output}=0,15 MPa, T = 773 Kand hydrogen separation ratio η = 0.8 is 0,25nm^3/h that exceeds the producing capacity of membrane element with the B1 alloy under the same conditions.

4 Conclusions

The Pd-8 wt % Pb composition is optimum and alloy shows promise for application in membrane elements for separation of high-purity hydrogen from products of the hydrocarbon fuel conversion.

Keywords: methanol electrooxidation, direct methanol fuel cell, platinum, nickel, polyol method

1 Introduction

Fuel cells powered by hydrogen or small organic molecules, e.g. methanol, may have the potential to meet requirements for energy sources with high efficiency and low emissions. Although Pt-based catalysts are still considered as optimal catalysts for fuel cell applications, substantial research has been conducted to improve them in terms of activity and stability. It was found, in particular, that adding a less noble element (Fe, Sn, Ni, Ru, etc.) can significantly improve catalyst resistance towards poisoning with intermediate CO. Two different mechanisms were proposed to be responsible for the performance enhancement. First, so-called bi-functional mechanism, explains decrease in poisoning by oxygen activation on the second metal (or its oxide). The second, electronic mechanism or ligand effect, assumes that the second metal can modify the electronic properties of Pt destabilizing the interaction between the CO molecules and the Pt surface and hence weakens the Pt−CO bonding.

In this study, we report on the preparation and comprehensive characterization of PtNi nanocatalysts supported on oxygen functionalized carbon nanotubes (FCNTs) by the polyol method in which ethylene glycol (EG) is used as solvent and reducing agent at the same time.

2 Experimental

PtNi catalysts with different Pt:Ni ratios (1:1, 2:1, 3:1, 3:2) were prepared by the polyol method. FCNTs support was mixed with required amount of metal salts (H_2PtCl_6, $Ni(NO_3)_2$) dissolved in ethylene glycol. The resulting slurry was stirred and sonicated and then split in two series for further treatment. Two essentially different approaches were used for metal ion reduction and later alloy formation. A first set of samples was refluxed in an oil bath at 160°C for 6 h after which it was allowed to cool down to room temperature under stirring and the solid product was centrifugated and washed and dried at 80°C. The resulting solid product was then heat treated in N_2 flow at 200 and 400°C. The second series was prepared using microwave (MW) radiation for metal reduction. The CNTs and metal salts containing slurry was transferred into a microwave reactor where it was irradiated at 700 W either continuously for a defined time or in a pulsed mode with pulse duration of 20 s (10 s on and 10 s off) for a specific number of pulses. The microwave step was followed by aging of the catalyst under stirring overnight. Two reference samples were prepared, one without aging and one with pH modification during the aging step by the addition of 250 mL of 0.1 M HNO_3.

All samples underwent a set of characterization techniques including inductively coupled plasma-optical emission spectrophotometry (ICP-OES) to determine bulk composition, X-ray diffraction (XRD), X-ray photoemission spectroscopy (XPS), Ion Scattering spectroscopy (ISS), X-ray absorption spectroscopy (XAS), Transmission Electron Microscopy (TEM), including state-of-the-art high resolution (HR) aberration-corrected TEM coupled with energy-dispersive X-ray-spectrometry (EDXS) for elemental mapping. The catalysts were tested toward methanol electrooxidation activity in 1M CH_3OH/0.5 M H_2SO_4 solution using cyclic voltammetry (CV) and

chronoamperometry. CO stripping was used to determine the electrochemical surface area (ECSA).

3 Results and discussion

Both XPS and XAFS studies reveal that the platinum state in the catalysts under study is metallic, with clear indications of alloy formation [1, 2]. However, besides metallic Ni significant Ni oxide contributions are also detected, and after heat treatment oxides are the only Ni species detectable by XPS. In accordance, XRD detects the presence of alloys with the degree of alloying decreasing, however not completely vanishing, after heat treatment. Oxidic species, however, are not detected by XRD. The XPS-derived near surface Pt:Ni atomic ratios, are considerably different from the bulk ones obtained by ICP-OES, indicating thus a PtNi alloy core surrounded by a Pt enriched shell with some Ni oxides present outside. The ISS depth profiles are in line with this conclusion, showing rapid drop of Pt signal comparing to Ni towards deeper sample layers. Further Pt segregation occurs during heat treatment and aggravated by stirring the catalyst in HNO_3.

Methanol electroxidation measurements with heat-treated catalysts have clearly shown their superior tolerance toward CO poisoning as well as higher activity comparing to industrial Pt/C (ETEK). In particular, for PtNi(2:1), PtNi(3:1) and PtNi(3:2) catalysts, the activities are close to each other, which is due to similar atomic Pt to Ni ratios of 3:1 as determined with ICP-OES analysis, with PtNi(3:1) providing the highest activity among all catalysts. Additionally, the mass specific activities (MSA) found by us [1] are higher than those reported in literature [3, 4]. Heat treatment at 200°C results in higher catalytic activity for most of the PtNi/FCNTs in terms of mass activity than the as prepared catalyst which can be attributed to a cleaning of the catalyst surface from adsorbed organic residuals. However, after treatment at 400°C the surface and mass specific activity decreases dramatically for all catalysts. This can be attributed to the catalyst restructuring upon heat treatment.

For the samples prepared using microwaves, the continuous mode of irradiation is more effective in preparing nanoparticle catalysts than the pulsed mode. In general, the optimized catalysts reported in this study showed higher MSA, up to 1.5 fold [2] than that obtained with PtNi catalysts with the same atomic ratio prepared by thermal post-treatment and also higher than the activity of PtNi catalysts reported recently by other groups.

4 Conclusions

PtNi/FCNTs with different Pt:Ni ratios have been prepared with ethylene glycol as reducing agent (polyol method). The catalysts display the Pt fcc structure with indications for alloy formation but also proofs for the presence of Ni oxides. A model based on the combination of advanced characterization techniques is suggested where Ni-rich phases form close to the FCNTs which are surrounded by a Pt-rich alloy. The highest catalytic activity was found for a Pt/Ni ratio of 3, which could be attributed to the availability and proper population of active Pt sites required for methanol adsorption and the easy removal of intermediate CO. Phase separation by heat treatment leads lower catalytic activity. For MW assisted catalyst preparation the irradiation mode influences both the metal loading and the activity of the prepared catalysts where catalysts prepared under continuous irradiation show higher electrocatalytic activity.

Keywords: Methane, oxidation, Mn-hexaaluminate, Pt-catalyst, Pd-catalyst

1 Introduction

Wide interest to the catalytic combustion chamber (CCC) of gas turbines [1,2] stimulates further researches on development of Pd-based catalysts with respect to decrease of the light-off temperature, increase of the efficiency in the hydrocarbon fuel combustion and thermal stability. Mn-hexaaluminates and aluminas modified by manganese cations have high thermal stability, sufficient specific surface area and high hydrocarbon oxidation reactivity and are considered both as catalysts for high-temperature combustion of natural gas, and as thermally stable supports for deposition of Pt-group metals [2-4]. We also observed a non-additive increase of the catalytic activity in the high-temperature oxidation of methane over Mn-alumina catalysts after their modification by Pd [5], resulting in a decrease of the light-off temperature. Here we studied an effect of Pt addition to improve the catalytic performance of the high-temperature Pd-Mn-hexaluminate in the oxidation of methane, especially in SO_2 and water presence, and compared them with the properties of Pd/Al_2O_3 catalysts. The redox properties, particle morphology, XRD-composition and active sites of the initial and spent PtPd-Mn-hexaluminates were examined in order to find a reason of high efficiency and thermal stability of the catalysts.

2 Experimental

The Mn-hexaaluminate catalyst with $MnLaAl_{11}O_{19}$ phase was prepared according to the procedure described elsewhere [5]. Its low-temperature precursor was doped with Pd and Pd by incipient wetness impregnation with chloropalladic/chloroplatinic acid or palladium/platinum nitrates followed by calcination at 1000°C. Pt+Pd content was 1.0 wt%, Pt/Pd atomic ratio was in a range 0.1-1.0.

The catalysts were tested in the methane oxidation at conditions typical to Small Gas Turbine Power Plants: 670°C and 10000 h^{-1}. Gas feed was 5 vol%CH_4, the coefficient of oxygen excess over the stoichiometric value was 3. After achievement of steady value of CH_4 conversion, 3 wt% H_2O and 1000 ppm SO_2 were introduced in the feed, CH_4 conversion was measured again. The composition, particles morphology and structures of active site in Pd- and Pt(Pd)-hexaaluminate catalysts were studied by XRD, H_2-TPR, O_2-TPR, FTIR, XPS, HRTEM.

3 Results and discussion

The Pt-doped Pd-Mn-hexaaluminate catalysts provided deep methane oxidation at 670°C and 10000 h^{-1} (Fig.1). At the same content of noble metals, substitution of part of Pd by Pt to the atomic ratio of Pt/Pd equal to 0.25-0.27 had no impact on the efficiency of methane oxidation, at a further increase of Pt fraction the tendency of a reduction of the methane oxidation efficiency was observed. The ex-nitrate catalysts were more active as compared with ex-chloride catalysts. Besides, for the ex-chloride samples the weak tendency to deactivation was observed eventually.

The presence of water vapor had a weak deactivating effect on the catalytic activity of

unmodified and Pd-modified Mn-hexaaluminate catalysts. The deactivating influence of water was amplified with sulfur dioxide addition to the air-fuel feed, so methane conversion in their presence decreased from 99% to 85-87% and 82-83% over Mn-hexaaluminate and Pd-Mn-hexaaluminate catalysts, respectively (Fig.1, c.1,2). The Pt-doped Pd-Mn-hexaaluminate catalyst with Pt/Pd=0.27 was the most stable to water vapor and sulfur dioxide (Fig.1, c.3). Note, that this catalyst was resistant to deactivation at lower temperatures also (500°C) at which high deactivation of PdO/Al_2O_3 is usually observed [6]. However, a further increase of Pt loading in the catalyst (to Pt/Pd=1.1) caused a decrease of its stability, so CH_4 conversion at 670°C falled from 99% to 90% and 30% after water and water with sulfur dioxide addition, respectively.

XRD and O_2-TPR study of the Pd-Mn-hexaaluminate and Pt-doped samples showed that the positive effect on the methane oxidation activity is due to increase in a PdO fraction and its high thermal stability (Fig.2). A PtPd-alloy formation, that was observed in spite of PdO by H_2-TPR, O_2-TPR, and XPS in the catalyst with Pt/Pd=0.27, well correlates with its high water tolerance. PdO is less stable in the presence of water in comparison with metallic Pd [6].

The FTIR absorption bands at 1145 and 1065 cm^{-1} confirmed sorption of sulfate-groups on the surface of the Mn-hexaaluminate samples. The sulfate content (thermogravimetric DTA) in them depended on the catalyst composition and increased as: $PtPd(0.27)/MnLa\text{-}Al_2O_3$ < $Pd/MnLa\text{-}Al_2O_3$ < $PtPd(1.1)/MnLa\text{-}Al_2O_3$ < $MnLa\text{-}Al_2O_3$. XRD and HRTEM indicated that structure of the aluminate phase in the spent samples does not change, interplanar distances characteristic for $MnLaAl_{11}O_{19}$ remain. EDX data showed there is sulfur which mainly settles down on large particles of aluminate phase while the sulfur is not present on Pd particles.

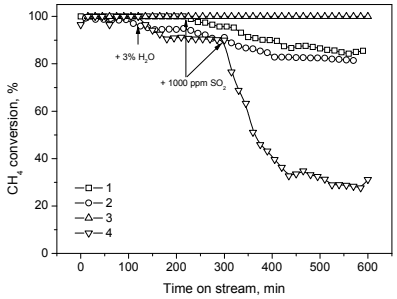

Fig. 1. Methane conversion over $MnLa\text{-}Al_2O_3$ (1), $Pd/MnLa\text{-}Al_2O_3$ (2), $PtPd(0.27)/MnLa\text{-}Al_2O_3$ (3); $PtPd(1.1)/MnLa\text{-}Al_2O_3$ (4) in water (3 wt%) and SO_2 (1000 ppm) presence. Temperature of the catalyst bed was 670°C and GHSV is 10000 h^{-1}.

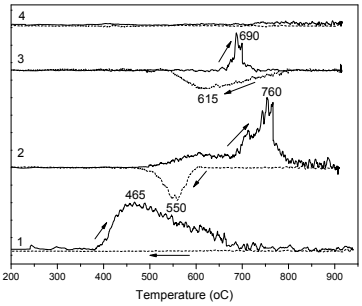

Fig. 2. Oxygen elimination and consumption during heating and cooling ramp of O_2-TPR with $MnLa\text{-}Al_2O_3$ (1), $Pd/MnLa\text{-}Al_2O_3$ (2), $PtPd(0.27)/MnLa\text{-}Al_2O_3$ (3); $PtPd(1.1)/MnLa\text{-}Al_2O_3$ (4).

4 Conclusions

The addition of Pt to Pd-Mn-hexaaluminate catalyst up to Pt/Pd ratio close to 0.25 improves its stability in the methane oxidation in water and sulfur dioxide presence without decreasing the high-temperature methane oxidation activity. Such performance of $PtPd(0.27)/MnLa\text{-}Al_2O_3$ can be explained by the formation of both PdO and PtPd-alloy in the catalyst.

Keywords: electrocatalysis, nickel, hydrogen evolution, biomimetic, cyclic, voltammetry

1 Introduction

The [FeFe]-hydrogenase enzyme can both produce and oxidize H2 at turnover frequencies of ≥9000 s^{-1}. Recent advances in Ni-based bio-inspired catalysts, such as [Ni(PR2NR'n)2]2+, demonstrated the possibility of cleaving H2 or generating H2 heterolytically with turnover frequencies comparable or superior to those of hydrogenase enzymes. In these catalysts the transformation between H2 and protons proceeds via an interplay between proton, hydride and electron transfer steps, and involves the interaction of a dihydrogen molecule with both a Ni(II) center and pendent amine bases incorporated in six-, seven or octa-membered rings, which function as proton relays. The catalysts with ligand 8-membered ring achieved the high electrocatalytic H2 production rates, up to 1540 s-1 in dry acetonitrile and up to 6700 s-1 in water-acetonitrile solutions with [(DMF)H]OTf acid as proton source.

2 Results and discussion

We report new data on the unexpectedly high activity of nickel complexes with 8-membered ring 1,5-diaza-3,7-diphosphacyclooctane ligands with the *ortho*-pyridyl substituents at the phosphorus atoms vs. phenyl with the same substituents at nitrogen (Scheme 1). These complexes demonstrate similar two reversible one-electron reductions, but have different electrocatalytic behavior in the presence of proton source [1-4]. We have observed a unique reactivity of pyridine-substituted analogue, its effectiveness exceeding that of all known relative complexes under the selected conditions. The introduction *o*-Py substituents at phosphorus as additional basic center is caused by the changing of voltage-current picture and significantly catalytic current enhancement. For example, TOFs being 100 and 15200 s^{-1} for benzhydryl substituents at nitrogen and Ph or o-Py at phosphorus respectively (Figure 1).

In situ EPR investigating of the Ni(I) state forming at the potential Ni(II/I) was performed for all nickel complexes. The formation of Ni(I) complex bound with four phosphorus atoms during the reduction of Ni(II) complexes was detected by ESR spectra in CH_3CN at room temperature under spectroelectrochemical conditions, g-factor values close to known literature values, for example for $Ni^{+1}(P^{Ph}_{2}N^{C6H4CH2P(O)(OEt)2}_{2})_{2}$ or $Ni^{+1}(P^{Ph}_{2}N^{Ph}_{2})_{2}$ [5-6]. The increasing ESR spectra intensity after temperature could be explained by formation of dimeric structure of NI(I) in CH3CN. This conclusions supported by DFT calculations.

7	R'=Ph	R=Ph(CH)Ph;
8	R'=Ph	R=Bn

Scheme 1. Studied nickel complexes.

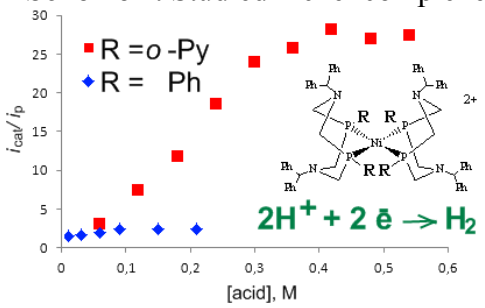

Figure 1. Plots of the i_{cat}/i_p vs. acid concentration for nickel complexes with Ph and o-Py substituents at phosphorus.

4 Conclusions

Thus, the new nickel catalysts with high catalytic hydrogen evolution rates in dry acetonitirile was obtained. Behavior and activity of catalysts were found to differ strongly for the complexes with Ph and *o*-Py substituents at the phosphorus atom at the same substituent at the nitrogen (Ph(CH)Ph). The introduction of *o*-Py substituent at the phosphorus atom causes significant TOFs increasing and changing the voltage-current picture in the acid presence. The different behavior of $[Ni(^{Po\text{-}Py}{}_2N^{Ph(CH)Ph}{}_2)_2]^{2+}$ in catalytic reaction caused by pre-protonation of *ortho*-pyridyl substituent in the acid presence.

Effect of CH_4 Flow Rate and Catalyst Load on the Activity Stability of Mo/HZSM-5 in the Methane Dehydroaromatization at 1073 K in an Integral, Fixed-Bed Reactor

Xu Y., Song Y., Suzuki Y., Zhang Z.-G.*

National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba-shi, Japan

* z.zhang@aist.go.jp

Keywords: methane, benzene, Mo/HZSM-5 catalyst, catalyst load, CH_4 flow rate

1 Introduction

The worldwide shale-gas revolution and the increasing benzene demand in chemical industry are expected to motivate more R&D activities on the Mo/HZSM-5-catalyzed non-oxidative methane dehydroaromatization. Case studies have suggested this reaction should be operated at temperatures not lower than 1073 K and a CH_4 space velocity as high as possible to gain a performance-acceptable CH_4 conversion and a high hourly benzene formation yield simultaneously. Since the space velocity here is not a simple variable but a combined value by dividing a given CH_4 flow rate with a given catalyst load, there is a need to clarify which of these two operating factors is more crucial for maximizing the catalytic performance of the catalyst. For the reaction, the aromatics formation rate is most likely limited by mass transfer, and the secondary coke reactions of products could occur in the upper part of the catalyst bed to speed up the catalyst deactivation there and lower the catalytic efficiency of the whole bed [1,2]. This suggests there must exists a suitable combination of CH_4 feed rate and catalyst load (bed height) for the system to reach its maximum performance. Additionally, knowing limitations on both catalyst load and superficial gas rate is also essential for design of real reactors.

2 Experimental

A certain amount of fluidizable 6%Mo/HZSM-5 catalyst sample ranging from 50 mg to 1600 mg was charged into an up-flow fixed bed reactor (i.d. 8 mm) for each test. The sample was carburized in-situ in a CH_4 stream at 923 K for a pre-determined period. Subsequently, the carburized catalyst was heated to 1073 K in a H_2 stream and kept there for 5~80 min to remove most of the coke accumulated in the carburization period. Finally at the same temperature the catalyst was subjected to a CH_4 flow of 13.7~90 mL/min to start the reaction. The reaction last until the sample lost all its benzene formation activity. CH_4 conversion and the benzene concentration in the reacted stream were measured on-line using two gas chromatographs.

3 Results and discussion

Fig. 1 shows the effect of catalyst load on the time-dependence of the formation rate of aromatics at 1073 K for four different CH_4 flow rates. At each CH_4 flow rate, the catalyst lifetime for aromatic formation increases with increasing the catalyst load. This can be a consequence of the increase of active sites in the bed. However, the obvious increase in the liftime aromatics yield only ocuured in a low range of catalyst load at each CH_4 feed rate. As the catalyst load exceeds a cretain level the lifetime aromatics yield slows down its increasing pace and approaches to a fixed level. This suggests that there exists a proper catalyst load for a given CH_4 feed rate to maximize the catalytic effciency of the test catalyst and the overloaded part would not play their catalytic role in the conversion of methane to aromatics. The data in Fig. 2 provide further support for this.

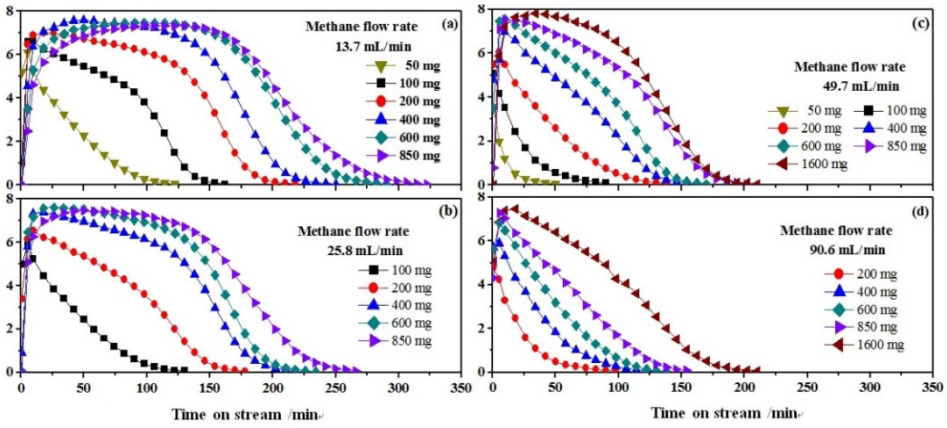

Fig. 1 Effect of catalyst load on the aromatic formation rate obtained over Mo/HZSM-5 catalyst at 1073 K.

As shown in Fig. 3, the four tests were conducted at the four different CH_4 space velocities from 6400 to 8220 mL/g/h, which were realized by reducing both CH_4 flow rate and catalyst load simultaneously. The catalyst stability does decrease, not increase with decreasing CH_4 space velocity. This is against our anticipation. It suggests that rather than catalyst load the superficial gas flow rate might be more crucial for maintaining the activity stability. While a lowered gas feed leads surely to a lower hourly aromatics production, a too high CH_4 flow rate could result in preferential coke formation in the near-surface layers of catalyst particles and/or of crystal agglomerates inside the particles [2] and speed up the catalyst deactivation. Therefore, there must exists a suitable combination of CH_4 feed rate and catalyst load (bed height) for the system to reach its maximum performance. As for the height of catalyst bed, as it is increased, catalyst particles in the upper portion of the bed might be severely deactivated prior to playing their catalytic role for more rapid coke formation originated from the decomposition of C2 species coming from the bottom portion of the bed. TG measurements of four spent samples (850 mg) collected after the reaction confirmed that the amount of coke formed in the bottom of catalyst bed was the largest and that in the upper of catalyst bed was the smallest.

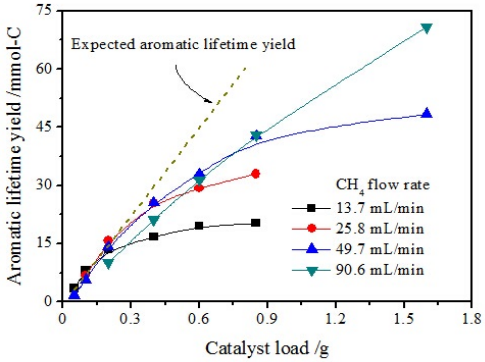

Fig.2 Effects of CH_4 flow rate and catalyst load on benzene lifetime yield over Mo/HZSM-5 catalyst at 1073 K.

Keywords: carbonaceous supports, Pt-Sn catalysts, direct methanol fuel cell

1 Introduction

Low temperature Direct Alcohol Fuel Cells (DAFCs) are extremely attractive as power sources for transportation, mobile and portable applications [1]. Methanol oxidation has been reported to involve the adsorption of CH_3OH followed by successive dehydrogenation steps, yielding linearly bonded CO. At sufficiently anodic potentials, the adsorbed carbon monoxide CO_{ads}, is belived to react with an adsorbed OH_{ads} intermediate. In general, it has been shown that pure Pt systems are not efficient catalysts for the oxidation of methanol because Pt is rapidly poisoned by the CO species produced as oxidation intermediates. For this reason, the modification of Pt electrode with other metals including Ru, Sn, Mo and Sb has been investigated extensively [2].

2 Experimental/methodology

The used supports were Vulcan carbon (VC) and multiple-wall carbon nanotubes (NT). The metallic precursors were $H_2PtCl_6.6H_2O$ and $SnCl_2.2H_2O$. Catalysts were prepared by deposition-reduction technique in liquid phase (called RB) using $NaBH_4$ as reducing agent. The catalysts were characterized by: temperature programmed reduction (TPR), X-ray photoelectron spectroscopy (XPS), H_2 chemisorption, benzene hydrogenation reaction, transmission electron microscopy (TEM), CO stripping, chronoamperometry measurements and finally tested in a DMFC cell.

3 Results and discussion

TPR profiles of Pt-Sn catalysts prepared by deposition-reduction in liquid phase by sodium borohydride and supported on VC and NT do not show practically any reduction peak in the zone where Pt is reduced in the impregnated catalysts (at about 230ºC). This would indicate that the major fraction of Pt would be in metallic state (Pt^0). However, nothing can be said about the reducibility state of Sn.

In order to find more information about the Pt and Sn reducibilities of the bimetallic catalysts supported on VC and NT, a XPS characterization was done. In each case, the concentration of the Pt surface oxidized species was lower than 35%, this meaning that most of Pt surface species (>65%) are in metallic state. XPS of Sn3d shows that Sn forms oxidized species and only a small proportion of Sn^0 (10-15%) was found, this small metallic fraction perhaps forming alloys with metallic Pt.

The bimetallic catalyst supported on VC showed chemisorption values higher than those of the corresponding monometallic catalyst, the similar catalyst supported on NT showed similar values to the corresponding monometallic one.

Benzene hydrogenation is a structure-insensitive reaction, which can be carried out one active metallic site. The activation energy value of the Pt-Sn catalyst is higher than the corresponding monometallic one only in the case of the series supported on VC. This would indicate that electronic effects are more important in the Pt-Sn/VC catalyst.

The cyclic voltammograms of CO stripping corresponding to mono and bimetallic catalysts

supported on VC and NT shows an important promoting effect (the beginning of the CO oxidation is shifted to lower potentials) of Sn over Pt. It can be observed that the Pt-Sn catalyst supported on VC does not modify these values of electrochemically active specific surface (EASS) with respect to Pt/VC one, while the EASS values for bimetallic catalyst supported on NT show a decrease that would be caused by the geometric effect of Sn over active Pt sites.

Electrocatalysts were also tested in a real cell fed with methanol. When tested in the DMFC, these Pt-Sn catalysts supported on VC and NT gave a better power density than a commercial one only at low current densities (Figure 1).

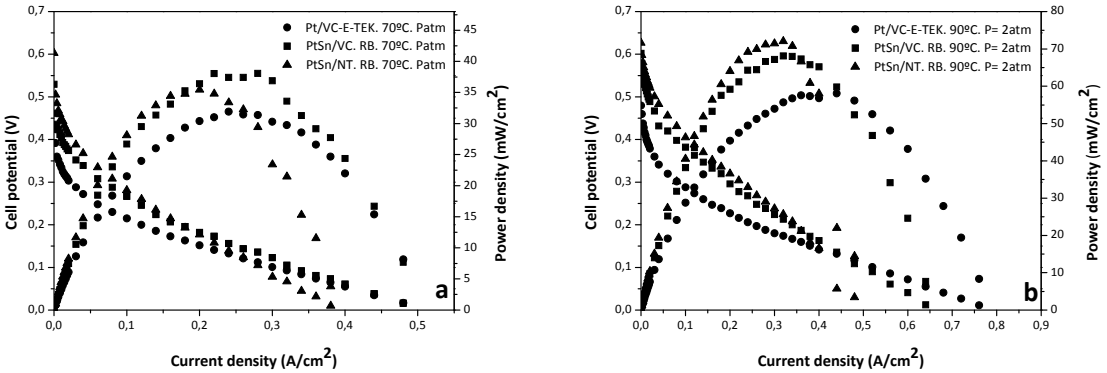

Fig. 1. Polarization and current density curves in a DMFC for Pt-Sn/VC. RB and Pt-Sn/NT. RB anodic catalysts compared to commercial Pt/VC (E-TEK 20 %wt) catalyst. As cathodic catalyst it was used a Pt/VC (E-TEK 30 %wt) one. a) 70 ºC, 1atm O_2 pressure, b) 90 ºC, 2 atm O_2 pressure. 2M methanol solution. The Pt loading was 1 mg cm^{-2} for both the anode and cathode.

Finally, Pt-Sn catalysts prepared on VC and NT were characterized by TEM showing that the presence of Sn modifies Pt during the deposition-reduction with $NaBH_4$, reducing the particle size and leading to a narrow particle size distribution than the corresponding monometallic catalysts supported on VC and NT.

4 Conclusions

The liquid phase deposition-reduction method with $NaBH_4$ (RB) to prepare bimetallic Pt-Sn catalysts gives a good Pt reducibility, and shows the presence of oxidized Sn species. A small fraction of the second metal (10-15%) stays in zerovalent state probably forming alloys.

For VC and NT as supports, it was found a low Pt-second metal electronic interaction but an important geometric effect that causes the promoting effect of Sn over Pt.

As Sn is found in the vicinity of small Pt particles, it produces an important promoting effect that makes CO electrochemical oxidation easier since it shifts the onset potential to lower values.

When tested in a DMFC, these Pt-Sn catalysts supported on VC and NT gave a better power density than a commercial one only at low current densities.

Keywords: hydrotreating, heteropolyanion, NiMoWS, HDS, HYD, HDN

1 Introduction

It is a world-wide tendency that more stringent environmental regulations require the production of higher quality fuels with lower sulfur concentration. The challenge is now to develop more active HDS catalysts for the ''deep refining'' of petroleum feedstocks to meet the new strict standards. Traditionally, bimetallic sulfide catalysts based on Mo or W, promoted by Ni or/and Co and supported on Al_2O_3 are used in the HDS processes. These catalysts exhibit high activity in removing sulfur from thiophene, benzothiophene, and some non-refractory dibenzothiophenes compounds. However, their activity is very low in removing sulfur from 4,6-dibenzothiophenes. Taking into account the specificity of the Mo and W based catalysts, the development of mixed Mo/W transition metal sulfides based catalysts can yield more efficient catalysts. The aim of the work was the preparation and characterization of alumina supported mixed SiW_nMo_{12-n} heteropolyanions (HPAs). For comparison purposes, catalysts based on separate $SiMo_{12}$HPA and SiW_{12}HPA were also prepared and studied.

2 Experimental

$H_4[SiMo_1W_{11}O_{40}]$ and $H_4[SiMo_3W_9O_{40}]$ HPAs were synthesized. Elemental composition and XRD determination confirmed their preparation. Catalysts with the same surface density of metals - d(Mo+W) expressed by $at.nm^{-2}$ - were synthesized by the incipient wetness method via impregnation of the supports with aqueous solutions containing the required amounts of $SiMo_{12}$HPA, SiW_{12}HPA, $SiW_{11}Mo_1$HPA, SiW_9Mo_3HPA, Ni carbonate and citric acid with molar ratio Ni/(W+Mo) = 0.5 and citric acid/Ni = 1.5/1 for promoted series. All impregnated solids were aged at room temperature overnight and subsequently air-dried at 110 ºC for 10 h without any further calcination. Chemical composition of the Ni promoted catalysts is shown in Table 1.

Table 1. Chemical composition of prepared catalysts

Catalyst	MoO_3, /wt. %	WO_3, /wt.%	NiO, /wt. %	d(Mo), /at.nm $^{-2}$	d(W), /at.nm $^{-2}$	d(Mo+W), /at.nm $^{-2}$
Ni-$SiMo_{12}$HPA/Al_2O_3	18.0	-	4.7	4.2	-	4.2
Ni-SiW_{12}HPA/Al_2O_3	-	26.2	4.2	-	4.2	4.2
Ni-$SiW_{11}Mo_1$HPA/Al_2O_3	1.4	24.2	4.3	0.4	3.9	4.2
Ni-SiW_9Mo_3HPA/Al_2O_3	4.2	20.1	4.3	1.1	3.2	4.2
Ni-$SiMo_{12}$HPA+SiW_{12}HPA/Al_2O_3 (a)	1.4	24.2	4.3	0.4	3.9	4.2
Ni-$SiMo_{12}$HPA+SiW_{12}HPA/Al_2O_3 (b)	4.2	20.1	4.3	1.1	3.2	4.2

[a] catalyst was prepared using co-impregnating solution of $SiMo_{12}$HPA and SiW_{12}HPA with molar W/Mo ratio 11/1,
[b] catalyst was prepared using co-impregnating solution of $SiMo_{12}$HPA and SiW_{12}HPA with molar W/Mo ratio 9/3.

The prepared samples were characterized by IR, Raman spectroscopies as well as by N_2 adsorption and H_2-TPR methods. The hydrotreatment activities were measured on a model feed (1000 ppm of sulfur, 3 wt. %. of naphthalene, 0.46 wt. % of quinoline and toluene as a solvent) in a bench-scale flow reactor under pressure of hydrogen. Before testing, the catalysts were activated by sulphidation. A mixture of DMDS (2 wt. % of **S**) and decane at 3.5 MPa was used in a stepwise procedure conducted over 10 h at 240 ºC and 8 h at 340 ºC. The conditions of the tests were the following: temperature 280^0C; pressure 3.0 MPa; feed space velocity 40 and 80 h^{-1}; a H_2 feedstock ratio 500 NL/L; catalysts volume 0.3 cm^3. The liquid product compositions of the samples collected every 0.5 h were determined using a GCMS-QP2010 Ultra. The HDS reaction was allowed to proceed for 10 h to evaluate the deactivation of the catalyst. To evaluate the catalytic performances, rate constants of the DBT HDS, naphthalene HYD and quinoline HDN reactions were determined [1]**.**

3 Results and discussion

Table 2 shows the hydrotreating results for the mixture of DBT, naphthalene and quinoline over the prepared samples.

Table 2. Performances of the catalysts in hydrotreating of DBT, naphthalene and quinoline

Catalyst	Conversion (%)						Rate constants ($\times 10^{-4}$ mol h^{-1} g^{-1})		
	DBT HDS		Naphthalene HYD		Quinoline HDN [a]				
	LHSV, h^{-1}						k_{HDS}	k_{HYD}	k_{HDN}
	40	80	40	80	40	80			
Ni-$SiMo_{12}HPA/Al_2O_3$	68	43	0.5	1	10	0.5	28	2	1
Ni-$SiW_{12}HPA/Al_2O_3$	65	44	14	10	3	1	27	12	2
Ni-$SiW_{11}Mo_1HPA/Al_2O_3$	78	53	14.2	7.9	3	4	37	19	3
Ni-SiW_9Mo_3HPA/Al_2O_3	72	48	8	10	2	2	31	9	2
Ni-$SiMo_{12}HPA$+$SiW_{12}HPA/Al_2O_3$	70	44	7	5	15	12	29	11	4
Ni-$SiMo_{12}HPA$+ $SiW_{12}HPA/Al_2O_3$	60	36	4	2	8.5	1.8	22	5	1

[a] conversion of quinoline and its N-containing products.

The conversion of all substrates during the tests varied from 0.5 to 78%. Conversions of reactants depending on the reaction type increased in the order HDN < HYD < HDS that correlated with the reactivity of the chosen compounds. It appeared that Ni-$SiW_{11}Mo_1HPA/Al_2O_3$ catalyst was the most active in all studied reactions. Ni-SiW_9Mo_3HPA/Al_2O_3 catalyst presented also interesting HDS activity but with lower hydrogenating property. Comparison of catalysts with same metal contents prepared with mixed $SiMo_nW_{12-n}HPAs$ and with the two separate HPAs ($SiMo_{12}HPA$ and $SiW_{12}HPA$) with the same metal content allowed us to conclude that the close interaction of both metal in the mixed HPA precursor is at the origin of the catalytic improvement.

4 Conclusions

It was found that the use of mixed $SiW_nMo_{12-n}HPAs$ as starting precursor yield high-efficient ternary transition metal sulfide HDT catalysts. This can originate from the close presence of both metals in the active sulfide phase as H_2-TPR results evidenced a modification of the metal oxides reduction. HRTEM are now in progress in order to evidence any change in the morphology of the sulfide active phase.

Keywords: diffusion, welding, palladium alloy foil, construction, materials, membrane element

1 Introduction

Due to rapid development of hydrogen power engineering and science intensive technologies there is a growing demand in use of high-purity hydrogen that puts a question about creation of effective, reliable and inexpensive industrial membrane elements and modules for its extraction and purification

2 Experimental/methodology

Comparative analysis of membrane elements designs showed that a construction of membrane filtering elements developed by us is the most perspective for industrial use. In our design flat membranes in the form of 50-150 mm diameter disks made out of palladium alloy foil of depth 50 – 10 micron. Due to membrane element flat design there is significant decrease of quantity of joints between membrane and constructions elements, it is important as joint leaktightness is one of the main problems of creating reliable membrane elements with increased operation life [1].

For extraction of high-purity hydrogen we have considered technology peculiarities of palladium filters production. Filter element consists of two walls, separating element and a branch pipe for removal of pure hydrogen. The wall represents a framework made of stainless steel with membrane made of palladium alloy. For fastening a membrane to framework were used technologies of soldering and welding by fusion, however such methods are labor-intensive and low-output.

Technology of the diffusion welding is the most appropriate method to obtain a joint of high quality which meets the above-mentioned requirements. Soldering technology requires a complex fitting; due to flowing of solder the last one may appear on the palladium foil and it can not be allowed; besides the whole process itself is hardly efficient. Fusion welding (argon-arc welding, laser welding and etc.) cannot be used by reason of appearing fragile phases of $FePd_3$ in welded joint, which reduce the strength of joint, due to joint melting of steel 12X18H10T and palladium.

By using an intermediate layer made of chrome-nickel alloy the quality will be slightly improved. Besides, fusion welding for this product is also hardly efficient process.

3 Results and discussion

Diffusion welding technology provides a full-strength and tight joint of membrane with framework and it is the most optimal. For this purpose an intermediate layer made of nickel is put between membrane and framework to exclude a formation of fragile phases in welding zone and to intensify a process of diffusion mass exchange between connected materials. Diffusion

welding optimal parameters: temperature T= 950^{o}C, welding pressure P= 2 kilogram-force /mm^{2}, release time - 30 min. Process is implemented in vacuum. Yield (hermetically sealed wall on helium) with welding of stainless steel framework (thickness 0.5 mm) and palladium alloy foil (thickness 30 micron) is up to 85%.

4 Conclusions

The use of diffusion welding in the manufacture of palladium filters allowed to make a vacuum-tight full-strength connection of stainless steel with foil of palladium alloys and manufacture helium sealed wall of the membrane element with prospective to its use in industrial scale to produce high-purity hydrogen need for which has been growing steadily.

Keywords: water splitting, electrocatalysis, sacrificial, agent, manganese

1 Introduction

The growing political will behind an energy transition towards renewable energy sources (RES) is highlighting the need for efficient and economically viable energy storage solutions. For hydrogen production through water splitting, good electrocatalysts are needed for the anodic oxygen evolution reaction (OER), where most of the overpotentials limiting the process efficiency occur. PEM-electrolyzers require acidic conditions and so far only expensive Ir-based OER-catalysts are stably active under these conditions. Thus, activity and stability enhancement of earth-abundant OER-catalysts like Mn or Fe would be a major step towards making water splitting a commercially relevant energy storage solution. In this regard, El-Monein et al. have reported a significant activity and stability enhancement in electrodeposited Mn/Sn-mixed oxides.[1] SnO_2-based anodes are known for their high corrosion resistance in acidic conditions[2], which make Mn/Sn mixed oxides promising candidates for low-cost and efficient OER-electrocatalysts.

We report a facile co-precipitation synthesis for Mn/Sn-precursors. After calcination, the precursors form active Mn-based OER-catalysts supported on tin oxide. OER-activities were assessed via detection of O_2-evolution in a standard sacrificial agent test. OER-tests using $(NH_4)_2Ce^{IV}(NO_3)_6$ as sacrificial agent have been proven to be suitable mimics of real water oxidation.[3] We show that Mn-specific OER-activity strongly depends on Mn/Sn-ratios and that with increasing tin content, the OER-activity could be preserved over increasing calcination temperatures. This indicates that the active OER-sites of Mn-oxides are preserved in the presence of tin. Also, temperature programmed reduction (TPR) experiments confirmed that low-temperature reduction features correlating with higher activity are preserved over calcination in tin-rich samples. As resistance against thermal decomposition is usually correlated with corrosion resistance, Mn/Sn-systems are promising candidates for water oxidation catalysis.

2 Experimental/methodology

Samples are produced via -co-precipitation at constant pH in an automated Labmax reactor system (Mettler-Toledo). A $KMnO_4/SnCl_4$-solution is constantly added to a Mn(II)-nitrate solution, while the pH is maintained neutral via the controlled addition of base. After washing and drying, samples are calcined at temperatures ranging from 300 to 700 °C. Characterization was performed using standard techniques available at FHI like XRD, BET, SEM-EDX, XRF and TG-MS. Sample were thoroughly studied by TPR experiments. OER-activity assessment was performed in a liquid batch reactor using cerium ammonium nitrate (CAN) as a sacrificial electron acceptor in solutions of pH below 1. The air-tight reactor was kept under constant Ar-stream and outlet gas were analysed via mass spectrometry in order to detect oxygen evolution. Initial rates were used as an element of comparison between the samples.

3 Results and discussion

The products of the co-precipitation synthesis are amorphous, highly hydrated Mn/Sn-hydroxides. TG-MS shows that upon calcination to 300 °C, samples loose up to 10% in mass due to water and hydroxyl group removal. At 300 and 400 °C, no XRD-patterns can be distinguished, except for broad features attributed to SnO_2. At 500/600 °C, for Mn-contents above 67%, clear crystallisation of an α-MnO_2 is observed via XRD. SEM-EDX shows the concomitant appearance of segregated Mn-rods, characteristic for the α-polymorph of MnO_2 (Fig. 2). Below 67% of Mn, the Mn-phase remains XRD-amorphous up to 700 °C.

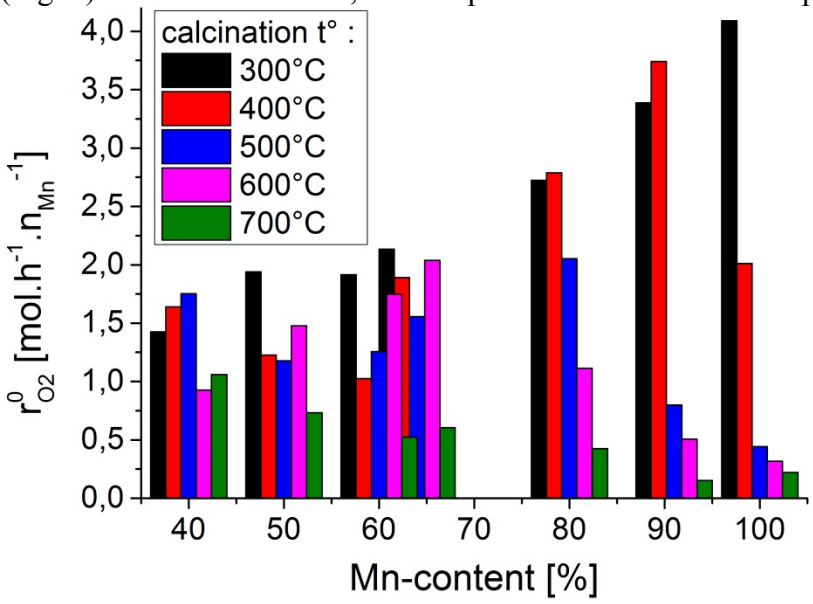

Fig. 1. Initial O_2-evolution rates for Mn/Sn OER-catalysts with varying Mn/Sn ratios and calcination temperatures with respect to the Mn-content

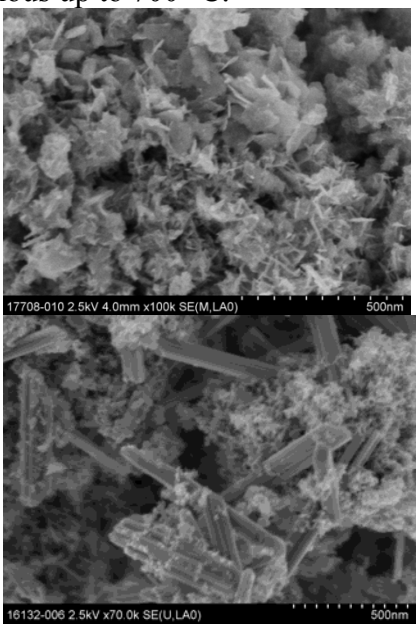

Fig. 2. SEM-image of 80%-MnO_x/SnO_2 calcined at 400°C (top) and 600°C (bottom)

Even though α-MnO_2 is sometimes reported as the most active MnO_2-polymorph, its appearance at 500 °C for samples with high Mn-content correlates with a sharp loss of activity (see Fig. 1). The XRD-amorphous Mn-phase obtained below 400 °C was identified as the active phase. Higher stability towards thermal decomposition is achieved by increasing Sn-contents. This behaviour correlates with low-temperature reduction profiles attributed to Mn-oxides in TPR and that are still observed after higher calcination temperatures in Sn-rich samples. First tests using repeated sacrificial agent injections indicate that the thermal resistance correlates with resilience against corrosion.

4 Conclusions

We conclude that for Sn-loadings above 33% there exists a synergetic effect of Mn- and Sn-oxides, that stabilizes the active OER-sites of an amorphous Mn-oxyhydroxide towards thermal decomposition. First tests suggest that this synergy correlates with resilience against corrosion. Thus Mn/Sn-based OER-catalysts are promising candidates for OER-electrocatalysis.

Keywords: hydroprocessing, heteropolyanion, NiWS, ULSD, HDS, HDN

1 Introduction

Production of clean fuels with less than 10 ppm sulphur content is one of the most important and claiming the attention problem in recent petroleum refinery. In years to come, hydrotreating will remain the largest scale process of petroleum refining, and its role will continue to grow. This trend requires more active catalysts, thus spurring intensive research both in industry and academia.

It is known that carbon as a support is reportedly preferable to alumina because of its high surface area and low acidity. However, carbon supports have a significant disadvantage: their low packing density, which limits their application in commercial hydrotreating catalyst formulations. The objective of this work was to investigate the co-effect of 12-tungstophosphoric heteropolyacid (HPA), nickel citrate and carbon-coated alumina (CCA) in preparation of NiW catalysts for HDS, HYD and HDN reactions. The HDS of dibenzothiophene (DBT), HYD of naphthalene and HDN of quinoline were the reactions selected to evaluate the catalytic properties of the materials. The results of this study should provide a better understanding the W based catalysts' structure and their HDS, HYD and HDN performances.

2 Experimental

A synthesis of CCA supports was carried out by the pyrolysis of a mixture of *iso*-propanol with glycerin on alumina in a bench-scale flow reactor at 600 ºC in N_2 atmosphere. The Ni_6-$PW_{12}S/C_x/Al_2O_3$ catalysts were prepared by the incipient wetness technique via impregnating the support with aqueous solutions containing the required amounts of $H_3PW_{12}O_{40}\times 3H_2O$, $NiCO_3$ and citric acid with molar ratio citric acid/Ni = 1.5/1. All impregnated solids were aged at room temperature overnight and subsequently air-dried at 110 ºC for 10 h without calcination. The contents of W and Ni in the catalysts were 15 and 3.9 wt. %, respectively.

The prepared samples were studied by N_2 adsorption, Raman spectroscopy, XRD, H_2-TPR, HRTEM and XPS methods. Catalysts were tested in a hydrotreating of model feed (1000 ppm of sulfur, 3 wt. %. of naphthalene, 0.46 wt. % of quinoline and toluene as a solvent) in a bench-scale flow reactor under pressure of hydrogen. The conditions of the tests were the following: temperature 280^0C; pressure 3.0 MPa; feed space velocity 40 and 80 h^{-1}; a hydrogen : feedstock ratio 500 NL/L; catalysts volume – 0.3 cm^3.

3 Results and discussion

Using the CCA as supports of the Ni_6-$PW_{12}S/C_x/Al_2O_3$ catalysts altered the morphology and structure of the NiWS active phase. With the rise of carbon content in the CCA up to 5 wt. %, reducible reactivity, sulphidation degree, average length and stacking number of $NiWS_2$

crystallites in the catalysts increased. Observed changes can be explained by weakening interaction between metal oxide species and carbon-coated support. Therefore, covering alumina surface by coke is beneficial to tuning the metal-support interactions, which causes easier reduction of tungsten. This property allows the CCA supported catalysts to be deeper sulphided compared with the Ni_6-$PW_{12}S/Al_2O_3$ reference.

The increase of carbon content led to the rise of the average slab length and the average stacking number of the $NiWS_2$ crystallites from 4.4 to 5.6 nm and from 1.7 to 2.3, respectively. It was shown that the increase of carbon content in the CCA allowed to essentially increase the Ni content in NiWS phase, that led to producing of high-effective catalysts. Full promotion of NiWS edges by nickel was achieved in the catalysts supported on CCA with carbon content equal 0.3 wt. % and more. Activities of the catalysts in DBT HDS, naphthalene HYD and quinoline HDN were essentially depended on the carbon content in the CCA-support (**Fig. 1**).

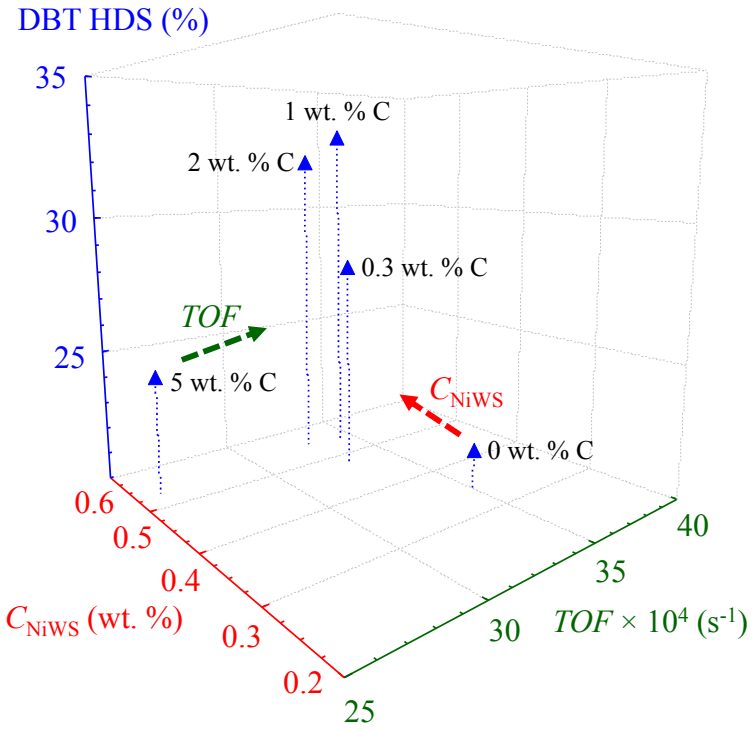

Fig. 1. 3D dependence of DBT conversion in HDS on effective Ni content in NiWS phase and TOF number for Ni_6-$PW_{12}S/C_x/Al_2O_3$ catalysts (legends at markers correspond to the carbon content in the CCA). Dotted lines show the ways of increasing DBT conversion.

Ni_6-$PW_{12}S/C_1/Al_2O_3$ catalyst showed maximal conversions of the substrates in studied reactions. This result achieved due to an optimal balance between TOF value of the active sites and their content.

4 Conclusions

Comparing the active phase morphology, the $(Ni/W)_{edge}$ ratio and catalytic properties of the Ni_6-$PW_{12}S/C_x/Al_2O_3$ catalysts it was found that TOF numbers in HDS, HYD and HDN linearly increased with the decrease of both the average length of the species of the active phase and the $(Ni/W)_{edge}$ ratio. Further improvements of supported NiW catalysts may be achieved by increasing the dispersion of the active phase species and optimizing the $(Ni/W)_{edge}$ ratio.

Keywords: CO_2 reduction, carbon catalysts, non-noble metals, metal nano-particle (NP), renewable fuels

1 Introduction

The continuous rise in the global energy need, falling fossil fuel reserves and the drastic rise in CO_2 levels in the atmosphere creates a great opportunity towards the research for production of renewable fuels 0. This is high time that we take up this problem and develop a viable long term solution and start repairing the damage already caused to a balanced cycle. As a tiny contribution towards renewable carbon fuels, we report on the non-noble metal loaded carbon based electro-catalytic reduction of CO_2 for the production of liquid fuels under gas and liquid phase conditions 0. The experiments were performed in different homemade electro-catalytic (EC) cells for gas and liquid phases, designed on purpose to maximize the electro-catalytic area and reduce the volume of the aqueous solution. Initially, experiments were conducted using Cu thin film electrodes. Then, metal nano-particle (NP) based catalysts (using Fe, Cu, Co deposited on carbon-based substrates) were synthesized in order to improve the productivity and fine tune the selectivity in achieving longer chain hydrocarbon fuels. NMR analysis is used to determine the fuel productivities and also a comparative study with gas phase results was carried out.

2 Experimental

Preparation of metal-doped carbon layer

Carbon black (Vulcan XC-72) and commercial Carbon Nano-tubes (cup-stacked CNT from Pyrograph Inc, PR-24XT) were used as starting material for the synthesis of the electro-catalysts. Different types of oxygen functionalities were generated by suspending 1 g of carbon black/CNT in 50 mL HNO_3 (65 % Sigma Aldrich) and treated in reflux at 100 °C for 3 h, followed by rinsing to neutral pH, filtering, and drying overnight.

Then, metal NPs (Fe Cu and Co) were deposited on carbon black and CNTs by incipient wetness impregnation methodology using an ethanolic solution containing the appropriate metal precursor, $Fe(NO_3)_3{\cdot}9H_2O$, $Cu(NO_3)_2{\cdot}3H_2O$ and $Co(NO_3)_2{\cdot}6H_2O$, respectively. After drying at 60 °C for 24 h, the samples were annealed for 2 h at 350 °C. The total amount of metal loaded onto the carbon black and CNT surface was 10 wt. %. It is a good comparison to that of the metal loading used in the electro-catalysts for PEM fuel cells (usually 10-20 wt. %), which corresponds to a metal loading in the final catalyst of about 0.5 mg/cm^2.

Finally, an ethanol suspension of functionalized carbon black/CNT impregnated with metal NPs was deposited on a commercial gas diffusion layer (SIGRACET GDL 25BC, supplied by SGL Group) based on carbon fibres. To complete a working electrode, a Nafion membrane is attached with active phase (direct contact for Gas phase/ indirect for Liquid phase). The goal is to obtain C-based nanostructured electrode which can be assembled to form a multilayered composite with good proton mobility and electron conductivity and also, an improved fuel

production efficiency.

3 Results and discussion

The multi-electron processes underlying the CO_2 electrochemical reduction can lead to a large variety of products ranging from CO to various oxygenates such as alcohols, aldehydes and carboxylic acids by a complex multistep mechanism that is probably quite different comparing gas and liquid phase conditions.

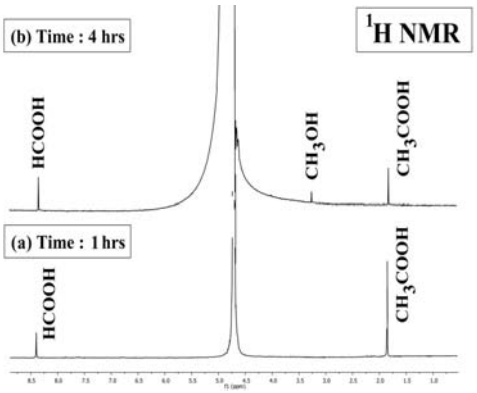

Fig. 1: NMR spectra for Fe/C showing products at times 1hr & 4 hr.

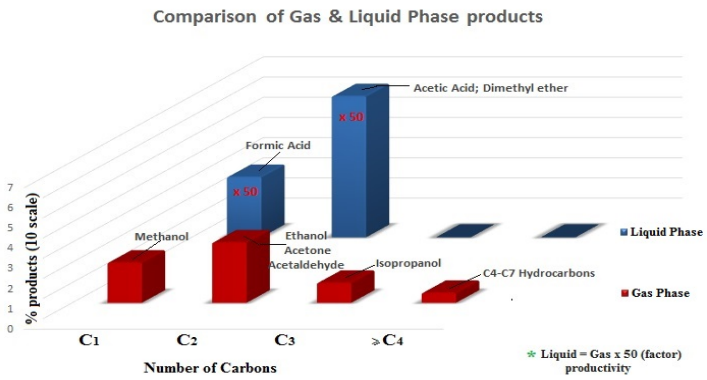

Fig. 2: Comparison of types of products in the gas & liquid phase CO_2 reduction

Fig. 1 shows the NMR spectra (using Varian NMR 500) of products for Fe based carbon catalyst under liquid phase conditions with molar concentrations of Acetic Acid and Formic Acid of $5.6*10^{-4}$ M and $6.3*10^{-4}$ M, respectively. Fig. 2 provides a comparative study on the various products formed under gas and liquid phase conditions. The ratio of the total productivities in liquid and gas phase conditions were measured to be in the range of (25-75):1, respectively for different non-noble metal based carbon electrodes experimented.

4 Conclusions

With the base motive of CO_2 reduction, the reactions performed under gas and liquid phase conditions cropped in the understanding of the improvements of the electro-catalytic activity for various non-noble metals on carbon. A notable point of interest, is that non-noble metals yielded in good fuel productivities in-place of the costly metals like platinum, gold etc. Much work needs to be done to cover all the non-noble metals and arrive at a conclusive statement, but from current work we can deduce that Fe based catalyst showed better activity than Cu followed by Co. The productivities were observed to be better in liquid phase but the gas phase yielded in better formation of oxygenates and higher chain hydrocarbons.

Keywords: PROX, operando XAS, PEMFC, XANES reduction

1 Introduction

The hydrogen-fueled proton exchange membrane fuel cell (PEMFC) is an attractive pollution-free and energy-saving power source for portable and stationary applications. An efficient operation of PEMFC requires a high-purity H_2. Even ppm concentrations of CO severely poison the Pt anode catalyst, therefore, very deep H_2 purification for obtaining CO-free H_2 is crucial. In this regard, catalytic preferential CO oxidation (PROX), i.e., $CO+H_2+0.5O_2 \rightarrow CO_2+H_2$, is a key reaction for removing traces of CO from the H_2-rich stream.

Promising and frequently investigated catalysts for PROX are known to be supported noble metal (Pt, Rh, Ru, Ir) catalysts [1]. Due to the price and the limited availability of noble metals, increasing attention in recent years has been paid to noble-metal-free alternatives, i.e, transition metal oxides. Among these oxides especially cobalt oxide and cobalt oxide-cerium oxide have turned out to be perspective catalysts for PROX [2-4]. However, the current understanding of PROX over these catalysts is based only on the pre- and post-catalyst characterization. Open questions that often arise are: what is the electronic and geometric structure of Co and Ce during PROX, what are the active sites and reaction pathways. In this study, we aimed to shed a light on these questions and boost the understanding of PROX over cobalt based oxide catalysts.

2 Experimental/methodology

Operando X-ray absorption spectroscopy studies (XAS) at the Co K (7709 eV) and Ce L_3 (5723 eV) edges were carried out in transmission geometry at the l811 beamline at the Max-lab II in Lund, Sweden in the reaction cell designed by Max-lab II. Typically, 2.5 mg of the catalyst diluted with 10 mg of BN was loaded into the cell and pretreated in 20 %vol O_2 in He at 400 ^oC for 30 min (total flow 50 mL/min). The sample was then cooled to RT and purged with helium at RT for 15 min before the PROX reaction mixture of 1 %vol CO, 1%vol O_2, 50 %vol H_2 (total flow 50 mL/min) was introduced. The XAS spectra were recorded at RT and during subsequent heating to 350 ^oC. The reaction products were monitored with a mass spectrometer. In addition to PROX, CO- and H_2-tempearture programmed reduction experiments were performed. XAS data were analyzed using the IFEFFIT software package. The XAS experiments were complemented by in-depth catalyst characterization and catalytic tests in a flow reactor.

3 Results and discussion

The operando Co K edge X-ray absorption near-edge (XANES) spectra of Co_3O_4 catalyst during heating from RT to 350 ^oC in the PROX reaction mixture are shown in Fig. 1. (A). The analysis of XANES reveals that from RT to 250 ^oC the phase of the catalyst doesn't change in the PROX reaction mixture and that cobalt oxide is present as Co_3O_4. In the temperature region starting from around 70 ^oC, CO oxidation takes place; however, at around 200 ^oC water

production begins. Interestingly, methane production starts at 250 °C and increases with the increase of temperature, even though the bulk structure of the catalyst is Co_3O_4. However, the surface might have already a defective/reduced structure. Only at 300 °C Co_3O_4 is partially reduced to CoO and further heating to 350 °C induces complete reduction of cobalt oxide to Co metallic. The comparison of operando XANES spectra during PROX with CO-TPR and H_2-TPR XANES spectra demonstrates that the reduction temperatures of Co_3O_4 in CO/He and H_2/He atmospheres are lower than in the PROX reaction mixture. Reduction of cobalt oxide in H_2/He starts directly after 250 °C, and at 300 °C the catalyst is already metallic, whereas in CO/He atmosphere reduction starts at 250 °C but at 300 °C cobalt carbide is present in addition to the cobalt oxide phase. Moreover, CO-TPR XAS analysis of Co_3O_4 in combination with mass spectrometry analysis reveals three pathways of CO-TPR: CO removal of lattice oxygen, surface water-gas shift reaction and CO disproportionation. Delayed reduction of Co_3O_4 in the PROX reaction mixture in comparison to H_2/He or CO/He atmospheres might be because of the: 1) strong adsorption of CO and O_2 to the surface of Co_3O_4 (also evidenced by CO- and O_2-temperature programmed desorption) that prevents H_2 adsorption and reduction of Co_3O_4; 2) CO disproportionation on the catalyst surface and coverage by elementary carbon (also evidenced by in situ X-ray photoelectron spectroscopy) that hinders H_2 adsorption. Based on these results, we can exclude the redox Mars-van-Krevelen mechanism of PROX on the Co_3O_4.

Detailed analysis of operando XANES spectra at the Co K edge and Ce L_3 edge of CeO_2-Co_3O_4 during PROX, CO- and H_2-TPR demonstrates that the reduction temperatures of CeO_2-Co_3O_4 in CO/He and H_2/He atmospheres, likewise to Co_3O_4, are lower than in the PROX reaction mixture. When comparing operando XANES of CeO_2-Co_3O_4 to Co_3O_4 during PROX, an increase of the reduction temperature of cobalt oxide for CeO_2-Co_3O_4 was found as shown in Fig. 1 (B) which might explain the superior activity of CeO_2-Co_3O_4 in PROX.

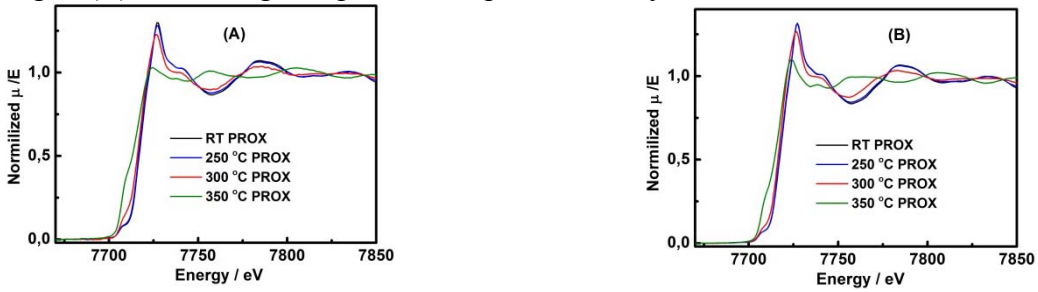

Fig. 1. Operando XANES spectra at the Co K-edge of Co_3O_4 (A) and CeO_2-Co_3O_4 (B) during PROX

4 Conclusions

Our operando XAS results demonstrate that the electronic structure of Co and Ce for Co_3O_4 and CeO_2-Co_3O_4 catalysts does not change in PROX when CO oxidation is the dominant reaction. The Mars-van-Krevelen mechanism for PROX on these catalysts is rather excluded.

Keywords: formic, acid, dehydrogenation, hydrogen, production, gold, catalysis

1 Introduction

Hydrogen can be efficiently used to generate electricity in fuel cells, releasing only water as by product. Traditionally, hydrogen is produced from natural gas or coal via intense CO_2 emission processes. Therefore, developing methods to produce hydrogen economically from renewable energy resources could lead to substantial reductions in fossil fuel consumption as well as global CO_2 emissions.

Recently, researchers have identified formic acid as one of the most promising materials for hydrogen storage because formic acid is a liquid that contains 4.4 wt.% of hydrogen with a volumetric capacity of 53.4 g/l at standard temperature and pressure [1]. CO-free H_2 can be produced via formic acid (HCOOH) dehydrogenation (Eqn. 1). It is a convenient way of producing H_2 for fuel cells designed for portable use. However, undesired reactions such as dehydration of formic acid (Eqn. 2) also occur during reaction.

$$HCOOH \rightarrow H_2 + CO_2 \quad (1)$$

$$HCOOH \rightarrow H_2O + CO \quad (2)$$

Trace amount of CO in H_2 will severely deactivate the Pt-based catalysts that are used as the anodes of fuel cells. The aim of this work is to develop new catalysts which are not only active for formic acid decomposition, but also extremely hydrogen selective. In particular, the relationship between the performance of Au/Al_2O_3 and the Au particle size was investigated.

2 Experimental

Au/Al_2O_3 (1 wt. %) was prepared via two methods; (1) sonochemical and (2) deposition-precipitation. In the sonochemical technique, $HAuCl_4.xH_2O$ and the capping reagent (lysine) were added to the catalyst support. The pH of the suspension was adjusted to 5-6 with NaOH solution. Freshly prepared reducing agent, $NaBH_4$, was introduced into the solution as it was being sonicated to facilitate the deposition of Au colloids on the support. After the reaction, the suspension was washed with deionised water for five times with a centrifuge. The suspension was then dried at 100°C and finally calcined at 250°C for 4 h. This sample is denoted as Au/Al_2O_3-S. In the deposition-precipitation method, aqueous solution of $HAuCl_4.xH_2O$ was added to suspension of Al_2O_3 at 80°C and a pH of 7, moderated by NaOH under constant stirring for 1 h. The sample was rinsed with deionised water and dried at 100°C and finally calcined at 600°C for 2 h. The catalyst is denoted as Au/Al_2O_3-DP.

The samples were characterized using X-ray diffraction (XRD), transmission electron microscopy (TEM), UV-vis and diffuse reflectance infrared fourier transform spectroscopy (DRIFTS) of formic acid. Dehydrogenation of formic acid (10 vol%) was performed in a fixed

bed reactor from 100°C to 300°C at atmospheric pressure. The catalysts were reduced at 250°C for 1 h prior to the reaction.

3 Results and discussion

The catalytic performances of the Au catalysts were evaluated at different temperatures for their activities in formic acid dehydrogenation. Fig. 1(a) shows that Au/Al_2O_3-S has a higher formic acid conversion than Au/Al_2O_3-DP. At 300°C, formic acid is fully converted over Au/Al_2O_3-S catalyst while the conversion for Au/Al_2O_3-DP is only 90.1%. The CO_2 selectivity of Au/Al_2O_3-S has a maximum value of 99.0% at 250°C, following which dehydration occurs, resulting in a decrease in CO_2 selectivity to 98.2% at 300°C (Fig. 1(b)). The CO_2 selectivity of 96.8% and 93.3% is smaller over Au/Al_2O_3-DP at 250°C and 300°C, respectively. These results indicate that Au/Al_2O_3-S has a more superior catalytic activity than Au/Al_2O_3-DP in formic acid dehydrogenation. Preliminarily, the higher catalytic activity of Au/Al_2O_3-S is likely to be related to the particle size of Au. TEM micrographs in Fig. 2 show the high resolution image of metal Au particles. The mean particle size of Au/Al_2O_3-S and Au/Al_2O_3-DP is 6 nm and 20 nm, respectively. Smaller Au particle size gives a higher activity in formic dehydrogenation, a finding in agreement with Ojeda et al. [2].

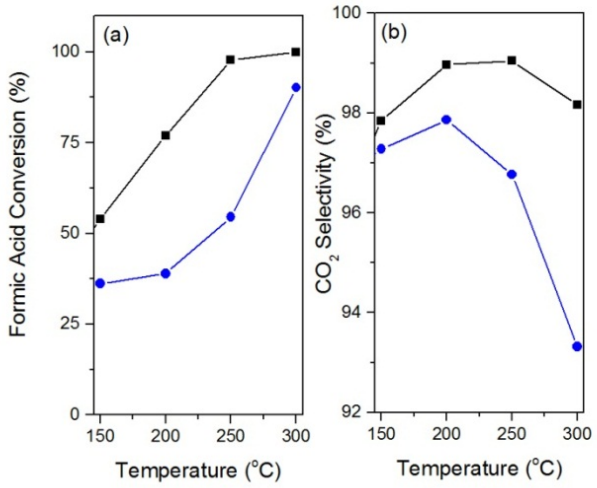

Fig. 1. Formic conversion (a) and CO_2 selectivity (b) over Au/Al_2O_3-S (■) and Au/Al_2O_3-DP (●).

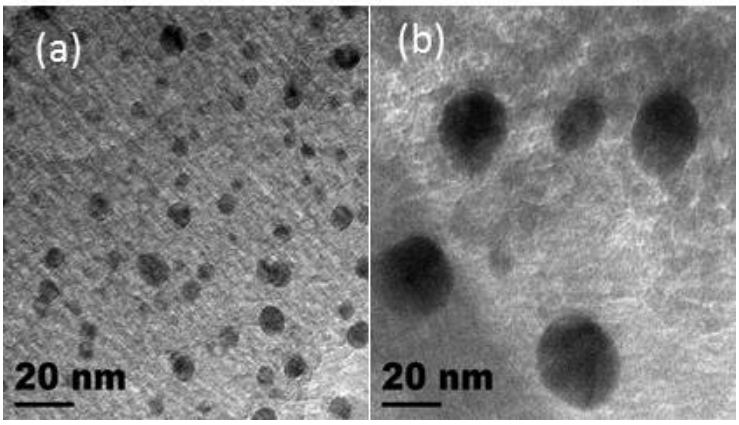

Fig. 2. TEM micrographs of (a) Au/Al_2O_3-S and (b) Au/Al_2O_3-DP.

4 Conclusions

Gold nanoparticles were deposited via sonochemical technique and deposition-precipitation method. TEM reveal that sonochemical method produces small gold nanoparticles. Catalyst

activity for formic acid dehyrogenation and selectivity to hydrogen is increasing with decreasing gold particle size.

Iron(II) Clathrochelates as Homogeneous Electrocatalysts of Hydrogen Production at Low Ph

Dolganov A.V.*, Novikov V.V., Nelyubina Yu.V., Lebed E.G., Voloshin Ya.Z.

A.N.Nesmeyanov Institute of Organoelement Compounds of Russian Academy of Sciences, Moscow, Russia

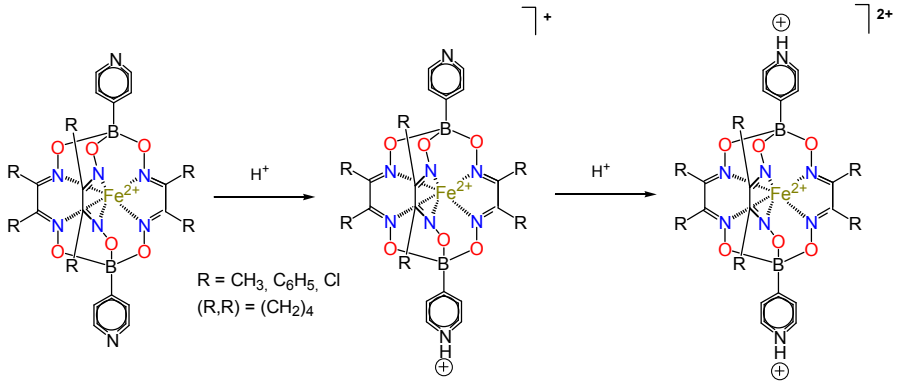
Keywords: clathrochelates, iron complexes,eElectrocatalysis, hydrogen production

1 Introduction

Increasing energy demands of an ever-growing population calls for new energy sources, one of them being molecular hydrogen. To make hydrogen-based economics a reality, highly efficient and chemically stable catalysts for hydrogen production that do not contain precious platinum group metals need to be designed. For this purpose, we suggest to use iron(II) clathrochelate complexes with functionalizing pyridinyl substituents, which emerged as effective homogeneous electrocatalysts for hydrogen evolution at low pH; we expected the protonation of these complexes to increase their solubility in water due to the formation of salts (Scheme 1).



Scheme 1

2 Experimental

2.1. Cyclic voltammetry: cyclic voltammetry experiments were carried out in acetonitrile solutions with 0.1 M $((n\text{-}C_4H_9)4N)BF_4$ as a supporting electrolyte using a model Parstat 2273 (Prinston Applied Research, USA) potentiostat with a conventional one-compartment three-electrode cell (10 ml of solution) at a scan rate 200 mV s^{-1}. All solutions were thoroughly deaerated by passing argon through them before the cyclic voltammetry experiments and above them during the measurements. Glassy carbon electrode (active surface area of 0.125 cm^2), platinum electrode and standard $Ag/AgCl/KCl_{aq}$. electrode were used as working, counter and reference electrodes; those were thoroughly polished and rinsed before each measurement.

2.2. Controlled-potential electrolysis: 50 mM acetonitrile solutions of methanesulfonic acid, $HBF_4 \cdot O(C_2H_5)_2$ and triethylammonium hydrochloride with 0.1 M $((n\text{-}C_4H_9)_4N)BF_4$ were electrolyzed in the presence of iron(II) clathrochelates for one hour. Molecular hydrogen production was confirmed by gas chromatography; injections (250 μL) were performed *via* a sampling loop, helium flow rate was 40 ml min^{-1}, and retention time of gaseous H_2 2.48 min.

3 Results and discussion

Electrochemical characteristics of these iron(II) clathrochelates are summarized in Table 1.

All peaks observed in their cyclic voltammograms are characteristic of diffusion-controlled current processes. In the cathodic range of these cyclic voltammograms, only one one-electron quasi-reversible wave is observed, which was assigned to redox-processes $Fe^{2+/+}$.

Table 1. Oxidation and reduction potentials (mV) and characteristics of electrochemical processes for the iron(II) clathrochelates.

Complexes	Oxidation, E_{ox}			Reduction, E_{red}			k_{obs}
	E_a	E_c	ΔE	E_c	E_a	ΔE	
$FeNx_3(B4\text{-}Py)_2$	1370	1280	90	– 1080	–870	210	953
$FeDm_3(B4\text{-}Py)_2$	1450	1360	90	– 1030	– 900	130	874
$FeBd_3(B4\text{-}Py)_2$	1480	1400	80	–1050	– 800	250	658
$Fe(Cl_2Gm)_3(B4\text{-}Py)_2$	1910	1800	110	– 450	– 380	70	1900

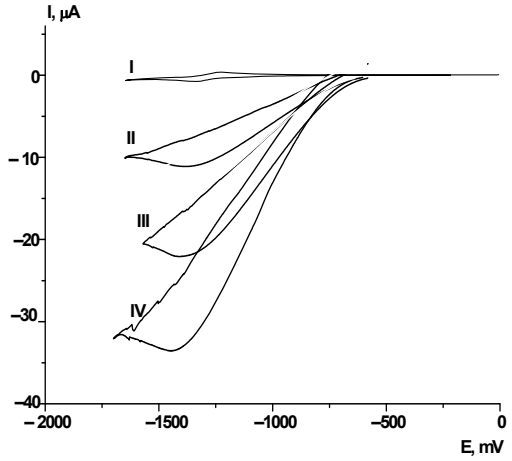


Fig. 1. Cyclic voltammogram for 0.5 mM acetonitrile solutions of $FeNx3(B4\text{-}Py)_2$ on a glassy carbon electrode in the absence and (top–bottom) in the presence of 5, 10, 15 and 25 mM of CF_3COOH.

The complexes obtained efficiently electrocatalyze hydrogen evolution (Fig. 1) from an acid solution in acetonitrile as well as from aqueous buffers with low pH (1 – 4). NMR spectroscopy data confirmed that protonation of both the pyridine moieties occurred, thus giving protonated species that were stable in these conditions. Titration of an acetonitrile solution of a clathrochelate with an acid resulted in a significant increase of the current assigned to the $Fe^{2+/+}$ pair, while the peak of the reverse process vanished. Kinetic parameters and overall efficiency of the catalytic process depended greatly on the nature of ribbed substituents in chelate fragments of these clathrochelates. Based on the dependence of the rate of the electrocatalytic process $2H^+/H_2$ on the pH value of the aqueous solution, a limiting step was identified and a catalytic mechanism elucidated experimentally. All proton reduction reactions were first order in the catalyst's concentration and second order in the acid's concentration; for all of them, rate constants and activation energies have been obtained.

4 Conclusions

Pyridinyl-functionilized iron(II) clathrochelates emerge as first homogeneous electrocatalysts of hydrogen evolution at low pH; varying their ribbed substituents allows designing electrocatalysts with better performance and stability in harsh near-industrial conditions.

Keywords: steam reforming, dry reforming, platinum, rhodium, bimetallic system, $MgAl_2O_4$ spinel

1 Introduction

Among the different alternatives for the searching of renewable energy sources, the use of biogas results interesting because it is produced by the anaerobic combustion of biomass [1]. This CH_4 source may be employed for the production of heat or for the generation of syngas throughout reforming processes. However this non-conventional gas presents a high level of CO_2 that reduces its energetic density and influences adversely the yield of the process and the catalysts efficiency. Consequently, specific catalysts must be developed, adapting those used in the conventional reforming of CH_4, in order to produce active and stable solids able to work under high levels of CO_2 and H_2O.

Since thermal stability is one of the main concerns of reforming catalysts, alumina is one of the most used supports. However this solid has an acidic character that promotes deactivation by coke formation. For that reason the doping of alumina with basic species is an interesting strategy for avoiding this effect. Concerning the active phase, the use of noble metals results an expensive alternative. Nevertheless they may allow to reduce the temperature for obtaining the maximum CH_4 conversion, which would represent energy savings that justify their employment[2].

In the present work, a $MgAl_2O_4$ mixed oxide was obtained for combining the thermal stability of alumina and the basic properties of MgO [3]. This material was used as support for the synthesis of Pt, Rh and Pt-Rh catalysts those being tested under specific dry and steam reforming conditions. The principal aim of this study is to analyse, from a structural point of view, the interaction of the $MgAl_2O_4$ support with the different active phases (Pt, Rh and the bimetallic system Pt-Rh), and to evaluate the influence of such interaction in the catalytic performance of the prepared solids during both, the dry and steam reforming reactions.

2 Experimental

For the synthesis of the $MgAl_2O_4$ support, a commercial alumina (Sasol®) was grounded and then mixed with an ethanolic solution of $Mg(NO_3)_2$. The mixture was continuously stirred and heated under vacuum until the obtaining of a dried solid. This was divided in different portions that were treated under different calcination programs: MgAl12 (900ºC, 12h), MgAl24 (900ºC, 24h), MgAl36 (900ºC, 36h) and MgAl48 (900ºC, 48h). The noble metals, Pt and Rh were deposited on the prepared solids by conventional impregnation. The nominal metal loading was fixed to 2wt. %. In the case of bimetallic system, Pt was impregnated before Rh, for obtaining a 1:1 molar ratio.

Characterization of the supports and catalysts were carried out by means of XRD, N_2 physisorption, XRF, TPR-H_2, SEM and Raman Spectroscopy. The catalytic tests were performed in PID Eng&Tech Microactivity equipment using a *Hastelloy C*® tubular reactor under atmospheric pressure at 750 ºC during 6h. The products were analyzed with a micro gas chromatograph equipped with Molsieve 5A and PoraPlot Q columns, and a TCD detector. Catalyst loading of 50mg, $100<\phi<200\mu m$, diluted in quartz is activated under H_2 atmosphere before the reforming reaction sequence

(steam and dry reforming reaction).

3 Results and discussion

Concerning the obtained supports, the XRD analysis showed that higher the calcination temperature and/or time, lower the segregation of MgO and higher the degree of $MgAl_2O_4$ formation. However, under these conditions, a strong decrease of the specific area was detected. As for the catalysts, the most interesting characterization result is the easier reducibility shown by the bimetallic system, as evidenced by the lower temperature of the TPR reduction process observed in such sample compared to those of the single metal systems.

The bimetallic solid exhibited the highest catalytic activity during both dry and steam reforming reactions (Figure 1A). However, the PtMgAl24 system presented a higher efficiency of CH_4 converted per mol of noble metal (Figure 1B). This is associated to the reduction of the MgO segregation and the higher Pt dispersion evidenced in this sample. Regarding the H_2/CO molar ratio, values below 1 were obtained for all systems during the dry reforming. However, for the steam reforming, H_2/CO molar ratios above 4 were attained being especially higher for the single noble metal catalysts calcined during 12 h.

Considering that for the Fisher-Tropsch synthesis the reformate gases must present a H_2/CO ratio close to 2, our catalytic results demonstrated that, under the studied conditions and using a single reforming process (wet or dry), our solids do not fulfil such requirement. Nevertheless, by means of simulation studies using the Aspen Plus® program, it was deduced that combining dry and steam reforming conditions, such H_2/CO ratio is achievable. The searching for the adequate experimental reaction conditions is currently under realisation.

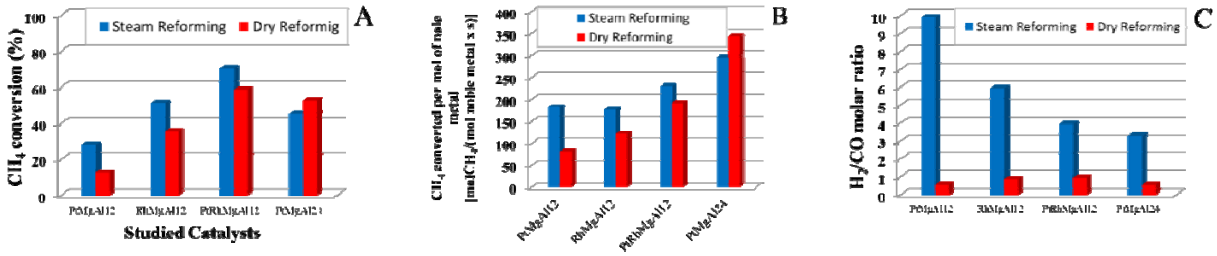

Fig. 1. Catalytic activity results during the dry and steam reforming: A) CH_4 conversion; B) Converted CH_4 per mol of noble metal; C) Obtained H_2/CO molar ratio

4 Conclusions

The time and temperature of calcination of the $MgAl_2O_4$ strongly influences the interaction of the cations and the segregation of MgO, affecting the catalytic activity and the metallic dispersion of the noble metal catalysts prepared. The systems with Pt are the most active ones, especially under steam reforming conditions. Simulation studies have demonstrated that combining steam-reforming and dry-reforming conditions allows to obtain a H_2/CO ratio of 2, and may be an adequate strategy in order to generate the required conditions for the syngas production after the reforming units.

Keywords: dehydrogenation, hydrogen storage, perhydro-m-terphenyl, m-terphenyl

1 Introduction

Continuous improvement of environmental standards leads to a significant increase of the interest in alternative energy sources, including hydrogen fuel cells. For their effective use, including transport, it is necessary to solve a number of technical problems associated with the rapid release and feeding of pure hydrogen to the fuel cell. On the other hand, highly explosive hydrogen requires the development of new effective and safe hydrogen storage systems. A radically new approach to this problem is based on employing organic chemical systems, i.e., organic compounds that possess a fairly high hydrogen capacity (6.0–8.0 wt %) and can operate in the reversible hydrogenation–dehydrogenation mode [1]. Hydrogen storage in the structure of chemical compounds makes such systems explosion-proof.

2 Experimental/methodology

Evaluation of the performance of catalytic composite systems was carried out by comparing the rate of hydrogen evolution from hydrogenated condensed aromatic chemical hydrides (decalin, bicyclohexyl, perhydroterphenyl) in the dehydrogenation process. Both commercial and prepared by hydrogenation substrates were used. Catalytic tests have been carried out at temperatures 280–340°C and flow rates 0,5-3 h^{-1} in a flow reactor and the optimal conditions for the dehydrogenation reaction were determined, including thermodynamic calculations.

Completeness of hydrogen saturation of the catalytic composite system for storage was evaluated by the hydrogenation reaction. Hydrogenation was carried out at a temperature of 180°C and pressure 70 atm in a laboratory high pressure autoclave PARR-300 by stirring the reaction mass. The catalytic activity was measured for commercial and prepared catalysts consisting of active components (Pt, Pd, Ni, Cr) and a support (alumina, silica gel, carbon) in varied proportions. The catalysts were prepared via an impregnation procedure based on the deposition of a metal precursor from an aqueous solution of a chloride complex followed by the reduction of the precursor with hydrogen.

3 Results and discussion (font style: Times New Roman bold 12pt)

The largest amount of hydrogen released as a result of perhydro-*m*-terphenyl dehydrogenation to *m*-terphenyl is observed with the 3%Pt/Sibunit catalyst at 320°C and 1 h^{-1}. Increasing or decreasing the amount of the active component supported on carbon leads to a decrease in the amount of hydrogen obtained in perhydro-*m*-terphenyl dehydrogenation. The maximum selectivity and conversion toward complete dehydrogenation in this case is 95%. The selectivity and conversion of *m*-terphenyl hydrogenation to perhydro-*m*-terphenyl with the 3%Pt/Sibunit catalyst reached 99%. Figures 1 and 2 show the curves of dehydrogenation of perhydro-*m*-terphenyl and hydrogenation of *m*-terphenyl on different catalysts: 1 - 10%Pt/C

(carbon BAU), 2 - 5%Pt/C (Sibunit), 3 - 3%Pt/C (Sibunit), 4 – 0.12%Pd-3.8%Ni-4.3%Cr/γ-Al_2O_3, 5 - 5%Pt/γ-Al_2O_3, 6 – 2.5%Pd/γ-Al_2O_3.

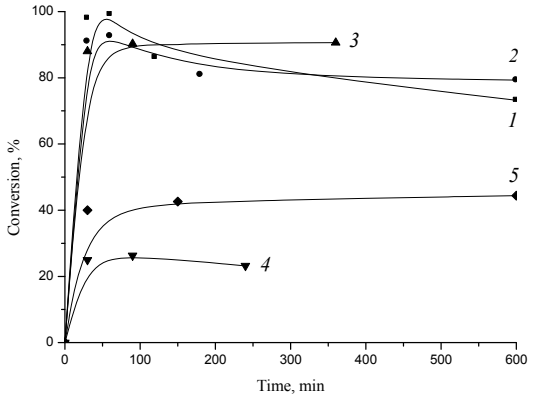

Fig. 1. Changes of the conversion on the time on stream in the dehydrogenation of perhydro-*m*-terphenyl (T = 320°C, V_L = 1 h^{-1}, P = 1 atm)

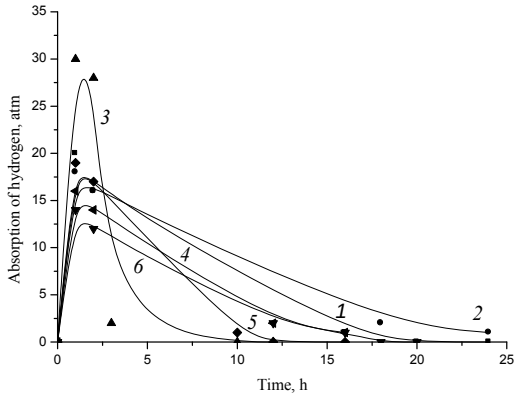

Fig. 2. Changes in the absorption of hydrogen on the time on stream in the hydrogenation of *m*-terphenyl (T = 180°C, P = 70 atm)

4 Conclusions

The experimental data shows that the use of the *m*-isomer of perhydroterphenyl as a substrate for the catalytic composite system allows us to achieve the capacity for hydrogen 6.5-7.3 wt.%. As a result of research, high conversion rates and volumes of generated hydrogen in the catalytic composite systems were obtained using some of condensed aromatic compounds in the flow reactor. The high purity of hydrogen was proved by chromatography in the dehydrogenation reaction [2].

Oxidative Coupling of Methane over Li Doped MgO on a Monolithic Structure

Nadjafi M., Yıldırım R.*

Department of Chemical Engineering, Boğaziçi University, Istanbul, Turkey

* yildirra@boun.edu.tr

Keywords: OCM, methane coupling, Li doped, MgO, monolith

1 Introduction

Abundant resources of natural gas, which is mainly methane, have motivated researchers to produce valuable products from this simple hydrocarbon. The aim of such conversion is to ease its transport and increase its value as a petrochemical feed. Oxidative coupling of methane (Eq. 1), which satisfies this aim in a single step, is a reaction of great interest [1].

$$CH_4+O_2 \longrightarrow C_2H_4 \text{ or } C_2H_6 + H_2O \quad (1)$$

However, this reaction has still not been put into practical application due to some drawbacks. Intensive researches have been done, and Li doped MgO showed higher performance than most other materials. However, all catalyst suffered from severe and drastic deactivation, especially at the beginning of the testing experiments [2]. Our aim is to investigate the effect of a monolithic structure on Li doped MgO prepared from different precursors and different preparation techniques. We also are investigating the effect of temperature and methane to oxygen ratio on both monolith and particulate catalyst. The best performing catalysts were also characterized using the methods like SEM, XRD and EDX.

2 Experimental/methodology

0.5wt% Li/MgO catalyst is used to compare the particulate and monolithic structure on OCM. Furthermore, temperature and methane to oxygen ratio effect on OCM is evaluated for both particulate and monolith. Finally, MgO is doped with different precursors of Li to see their effect on both structures. Each time, we put 200 mg of catalyst in particulate form or coated on monolith in a tubular quartz reactor with inner diameter of 10mm. In each run, after 30 minutes of reaching desired temperature, the data is taken using Shimadzu GC equipped with a thermal conductivity detector. Total flow is adjusted to 120 ml/min to have a real plug flow condition. N_2 is used as internal standard and carbon balance was always higher than 96%. Crushed and sieved quartz chips are used at top and bottom of the reactor to do preheating, mixing, and preventing undesired reactions [3].

Particulate catalyst preparation: Different precursors of Li (Li_2CO_3, Li_2O, $LiCH_3COO$, and $LiNO_3$) were doped on MgO using mixed milled and wet impregnation method. Afterward the prepared samples were calcinated at 400°C for 3hr. 0.5wt% catalyst then were crushed and sieved, only particles 0.63-0.18mm were used to reduce internal diffusion effect.

Monolith catalyst preparation: MgO is wash coated on monolith during immersing of monolith in MgO solution and drying it in a microwave furnace. When the desired amount of MgO is coated, Li is dopped. Dissolved lithium precursor (Li_2CO_3, Li_2O, $LiCH_3COO$, and $LiNO_3$) in sufficient amount of deionized water then is doped on wash-coated monolith by rolling it inside the solution or using wet impregnation technique. Afterward the prepared monoliths were calcinated at 400°C for 3hr. 0.5wt% Li/MgO catalyst is now coated on monolith and can be compared with particulate one.

3 Results and discussion

Figure 1 shows a case study of on monolith catalyst. Monolith catalyst is prepared using mixed milled method and $LiNO_3$ precursor. The methane conversion increased with increasing temperature while the C2 selectivity increased first, and then it decreased after 800 ^oC. However the C2 yield always increased within the temperature range studied because the increase in conversion was more dominant than the decrease in selectivity at higher temperatures.

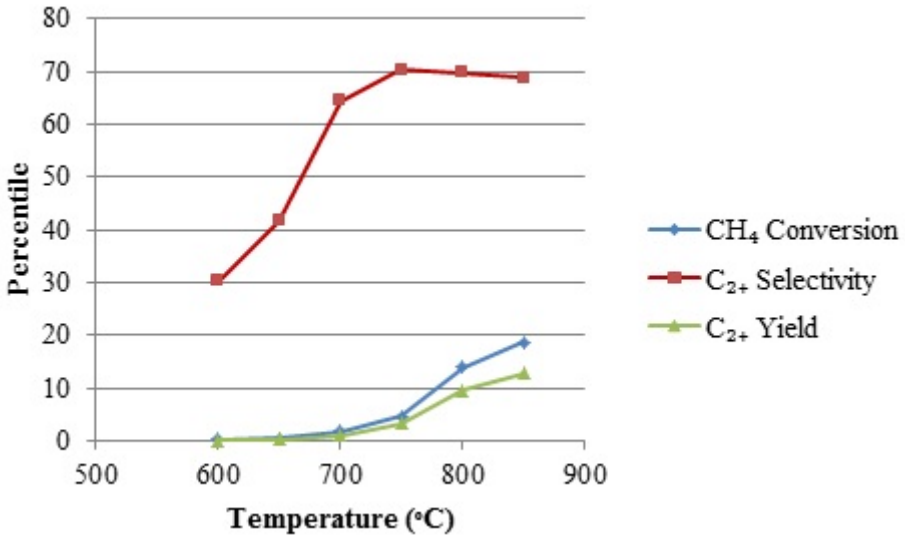

Figure 1. Case study of monolith catalyst

4 Conclusions

Our experiments show that oxidative coupling of methane can be performed over the monolithic structure, which are better for providing void volume for CH_3 combination reactions, and for better flow and heat management properties compared to particulate catalyst.

Ceria-Supported Cobalt Oxide Catalysts: Synthesis, Characterization and Catalytic Combustion of Producer Gas

Mungse P.[1], Saravanan G.[1], Rayalu S.[1], Dasappa S.[2], Labhasetwar N.[1*]

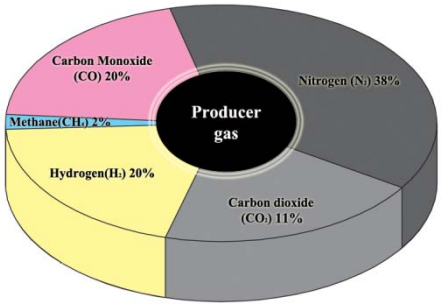
Keywords: producer gas, combustion catalyst, supported catalyst, Ce/CeO_2

1 Introduction

Producer gas is a mixture of both flammable (CO, H_2, CH_4) and non-flammable (N_2, CO_2) gases, which is formed by the gasification of carbonaceous substances including biomass. The typical stoichiometric composition of producer gas is shown in the **Fig. 1a**. This can be used as a fuel at large-scale industrial furnaces as well as gasifiers, with its relatively lower heating value than that of other gaseous fuels. Although producer gas possesses the potential as fuel, however, for certain technical reasons, it has not been explored much to meet the present energy demand. With depleting energy resources and increasing energy demand, producer gas presents a potential option to be used as a decentralized source of energy. Considering higher CO and hydrogen contents as well as presence of methane, the mixture may lead to partially incomplete combustion under the various conditions of gasifier operation. This may result in fuel slip with potential hazards from CO and hydrogen slips. We therefore, propose for the use of combustion catalyst for efficient and complete combustion of producer gas with concomitant control of CO and hydrogen slip. Only a very few studies have been explored on producer gas combustion, using heterogeneous catalysts, for instance zeolites, metal oxides and supported metal oxides [1], however, deactivation of active catalytic sites, less robustness, and poor thermal resistance were the limitations of these catalysts. Therefore, the materials with a high structural stability with improved redox properties may be alternatives to avoid these limitations. In this work, the catalytic combustion of the producer gas using conventional catalyst (e.g. Pt/Al_2O_3) and a non-noble metal catalyst (e.g. Co/CeO_2) was examined. The effect of temperature, flow rate etc. on catalytic combustion efficiency of the producer gas combustion reaction was studied.

2 Experimental/methodology

Ceria was prepared by using chitosan template method. Incipient wetness impregnation method was used to prepare the Co-incorporated catalysts. Stoichiometric amount of $Co(NO_3).6H_2O$ was impregnated on mesoporous ceria for the preparation of 10 wt. % Co/CeO_2. The synthesized catalysts were characterised using powder X-ray diffraction (*p*XRD), scanning electron microscopy (SEM). The redox properties of the synthesized catalysts were examined by hydrogen temperature programmed reduction (H_2-TPR). The catalytic combustion of producer gas was examined using fix bed laboratory evaluation assembly equipped with gas chromatograph, temperature controlled furnace and mass flow controllers as shown in **Fig. 1b**.



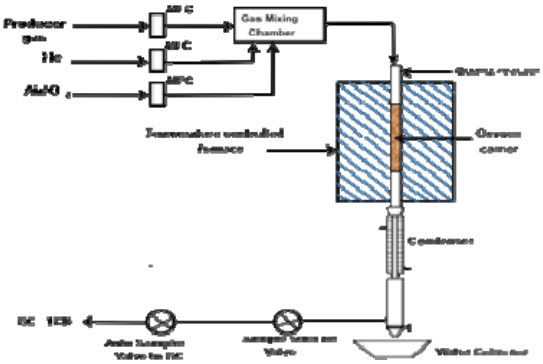


Fig.1a **Fig.1b**

Fig. 1. (a) Producer gas composition used and (b) schematic representation of experimental setup used for catalytic evaluations.

3 Results and discussion

The catalytic combustion activity of the producer gas using Co/CeO_2 is shown in **Fig. 2.** The initial concentration of CO (20%) and CH_4 (2%) of the producer gas decreases with the increase of temperature and showed 100% combustion efficiency at 300 °C and 700 °C, respectively. The combustion of CO and CH_4 produced CO_2 and H_2O and the mass balance of CO_2-formation is consistent with the stoichiometric combustion of producer gas (CO and CH_4), indicating that Co/CeO_2 can combust the producer gas completely. The TPR analysis of catalyst shows redox properties of catalyst, possibly responsible for the high catalytic activity.

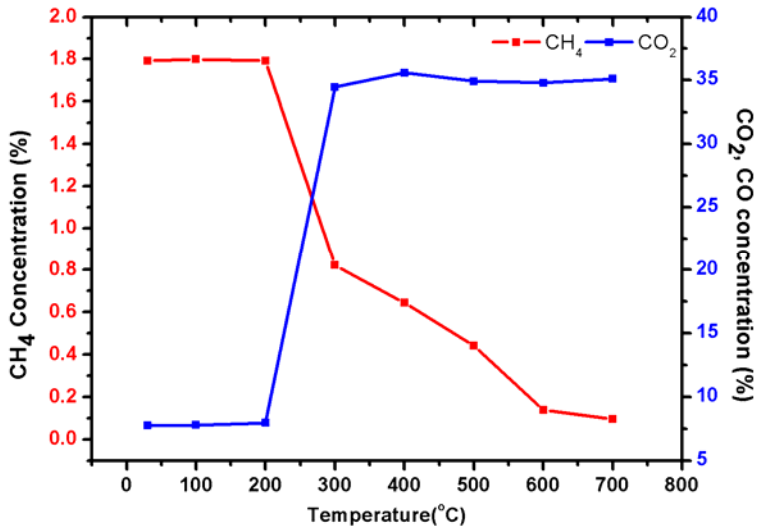

Fig. 2. Concentration of CH_4 and CO_2 on Co/CeO_2 catalyst as a function of temperature.

4 Conclusion

The catalytic combustion of producer gas has not been much explored. Since the use of producer gas as a fuel is expected to find more interest in future, it's important to study environmental and safety hazards associated with it. This study will draw the attention and need of catalytic combustion of toxic producer gas. Co/CeO_2 as producer gas combustion catalyst was synthesized through incipient wetness impregnation method and evaluated for its catalytic combustion efficiency. Our preliminary results inferred that the complete combustion of producer gas can be achieved even at moderate temperatures, commonly used for producer gas based combustion devices, thereby eliminating the risk of CO and hydrogen slip.

Cyclization of Normal Alkanes to Arenes and Cycloalkanes

Kashkina E.*, Mikhailova Y., Svidersky S., Loginova A., Isaeva E., Leontyev A.

United Research and Development Centre, Moscow, Russia

* KashkinaEI@rn-rdc.ru

Keywords: cyclization, cycloalkanes, arenes catalyst

1 Introduction

The cyclization reactions are the basis of important catalytic processes for aromatic hydrocarbons production, mainly toluene, benzene and xylenes, as well as gasoline having a higher detonation resistance [1]. The practical implementation of n-alkanes cyclization process is one of the promising directions of refining processes development. Applying the cyclization process will allow efficient converting of n-alkanes of petroleum and synthetic origin into valuable components of motor fuels and oils, such as cycloalkanes and arenes.

Naphthenic hydrocarbons (cycloalkanes) are the most valuable class of chemical compounds in the composition of oils and fuels and their most high-quality part, as well as high-quality raw material for catalytic reforming process. In particular, cycloalkanes, compared with other classes of hydrocarbons contained in diesel cut, possess an optimum ratio of density and cetane index [2-3]. They provide a high viscosity index in lubricating oil formulations. Naphthenic oils (group V by API classification) produced from special oils, reserves of which are steadily decreasing, have good performance and are widely demanded in the industry.

Aromatic hydrocarbons also have good performance characteristics: their presence in petroleum products has a decisive effect such important indices as octane number (for gasoline), density and viscosity (for diesel and jet fuel) and others. Monocyclic arenes with long branched alkyl chains provide good viscosity-temperature properties for lubricating oils. However, due to limitations of ecological nature, the content of aromatic compounds in products is currently regulated.

Today, developments in n-alkanes cyclization proved to be in demand and were further developed for the cyclization of synthetic hydrocarbons. Synthetic hydrocarbons obtained in Fisher-Tropsch synthesis (FTS) are a mixture of mainly n-alkanes, which contains almost no naphthenic or aromatic compounds, and this explains the poor values of such parameters as density, chilling point and pour point of products derived from them, especially synthetic jet fuels. Cyclization process will allow production of valuable products based on synthetic hydrocarbons - components of oils with a high content of naphthenic hydrocarbons and arenes enriched components of fuels.

2 Experimental/methodology

The objective of the research was to assess the current state of scientific research and the identification of promising areas in the field of cyclization of n-alkanes.

During the work, we analyzed the data on the supposed mechanism of the cyclization process and the catalysts applied.

3 Results and discussion

Considered literature suggests that mechanism of alkanes cyclization reactions over platinum catalysts has been studied well. The literature discusses two main ways of cyclization reactions [4]:

1) bifunctional mechanism by which both metal and acid sites of the catalyst participate in reactions; applicable to systems - Pt on acidic support (alumina, silica-alumina or zeolite);

2) monofunctional mechanism involving reaction only on the metal sites; applicable to catalysts - Pt on non-acidic support (zeolite L, NaZSM-5, non-acidic alumina).

It is shown that along with alumina, zeolites in the cyclization catalyst also have activity and selectivity to the cyclization of alkanes with 6 or more carbon atoms [5]. Acidity of the zeolite support negatively affects the yield of aromatic hydrocarbons, due to parallel reactions on acidic active sites, such as isomerization and hydrocracking. Reducing the acidity of the zeolite by ion exchange with alkali is a requirement for increasing the selectivity of the zeolite catalyst to aromatic hydrocarbons. For effective reactions of cyclization zeolite cells should have a diameter of ~7Å (12-member ring), one-dimensional structure is preferred. In terms of structure, L type zeolite (LTL) if the most promising for cyclization of n-alkanes [6-7].

It is established that monofunctional catalysts containing Pt as an active component deposited on a non-acidic zeolite (type L in K-form) exhibit high activity in reactions of cyclization of n-alkanes [4]. High activity of the catalysts based on KL zeolite in cyclization of n-alkanes is explained by their low acidity contributing reduction of adverse reactions intensity - hydrocracking and received arenes hydrogenolysis, and by geometry of zeolite structure, enabling preferential target dehydrocyclization and dehydrocyclooligomerization reactions.

Promoters are added to the catalyst composition to improve efficiency of cyclization process catalysts. The use of promoter may contribute to the occurrence of the target reactions, prevent the side reactions, as well as promote involvement of the side reactions products, light alkanes, in particular, resulting from hydrocracking, into the secondary transformations, namely, dehydrocyclooligomerization. Rhenium, iridium, palladium can be used to improve activity of the catalyst in the target reactions, either directly by improving conditions of the reactions of hydrogenation and dehydrogenation, and by preventing deactivation of active sites [8-9]. Tin and indium are used to suppress excessive hydrocracking activity, particularly on acidic supports [10]. In addition, introduction of these promoters contributes to the achievement of optimal dispersion and crystallite size of the active component. Oxide promoters (WO_3, Cr_2O_3, ZnO) can help improve the overall catalytic activity of the system, and the involvement of the hydrocracking products into the dehydrocyclooligomerization reaction [1, 11].

4 Conclusions

Results of the literature review on paraffin cyclization allow to determine the main directions of research to create a highly efficient catalyst for the cyclization of normal alkanes in the arenes and cycloalkanes.

Keywords: surfactant, nanocrystalline, XPS, methane conversion, SOFC anode

1 Introduction

Solid oxide fuel cells (SOFC) offer a promising way of converting chemical energy into electrical energy with great efficiency. The formation of ordered ceramic nanostructures with tunable morphology and composition are required for SOFC anode. SOFC devices need to possess simultaneously a good ionic conductivity induced by the presence of oxygen vacancies and a good electronic conductivity induced by the added metal together with a high porosity allowing the fuel transport through the anodic layer [1-2]. S. Jung et al. [3] showed the anode performance depend by synthesis route. Thus, the distribution and morphology of the Cu component in $Cu/CeO_2/YSZ$ composite anodes are affected by different impregnation procedures. Our proposed synthesis method favors uniformity of the crystalline network and the active species and an improvement of the ionic and electronic conductivity as well as of the catalytic activity. Electronic conduction type will be assured by Cu^0 species resulted from strong reducing environments, but also by reduction of Ti^{4+} to Ti^{3+} giving rise to free electrons. Ionic conductivity will be ensured by incorporating species with lower valence as Y^{3+}.

2 Experimental: Synthesis and characterization

(Cu, Ti) -YSZ were synthesized by a self-assembled method, using a nonionic surfactant – Triton X100 as template. Zirconium propoxide, yttrium acetylacetonte, titanium (IV) isopropoxide, nickel acetyl acetonate and copper acetate were used as inorganic precursors. 1-Propanol was used as solvent. The gels formed were dried several days at 50 ^oC, followed by calcination in air at 700 ^oC and 900 ^oC, respectively. **X-Ray diffraction analyses** were carried out on a Schimadzu XRD-7000 diffractometer using Ni-filtered Cu Kα radiation with λ=1.5418Å. **Scanning electron microscopy (SEM)** were performed with a Philips XL-20. **X-ray photoelectron spectroscopy (XPS)** - Surface analysis performed by X-ray photoelectron spectroscopy (XPS) was carried out on PHI Quantera equipment with a base pressure in the analysis chamber of 10-9 Torr. The X-ray source was monochromatized Al Kα radiation (1486.6 eV). The spectra were calibrated using the C1s line (BE = 284.8 eV).**The catalytic activity** for partial oxidation of methane (POM) was evaluated in a continuous fixed-bed tubular reactor (length of 300 mm and i.d. of 9 mm, Hasteloy X tube), equipped with a thermo well in the center of the catalyst bed, from PID &Eng Tech.

3 Results and discussion

The XRD pattern of sample CTST700 correspond to a cubic phase of fluorite type (Fm3m), with lattice parameter c= 5.073 Å. The cubic structure is stable at room temperature with the incorporation of yttria and titania in the zirconia-based lattice and the formation of a ternary oxide solid solution. XRD detects also a secondary phase with monoclinic symmetry (C2/c), isostructural with tenorite (CuO), with slightly enlarged lattice parameters, a= 4.695, b= 3.433,

c= 5.141, a= b = 90 deg, γ = 99.470 deg. Both phases have small nanocrystallite size, around 8 nm for the zirconia-based fluorite-type phase and 12 nm for the copper oxide-based tenorite-type phase, respectively. The XRD pattern of CTST calcined at 900 ^{o}C, can be indexed to monoclinic zirconia-based phase and tenorite as secondary phase. A significant growth of crystalline sizes for both the zirconia-based main phase: 30 nm, and CuO: 25 nm, was highlighted.

After data processing the XPS results revealed that Ti2p, Zr3d and Y3d prominent XPS transitions display typically 4+ and 3+ oxidation states, respectively. A close inspection of Cu2p photoelectron spectra reveal the presence of Cu^{2+} oxidation state for all samples following the assignments of the binding energies as well as the associated shake-up satellites and their relative intensities, in agreement with XRD results.

The conversion profile recorded for the catalytic partial oxidation of methane (Fig. 1a, b) showed that CTST materials are active above 400^{o}C. At low calcination temperature 700^{o}C methane is converted ~41%, while at high calcination temperature 900^{o}C the CH_4 conversion and CO selectivity are situated in the range 80-90%. CH_4 is totally converted to CO at 800^{o}C working temperature.

Conductivity measurements showed that addition of Cu leading to a predominantly an electron conductor behaviour with a n-type conductivity. Under wet hydrogen atmosphere the DC conductivity reached values of ~ $4 \cdot 10^{-4}$ S/cm at 780 ºC. The conductivity, electrocatalytic and catalytic properties are very influenced by the presence of reduced Cu species in the structure, enhancing those properties.

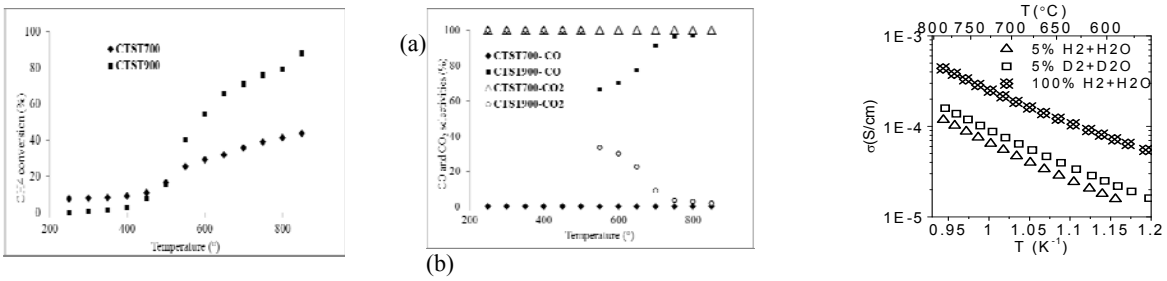

Fig. 1. Methane conversion (a), CO/CO_2 selectivity (b) and conductivity measurements at wet atmospheres (c)

4 Conclusions

The self-assembling method using Triton X100 as template was used for (Cu, Ti) –YSZ synthesis. The XRD patterns confirm formation of cubic phase of fluorite type at 700^{o}C and also a secondary phase with monoclinic symmetry, isostructural with tenorite (CuO) at 900^{o}C. The XPS results reveal that Ti2p, Zr3d, Y3d and Cu2p prominent XPS transitions display typically 4+, 3+ and 2+ oxidation states, respectively. The composite show high methane conversion and CO selectivity in the catalytic partial oxidation of methane (CPOM) at 800^{o}C. Conductivity results showed a predominately n-type behaviour, highlighting a promising IT-SOFC anode.

Keywords: photocatalytic oxidation, controlled periodic illumination, lifetime, active, species

1 Introduction

Heterogeneous photocatalytic oxidation of organic compounds on TiO_2 is considered as one of the most promising ways of air and water treatment. One of the approaches to increase quantum efficiency is the controlled periodic illumination (CPI), firstly suggested by Sczechowski et al. [1,2].

Working with fixed duty cycle Cornu et al. [3,4] investigated influence of t_{on} on the efficiency of methyl orange and formate oxidation. There were two sharp transitions in plots φ vs t_{on} at t_1 and t_2. Cornu et al. associated t_1 and t_2 with the lifetimes of oxidizing and reducing intermediates since they strongly depended on pH of the reaction suspension.

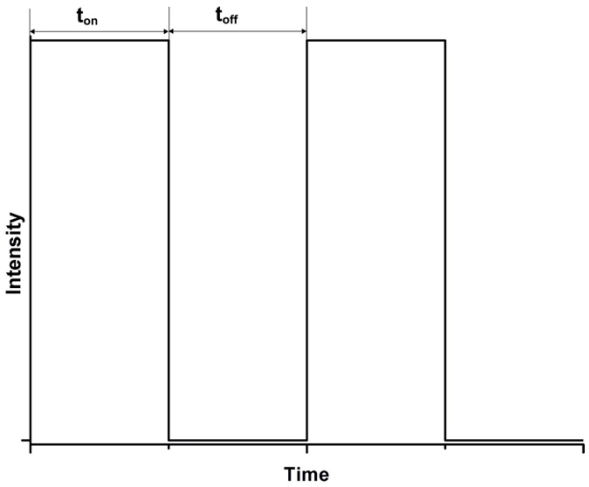

Figure 1. Schematic diagram of light pulses. Duty cycle, $\gamma=t_{on}/(t_{on}+t_{off})$. CPI period, $\tau=t_{on}+t_{off}$.

In this paper we present study of photocatalytic oxidation of acetone vapor under CPI. Equipment used in our experiment, such as extremely bright UV LED and arbitrary pulse generator, allowed us to use rectangular light pulses as short as 50 μs. Dependence of the photonic efficiency on the CPI period observed in our study is similar to the results obtained for water treatment by Cornu et al [3,4], although modelling approach and conclusions are rather different.

2 Experimental/methodology

All kinetic measurements were taken in a reactor which was installed in the automated setup. It allowed us to measure steady state values of the photocatalytic acetone oxidation in the flow-circulating mode. Standard operational parameters were the following: acetone concentration – 600 ppm, temperature – 40℃, relative humidity – 19±2%, volumetric flow rate (U) – 58 cm3/min. The CO_2 and acetone concentrations were measured using gas cell of FT-801 FTIR spectrometer (Simex, Russia)

3 Results and discussion

We investigated the effect of CPI period on photocatalytic acetone oxidation for two commercial TiO_2 samples: Degussa P25 and Hombifine N.

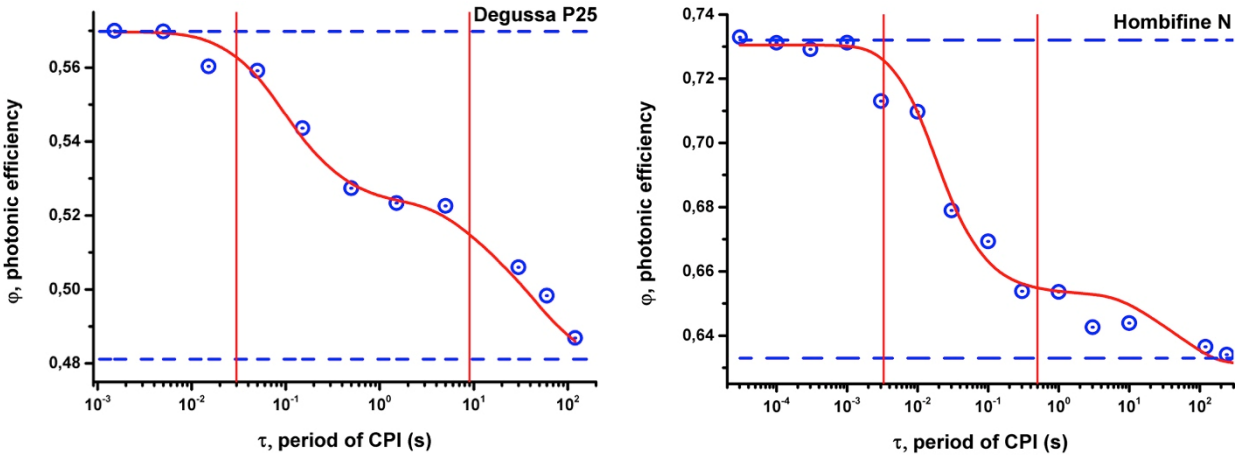

Figure 2. Photonic efficiency under CPI (duty cycle 0.5): circles – experiment, solid curve – model. Higher horizontal line – φ under constant illumination of the same average intensity, lower horizontal line – the same maximum intensity. Vertical lines indicate calculated lifetimes of active species.

The scheme for modelling experimental results in terms of active oxidative species kinetics was developed. We applied several kinetic schemes and most variants provided a good fit to the obtained data. Figure 2 shows the result of the simulation within the following system of differential equations:

$$\frac{d[Ox1]}{dt} = I - k_{Ox1} \cdot [Ox1] - k_{Rec1} \cdot [Ox1]^2; \qquad \frac{d[Ox2]}{dt} = I - k_{Ox2} \cdot [Ox2] - k_{Rec2} \cdot [Ox2]^2$$

Though various mechanisms provide a good fit, it does not affect conclusions we could make regarding mechanism of the photocatalytic oxidation. First of all lifetimes of active species are calculated and indicated on the Figure 2. Secondly our modelling shows that in terms of oxidation, at the high pulse rate the system does not distinguish how energy is provided: with the constant or intermittent illumination.

We studied the influence of intermittent illumination on photonic efficiency of acetone vapor oxidation. The general conclusion is that there are two kinetically distinguishable active species on the titania surface with lifetimes in range of 10^{-3}-10^{1} s. Since our experimental results are in good agreement with studies of Cornu et al., we can conclude that photocatalytic oxidation proceeds through the similar radical mechanism both for gas-solid and water solid interfaces.

Keywords: palladium-gold, electrocatalysts, carbon support, hydrogen, oxidation, reaction, CO, tolerance

1 Introduction

Bimetallic PdAu composites attract attention in view of their potential application at the anodes of polymer-electrolyte membrane fuel cells (PEMFCs) as the catalysts for the hydrogen oxidation reaction (HOR), since their resistance to CO poisoning, which is a critical issue for the low-temperature PEMFCs, may significantly exceed the CO tolerance of "conventional" anode Pt and PtRu catalysts. The aim of our work was to study the PdAu/C electrocatalysts with various surface compositions in HOR and their CO tolerance. Two different synthetic strategies were applied to prepare the PdAu/C catalysts: (*i*) electrodeposition of Pd coatings at the submonolayer level on carbon-supported Au nanoparticles (*a model approach*) and (*ii*) impregnation of the Au/C substrate with Pd(II) nitrate solution followed heat treatments for obtaining the proper Pd-Au alloying (*a pragmatic approach*). In both cases the particular attention has been paid to determination of the surface composition of PdAu nanoparticles providing the maximum catalyst activity in HOR and CO tolerance.

2 Experimental

As the catalyst supports, we used the proprietary carbon materials of the Sibunit family containing mostly 3-10 nm pores in the absence of micropores. The Au/C substrates containing Au particles of 1-5 nm in diameter were synthesized by "cationic adsorption" technique [1]. A series of PdAu/C catalysts with a variable Pd:Au molar ratio were prepared (*i*) by selective electrochemical deposition of Pd metal from the H_2PdCl_4 solution onto the carbon-supported Au particles as described in Ref. [2] and (*ii*) by incipient wetness impregnation of Au/C substrate with the $Pd(NO_3)_2$ solutions of required concentrations followed by calcination in Ar at 250°C and reduction with H_2 at the same temperature. The size, local elemental composition, electronic and structural properties of carbon-supported PdAu particles in the catalysts were studied by TEM/EDX, XRD, XPS and EXAFS using by common procedures. Electrochemical measurements were performed in a standard three-electrode cell using an Autolab PGSTAT 30 instrument. The HOR cyclic voltametry curves for the as-prepared and CO-blocked catalysts were measured at 25-60°C using a rotating disc electrode (RDE).

3 Results and discussion

By varying the time of electrodeposition of Pd on the 1.7% Au/C substrate we obtained a set of PdAu/C catalysts with a systematic variation of Pd coverage (θ_{Pd}) in the range from 0.2 to 0.8 monolayers (ML). The electrochemical data (cyclic voltammetry in a supporting electrolyte, H_{UPD} and Cu_{UPD} region analysis) confirmed that Pd is located exclusively on the surface of Au

particles through layer-by-layer growth. The RDE study demonstrates that the exchange current density (j_0) of the HOR (referred to the Pd surface area) monotonically increases with a decrease in θ_{Pd} from 0.5 to 0.2 ML. Reducing the size of the Au particles used as sites for Pd deposition from 16–19 nm to 1.5–5 nm results in *ca.* 2-fold increase in the j_0 value. The HOR current density measured after CO adsorption (j_{CO}) increases with a decrease in θ_{Pd}, passing through a maximum at θ_{Pd} = 0.30 ML, and the maximum value of j_{CO} exceeds that of the CO-blocked Pd/C catalyst at least by a factor of 10. An increase in the HOR activity observed for the CO-poisoned PdAu/C catalysts at the intermediate θ_{Pd} values is supposedly caused by an appearance of $[Pd]_{x>2}$ ensembles surrounded by $[Au]_y$ ensembles on the surface of PdAu particles, which are less favorable for CO adsorption than Pd "dimers" and "monomers".

The results of the experiments with the "electrodeposited" catalysts revealed good application prospect in the HOR for the catalysts that would contain the well-dispersed alloyPdAu particles. Implementing this idea, we have prepared a set of PdAu/C catalysts with bulk Pd:Au ratios from 0.5 to 3.9 mol/mol by the two-step procedure [3] including post-deposition heat treatments for obtaining the proper Pd-Au alloying. According to the characterization data, the catalysts comprise the alloy PdAu particles of 2-5 nm in size and with the bulk Pd:Au composition that is similar to the molar ratio of metals used in preparation. These particles are not the homogeneous alloys but have Au-enriched cores and Pd-enriched outer shells. The surface layer of PdAu particles contains more palladium at higher bulk ratio Pd:Au. However, increasing the temperature of catalyst calcination in H_2 up to 475°C leads to truly homogeneous distribution of Pd and Au in the bimetallic nanoparticles. The XPS spectra of the catalysts exhibit the negative shift increasing with the surface Pd:Au ratio that indicates a change in the electronic state of Au due to the "ligand" effect of Pd. The dependencies of j_0 and j_{CO} of the "pragmatic" PdAu/C catalysts on their surface composition generally coincide with those for the "electrodeposited" catalysts, but the absolute values of j_0 and, especially, j_{CO} were significantly higher for the alloy PdAu particles compared to Pd-electroplated Au particles with the similar surface composition.

3 Conclusions

The PdAu/C systems with controlled surface composition of the bimetallic sites prepared by selective electrodeposition of Pd on pre-immobilized finely dispersed Au particles are the valid and convenient tools for investigation of the influence of the PdAu surface composition on the catalyst HOR activity and CO tolerance. The formation of Pd-Au nanoalloys leads to a considerable increase in the HOR activity and CO tolerance of the carbon-supported bimetallic catalysts. The PdAu/C catalysts prepared by using the common procedures (ionic exchange, impregnation etc.) and containing the alloy Pd-Au particles of optimal surface composition are promising for application at the PEMFC anodes, since their CO tolerance exceeds that of the commercial available PtRu/Vulcan XC72 catalyst.

Keywords: photocatalytic conversion, CO_2 reduction, 3DOM catalyst

1 Introduction

Solar fuel production by CO_2 photocatalytic conversion provides a sustainable way for carbon recycling and is of significance in meeting energy demand and mitigating rising CO_2 levels. TiO_2 is by far the most common semiconductor in photocatalysis and is used in pollutant degradation, dye bleaching, and water cleaning[1]. The main drawbacks of TiO_2 are its large band gap and massive recombination of photogenerated charge carriers, which make the catalytic efficiency low. The design and synthesis of highly active photocatalyst is one of the most important scientific challenges involving light absorption, electron transfer/separation etc. for the photocatalytic reduction of CO_2. A photonic crystal is a periodic dielectric structure, which offers a unique way of light matter interaction to increase light harvesting via the slow-light effect, especially around the absorption edge of a semiconductor[2-3]. Therefores, we prepared three-dimensionally ordered macroporous materials (photonic crystals) by way of colloidal crystal-templating approach. And we designed and synthesized the novel catalyst of 3D ordered macroporous Ti-supported Au@CdS, Pt@CdS, Au@Pt core-shell NPs via the gas bubbling-assisted membrane reduction (GBMR/P) method[4-5]. These photocatalysts were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), UV–Vis diffuse reflectance spectroscopy, Brunauer–Emmet–Teller (BET) analysis of nitrogen adsorption isotherm, photoluminescence spectra (PL) and the surface photovoltage (SPV) technique. Moreover, 3DOM Ti-based catalysts exhibit efficient catalytic activity for the photocatalytic reduction of CO_2 with H_2O under simulated solar irradiation.

2 Experimental/methodology

Synthesis of monodispersed polymethyl methacrylate (PMMA) microsphere was synthesized using a modified emulsifier-free emulsion polymerization technique with water-oil biphase double initiators. And 3DOM TiO_2 support was prepared by the colloidal crystal template (CCT) method using tetrabutyl titanate as precursor solution. 3DOM Ti-supported catalysts were synthesized by the process of the gas bubbling-assisted membrane reduction-precipitation (GBMR/P) method. Photocatalytic reactions were performed in a stainless-steel reactor with a quartz window on the top of the reactor. The photocatalyst was placed on a Teflon catalyst holder without being immersed in water. The light source was a 300W Xe lamp(l=320-780 nm).

3 Results and discussion

As shown in Fig. 1A, the UV-Vis diffuse reflectance spectrum of 3DOM Au@CdS/TiO_2 catalyst displays distinct and well-defined surface plasmon absorption band centered at about 550 nm, which is the plasmon absorption peak of supported Au nanoparticles. With the

increasing of CdS shell content in 3DOM Au@CdS/TiO_2 catalysts, the intensity of the absorption band at visible region is remarkably increased. And in XRD patterns (Fig. 1B), the diffraction peaks (2θ) at 25.3, 37.8, 47.9, 53.8, 55.3 and 62.8° can be indexed to the (101), (004), (200), (105), (211) and (204) crystal faces of 3DOM TiO_2 with a tetragonal anatase structure (PDF# 21-1272), respectively. And the weak diffraction peaks (2θ) at 27.4 and 36.3° can be indexed to the (110) and (101) crystal faces of 3DOM TiO_2 with a tetragonal rutile structure (PDF# 65-0191). It indicates the co-presence of anatase and rutile crystallites for 3DOM TiO_2 support, which is similar to the phase structure of P25. As shown in Fig. 2, it clearly shows the formation of the core-shell structural Au@CdS NPs. One Au nanoparticle on the surface of 3DOM TiO_2 was covered by the CdS nanoparticles and formed the core-shell structural Au@CdS nanoparticles (Fig. 2C). 3DOM Au@CdS/TiO_2 catalysts can promote the formation of CH_4 and exhibit super photocatalytic activity, which the formation rate of CH_4 are more than 15 $\mu mol \cdot g^{-1} \cdot h^{-1}$.

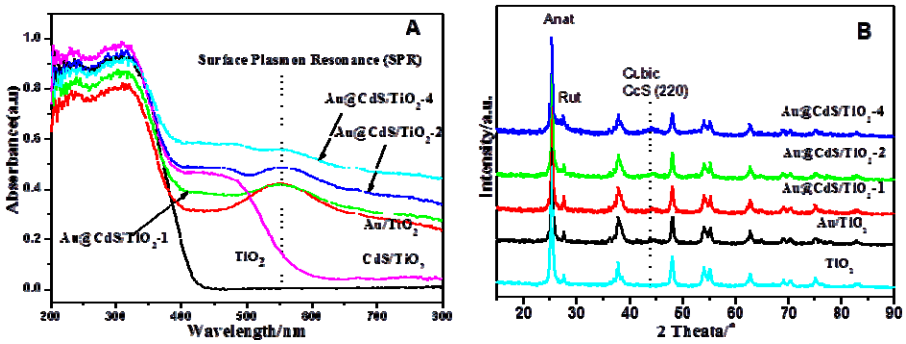

Fig. 1. The UV-Vis DRS spectra (A)and XRD patterns(B)of 3DOM Au@CdS/TiO_2 catalysts

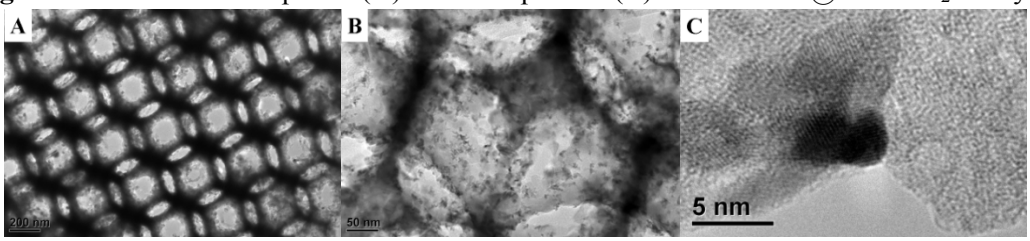

Fig. 2. TEM and HRTEM images of 3DOM Au@CdS/TiO_2 catalysts

4 Conclusions

In summary, we successfully fabricated 3DOM Ti-based catalysts by the process of GBMR/P method. The structure of catalysts is well-defined and uniformed. 3DOM Ti-based catalysts exhibit super catalytic activity for the photocatalytic reduction of CO_2 into methane. The fabrication of metal@oxides core-shell nanostructure on 3DOM oxides surface could be widely applied in various heterogeneous oxides-metals photocatalytic systems.

Advances in Catalyst Characterization by FTIR Spectroscopy

Tsyganenko A.*

* atsyg@photonics.phys.spbu.ru

Keywords: adsorption catalysis, FTIR spectroscopy, active sites, surface, characterization

1 Introduction

Catalyst characterization by means of IR spectroscopy has been mostly restricted to the estimation of acid site strength and concentration from the positions and intensities of the bands in the spectra of adsorbed test molecules. Low temperature adsorption of simple molecules, such as CO, H_2, N_2 and fluoroform, or symmetric highly absorbing molecules such as CF_4 or SF_6 enable us to get other information about the surface of catalysts.

2 Site Testing

Traditionaly, ammonia and pyridine were used as tests for acidity, capable to distinguish Brønsted and Lewis acid sites. Later on nitriles were suggested for the latter, while 2,5-dimethylpiridine (lutidine) was found to be a nice test for Brønsted sites [1]. Low temperature adsorption of simple gases such as N_2, H_2 or especially CO gives more detailed information about Lewis acidity, while frequency shifts of the molecules and of perturbed OH groups characterize the proton-donating ability of surface hydroxyls.

Basicity testing by adsorption of gaseous aprotonic acids, providing the data on the amount of sites, does not inform us about their relative strength. Such information can be obtained from the frequency shifts of CH proton donors: chloroform, HCN, acetylene or its derivatives. For strong basic sites fluoroform CHF_3 is the best, since it never dissociates on adsorption [2].

Ionic species, such as OH- or CN- formed as a result of dissociation of water or HCN, have certain advantage as tests, because due to their charge they interact specifically with the cations. Hydroxyl can bridge two metal atoms, testing dual cationic sites. Spectral manifestations of CO interaction with dual cationic sites were detected on basic zeolites [3]. Spectra of adsorbed cationic species, such as NH^{4+} or NO^{+} [4] are affected by the properties and local arrangement of the nearest oxygen anions.

According to the electrostatic model, frequency shifts of different test molecules can be considered as caused by linear or quadratic vibrational Stark effect [5]. More correct is the correlation of the field with the force constant, because the shift is partially due to other factors, such as the “wall effect” or the resonance interaction with other molecules. Both quantum chemical calculations and electrostatic approach predict the correlation between the electric field of the cations and integrated absorption coefficients, in a fair agreement with the experiment [6].

3 Linkage isomerism

To trap the unstable intermediates of catalytic reaction we can follow spectra evolution with temperature and observe the chain of reactant transformations, while the structure of intermediates can be clarified using isotopic substitution.

Some adsorption products, however, cannot be stabilized at low temperatures, but arise at the surface as a result of thermal excitation. So, CO forms with the cations in zeolites two kinds of complexes [7]. The energetically less favorable O-bonded species have the excess of energy and can be considered as an activated state, intermediate in catalytic reactions. Surface isomeric states were established for some other adsorbed species, such as cyanide ion CN^-[8]. The linkage isomerism can be explained by an electrostatic model, or quantum mechanical calculations. The ability for linkage isomerism depends on the local environment of the site.

4 Lateral interactions

The strength of surface sites is affected by lateral interactions between the adsorbed species. On oxides, repulsive static interaction weakens the neighbouring sites, while dynamic interaction shifts the bands of test molecules and leads to intensity redistribution between the bands [9].

Co-adsorption of acidic and basic molecules leads to mutual enhancement of adsorption. Besides the effect of induced Brønsted [10] or Lewis acidity, induced basicity in the presence of adsorbed bases has also been detected spectroscopically [11]. The concept of induced acidity is consistent with superacidity of oxides doped with SO_4^{2-} and explains the promoting action of aprotonic gaseous acids in the reactions catalyzed by Brønsted sites [12].

Due to extremely strong dynamic (resonance dipole-dipole) interaction between the molecules with very high absorbance, such as SF_6 or CF_4, which do not interact strongly with any surface sites, spectra of these molecules in adsorbed state are sensitive to the geometry of the adsorbed layer. Bandshape of these species is not the same for 2D adsorbed layers on flat crystal faces or chains of molecules in the 1D channels of zeolites [12]. This could become a new promising way for spectral characterization of catalyst surfaces.

Keywords: photocatalysis, TiO_2 nanodiamonds, water splitting, hydrogen production

4 Introduction

Natural resources of energy present on Earth are decreasing year by year. That is why it is necessary to find new ways of producing energy to solve the problem of global consumption. Production of hydrogen using solar energy is one of the key solutions that are envisaged to solve this problem. The process which allows to convert the photons from the sunlight into electrons, is called photocatalysis. In our study we are using titanium dioxide (TiO_2), a cheap and common semi conductor material, as a photocatalyst in order to chemically split the H_2O molecule **[1]**. The hydrogen produced by this process could be used in the future as a source of energy more efficient that gasoline.

The production of hydrogen by titanium dioxide could be improved by chemical or electronical modifications, for example by interaction at the nanoscale with other nanomaterials. The aim of the study is to add nanodiamonds to titanium dioxide and to observe the different interactions between the two materials.

Thus, concerning photocatalytic water-splitting production, the influence of (i) the way of synthesis of the Nanodiamonds/TiO_2 composites, (ii) the composition of the composites, *i.e.* the relative amount of nanodiamonds, (iii) the nature of nanodiamonds (as synthetized or hydrogenated), (iv) the presence or absence of Pt nanoparticules and (v) the addition of methanol acting as sacrificial agent will be discussed.

5 Experimental/methodology

Titanium dioxide is synthesised by a sol-gel process **[2]** and its activity toward H_2 production by water-splitting is compared to that of the reference TiO_2 (P25). For this purpose, titanium isopropoxide ($Ti(OCH(CH_3)_2)_4$) is mixed with ethanol. After vigorous stirring for 30 min at room temperature, a mixture of distilled water, ethanol and acetic acid is added drop by drop into the solution. The resulting solution is stirred at room temperature for 1 h, and then was kept for 24 h in the dark. The obtained sol material is dried at 110 ◦C overnight and then thermally-treated for 3 h in air at 400 ◦C.

The nanodiamonds are synthesized by detonation of high explosives method **[3]**. The Nanodiamonds /TiO_2 composite are elaborated from TiO_2 (as previously described) and detonation nanodiamonds. Different strategies of synthesis have been carried out in order to obtain the composite material. (1) The first one is based on the addition of nanodiamonds during the sol gel process in order to get TiOH gel with nanodiamonds inside the gel. After a calcination step at 400°C, the Nanodiamond/TiO_2 composite is finally obtained. (2) Another way of elaboration is based on the impregnation of already synthesized and crystallized TiO_2 with a suspension of nanodiamonds by mechanical mixing in an aqueous medium under inert gas, followed by a final drying step.

Nanodiamonds with different surface chemistry were investigated, oxygenated and hydrogenated (under H_2 flow at 700°C). Nanodiamonds were also associated with the TiO_2-P25 photocatalyst in order to compare the influence of the TiO_2 nature. The synthesized materials have been characterized by TGA, XRD, UV-visible, XPS, SEM and TEM (Figure 1).

Platinum has been added (as a co-catalyst) by impregnation of H_2PtCl_6 on the composite materials; the results observed with and without platinum will be compared.

6 Results

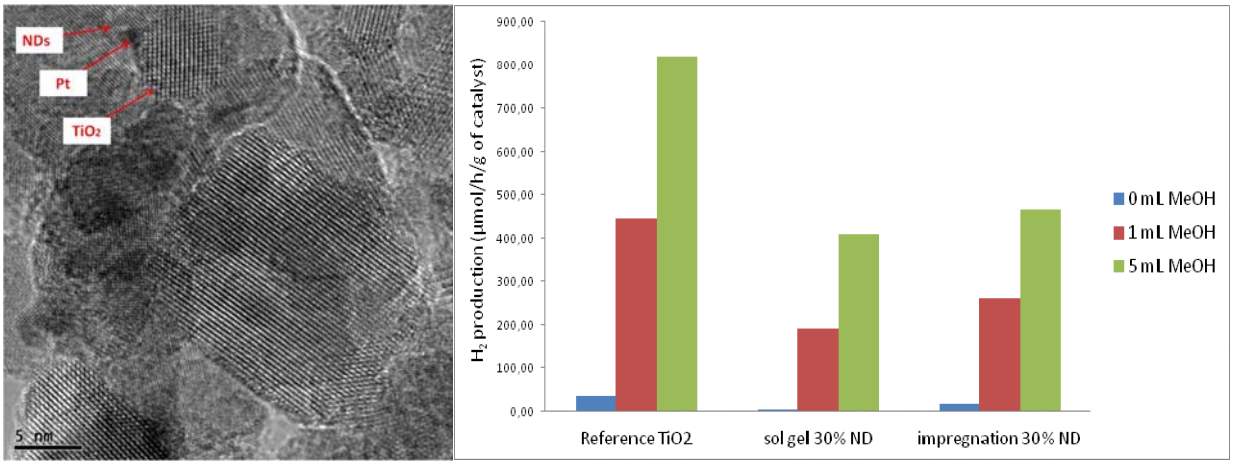

Figure 1: Left- TEM picture of a sol gel-based composite material made of 0.3 wt% Pt-ND/TiO_2; Right- Comparison of the H_2 production of 3 materials (TiO_2 sol gel, sol gel composite ND/TIO_2 with 30 wt% ND, composite ND/TIO_2 with 30 wt% ND obtained by impregnation) having 0.3 wt% Pt with different amounts of methanol added

Figure 1 shows that the sol gel synthesis incorporating nanodiamonds allows to obtain a composite material with physical contact between titania, nanodiamonds and platinum.

Water-Splitting tests were carried out into a quartz reactor containing 900mL of Ultra-pure water and 250mg of sample under flowing N_2 at 100cc/min. Methanol (from 0.1 to 1 vol. %) was used as a sacrificial agent in order to increase yields of hydrogen production. The sample activity (amount of H_2 produced) is measured by a gas phase µGC.

Figure 1 shows the amount of hydrogen obtained with the different composite materials. It allows us to compare the efficiency of the different synthesis and to say that the synthesis by impregnation of ND on TiO_2 gives a higher production of hydrogen than the sol gel synthesis.
An innovative result on the production of hydrogen from Pt-free composite Nanodiamonds/TiO_2 materials will be demonstrated.

7 Outlooks

As short-term perspectives of the project, the long time stability of the catalysts will be studied as well as the influence of the reaction temperature. The impact of the hydrogenated nanodiamonds will also be investigated.

Keywords: TiO_2, co-catalysts, sol-gel method, methanol, H_2 production, controlled surface reactions

1 Introduction

Photocatalytic hydrogen production is a promising approach for transforming solar energy into chemical energy for storage. Methanol which can be obtained from both fossil resources and biomass is a good starting compound for H_2 generation due to its high H/C ratio. Many efforts have been made for photoinduced reforming of methanol on semiconductive oxides in the presence of water providing H_2 and CO_2. Because of its good stability and efficiency, TiO_2 is one of the most frequently used photocatalysts. In the methanol photocatalytic reforming reaction its activity can be increased by at least an order of magnitude when a proper co-catalyst is involved. In addition to decreasing the charge recombination, promoting the charge separation and the transport driven by junctions/interfaces, co-catalysts can provide reaction sites for the elementary reaction steps independent of the light absorption [1]. Pt is a very effective co-catalyst for proton reduction [1] as it shows the lowest activation energy for H_2 evolution. In our previous work we found that in the presence of a Pt co-catalyst the Sn introduction increased the activity of TiO_2 obtained by sol-gel method (SG). In these samples the Sn was not incorporated in to the lattice but the surface of TiO_2 was decorated by amorphous tin-oxide islands [2]. Recent work has reported about a vectorial electron transfer of TiO_2 -> SnO_x ->Pt as the reason of the enhanced activity of Sn grafted TiO_2 [3]. A reliable method to anchor Sn to the surface is the Controlled Surface Reactions (CSR) between tin tetraalkyls and OH groups of the oxide supports [4]. This approach leads to very small SnO_x nanoparticles uniformly distributed on the surface.

Traditionally, noble metal nanoparticles on catalyst supports are formed by high temperature H_2 treatment after impregnation with the solution of the appropriate metal precursor. However, it is believed that the high temperature treatment may destroy the surface of certain semiconductors [5]. In order to prepare co-catalyst on the surface of the photocatalysts in a more gentle way, photodeposition, reduction by $NaBH_4$ or calcination of the impregnated sample are also often used. The aim of this work is to compare the behavior of Pt-SnO_x-TiO_2 catalyst systems prepared by different methods and to find relationships between their structure and catalytic activity.

2 Experimental/methodology

The TiO_2 (Degussa Aerolyst (DA)) was modified by CSR using $Sn(C_2H_5)_4$ dissolved in decane at 150^{o}C followed by O_2 treatment up to 350 ^{o}C according to the literature [4]. SG based tin free and tin modified TiO_2 samples were prepared as described before [2]. Briefly, in the presence of citric acid and absolute ethanol titanium-isopropoxide was stirred for 180 min at room temperature and then heated at 65 ^{o}C until gel formation. In case of Sn modified samples $SnCl_4x5H_2O$ was also introduced into the mixture. The gel was dried and calcined for 5 hours at 400 ^{o}C. The Sn load was 1 w% both in samples by CSR and SG. Pt (1 w %) was introduced from aqueous solution of $Pt(NH_3)_4(NO_3)_2$. The dried samples were either reduced for 1 hour at

400 °C in H_2 atmosphere or calcined for 1 hour at 300 °C. The catalysts were characterized by means of H_2 and CO chemisorption, Raman spectroscopy, BET, EDX, XRD and XPS.
The photocatalytic reactions were carried out at room temperature in a high-throughput system with 10 quartz batch reactors equipped with magnetic stirrers. N_2 gas with 20 ml/min flow rate was continuously bubbled through all reactor units in parallel. The initial concentration of methanol was 6 w% in distilled water. Osram HQL 125W lamps were used as light sources. H_2 formation was followed by GC analysis of the outlet gas upon using argon internal standard.

3 Results and discussion

BET specific surface of DA and SG TiO_2 with or without Sn was comparable (50±10 m^2g^{-1} vs. 75 ± 10 m^2g^{-1}). According to XRD and Raman spectroscopic measurements, DA contains a certain amount of rutile beside the anatase phase while the SG samples are composed of only anatase. The EDX elemental analysis indicates a roughly uniform Sn distribution in samples from both methods but Raman spectroscopy indicates the presence of separate SnO_2 phase in SG sample as a very small shoulder at about 747 cm^{-1} which did not appear in the CSR one.

Figure 1 shows the H_2 production over SG and CSR samples in the presence of Pt co-catalyst formed by calcination (Figure 1A) and H_2 treatment (Figure 1B). In case of the SG samples calcination after Pt loading is more favorable than H_2 treatment and the Sn introduction clearly enhances the activity after both treatments. Conversely, the Sn introduction by CSR is beneficial only in the calcined case, suggesting a difference in the nature of the Sn species in the SG and CSR samples. These observations will be discussed in detail based on XPS and chemisorption results.

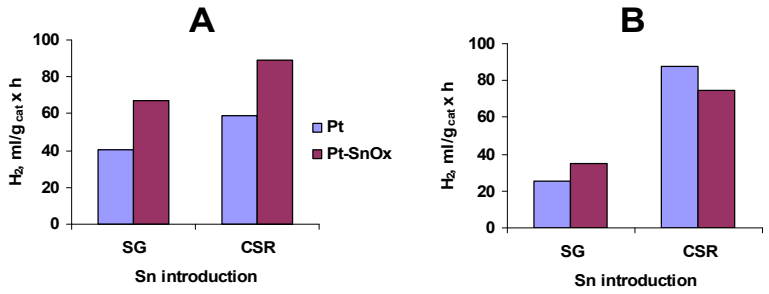

Fig. 1. H_2 formation over different TiO_2 based catalysts. SG: sol-gel prepared; CSR: Degussa Aerolyst TiO_2, Sn introduction by CSR; samples with Pt co-catalyst were calcined or H_2 treated (A and B)

4 Conclusions

Both the way of Sn introduction and the formation of the Pt co-catalyst have a decisive effect on the activity of the Pt-SnO_x-TiO_2 photocatalysts.

1 Introduction

It was proven by Honda and Fujishima in the early 1970s that water can be split photo-electrochemically [1]. Since then, several semiconductor materials for the conversion of harvested light energy into utilizable *solar* fuels have been investigated as heterogeneous photo- or electrocatalysts [2]. However, the usage of metal nanoparticles for catalysis has been investigated thoroughly [3]. Since the reaction rate for most typical metal catalyzed reaction increases due to a larger specific surface area, other effects, like a decreased overpotential or an enhanced charge-carrier separation, play a significant role for photocatalytic water splitting [4]. Still, noble metal promoters (Au, Pt, Pd, etc.) deposited on a semiconductor and sacrificial agents are needed for a reasonable efficiency [5]. It was shown previously that the deposition of Co_3O_4 led to an increased oxygen evolution rate [6].

2 Methodology

It was the aim of this work to investigate possible quantum size effects when depositing a promoter onto a semiconductor for the hydrogen evolution. Therefore, two reference semiconductors were chosen on which Co_3O_4 with different crystal sizes were deposited [7].

I. Synthesis. $Co(OAc)_2 \cdot 4\ H_2O$ was dissolved in an a mixture of ethanol, water and ammonia in different composition. After homogenizing, the Co^{2+} solution was transferred to a 50 ml autoclave, sealed and incubated for 3 h at 150 °C. The resulting suspensions of Co_3O_4 particles were centrifuged and dried at 60 °C for 4 h. These particles were deposited onto g-C_3N_4 (graphitic carbon nitride) and TiO_2.

II. Material Characterization. The resulting materials were thoroughly characterized with N_2-sorption, elemental analysis, diffuse reflectance UV/Vis, XRD, photoluminescence and SEM. Thus, detailed information about the semidconductor material was gained for interpreting the differences in their photocatalytic activity.

III. Catalytic Testing. A 150 W Hg-medium-pressure lamp was used to irradiate a 380 ml aqueous suspension of 100 mg catalyst (incl. 0.5wt.-% Pt^0) in 10 vol-% MeOH. The resulting gases were analyzed every 2.5 min by gas chromatography to monitor the hydrogen evolution over time.

3 Results and discussion

UV/Vis spectra (Fig. 1) of Co_3O_4 suspensions show that different crystal sizes of this material result in different absorption coefficients. The larger the crystal the higher is the light absorption. These results prove that quantum size effects might play a role in the photocatalytic activity of these materials. It was shown previously that Co(II) salts or oxides have an impact on the photocatalytic activity of semiconductors towards oxygen evolution from water. This

behavior might be explained by a reduced overpotential for oxidation reactions *or* an improved electron-hole separation. In this study Co_3O_4 was deposited on TiO_2 and g-C_3N_4. The samples were tested towards their hydrogen evolution rate (HER). The presence of Co_3O_4 increases the hydrogen evolution rate of graphitic carbon nitride (Fig. 1). Thus, it was the aim of the presented work to investigate the size-dependency of cobalt oxide nanoparticles, which were deposited on the solid surface of TiO_2 and g-C_3N_4. As the results imply, such a size-dependency can be found. Although cobalt oxide accelerates the reaction, this effect is stronger for the small and large nanoparticle with a size of 6 nm and 15 nm, respectively. Generally, such an effect is explained by the alternated percentage of different surface atoms. Still, the results might be an artifact from cobalt oxide nanoparticle giving different shapes caused by the hydrothermal reaction conditions. Cyclovoltammogramms and photoluminescence measurements might clarify the role of the cobalt oxide deposited on the semiconductor materials.

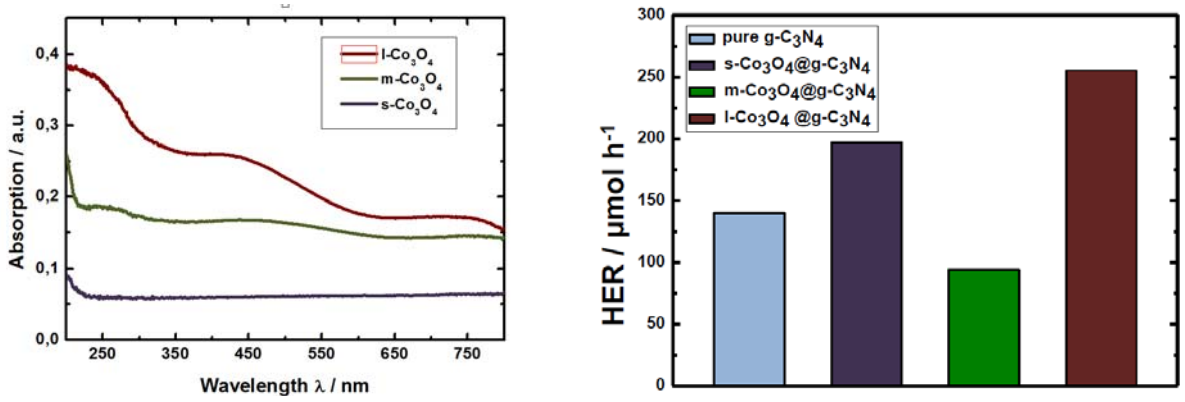

Fig. 1. Left: UV/Vis spectra of aqueous suspensions of 50 mg/l cobalt oxides. Crystallite sizes: l-Co_3O_4 15 nm, m-Co_3O_4 8 nm and s-Co_3O_4 5 nm. Right: Photocatalytic hydrogen evolution rates (HER) from modified g-C_3N_4 show that cobalt oxide acts as a promoter. The results imply a size-dependent effect.

4 Conclusions

The deposition of Co_3O_4 was investigated towards photocatalytic water splitting on two types of semiconductor. Electrostatic adsorption was used to deposit Co_3O_4 on semiconductors. While the presence of Co(II) compounds were previously shown to enhance the photocatalytic activity of semiconductors, the effect of nanoparticle size investigations have not been reported yet. In order to study the success of the particle deposition and the size of the cobalt oxide particles, the modified semiconductors were examined thoroughly. Co_3O_4 was discussed to decrease the overpotential of the water oxidation reaction and stabilize electron holes leading to a higher photocurrent. Nevertheless, a promoting effect was evident.

Keywords: mesoporous, SnO_2, hydrothermal, anodes for PEMFC

1 Introduction

Tin dioxide (SnO_2) is an important n-type semiconductor material, which has been widely used in many applications such as catalysis, hazardous gas sensors, heat reflecting mirrors, transparent conducting electrodes for solar cells, optoelectronic devices [1, 2]. These applications strongly depend on the structure and morphology of the SnO_2 samples, therefore special attention must be paid to the development of reproducible and cost efficient preparation methods of this material. A number of processing methods such as co-precipitation, sol-gel, chemical vapour deposition, laser ablation and thermal redox process have been developed for the preparation of SnO_2. In this study, the synthesis of mesoporous SnO_2 by a hydrothermal route, using a nonionic surfactant – Triton X100 as template, is reported.

2 Experimental

Mesoporous SnO_2 was prepared by a hydrothermal synthesis route as following: $SnCl_4$ aqueous solution was added to the micellar solution formed by a very well dispersion of template- Triton X100 in deionized water. The tetrabuthylammonium hydroxide solution was used to adjust the pH value at 11. After vigurous stirring, the obtained solution has been hydrothermaly treated at 160 ºC for 48h under autogenously pressure. The resulted precipitate was filtered and washed with distilled water, dried at 100 ºC and calcined at 600 ºC for 8h in air. **The differential thermal analysis and thermogravimetric analysis** of the dried precursors were carried out using a TG-DTA analyzer Shimadzu DTA- 60 instrument on 4-6 mg samples in N_2 atmosphere with a heating rate of 5 °C/min from room temperature to 900 °C, using alumina as reference. **X-Ray diffraction analyses** were carried out on a Schimadzu XRD-7000 diffractometer using Cu Kα radiation (λ = 1.5418 Å, 40 kV, 40 mA) at a scanning speed of 0.10 degrees min^{-1} in the 2θ range of 6 – 70 degrees with a step size of 0.02º and scan time of 2°/min. **Porosity Analysis (BET)** - Brunauer–Emmett–Teller adsorption–desorption isotherms of N_2 were investigated using a Micrometrics instrument (ASAP2010) by N_2 adsorption at the nominal temperature of liquid nitrogen (77K) and at a wide relative pressure range from 0.01 to 0.995. Prior the analysis, the samples were degassed at 150 °C for 5h using helium. **Surface analysis** performed by X-ray photoelectron spectroscopy (XPS) was carried out on **PHI Quantera** equipment with a base pressure in the analysis chamber of 10^{-9} Torr. The X-ray source was monochromatized Al Kα radiation (1486.6 eV) and the overall energy resolution is estimated at 0.65 eV by the full width at half-maximum (FWHM) of the $Au4f_{7/2}$ photoelectron line (84 eV). Although the charging effect was minimized by using a dual beam (electrons and Ar ions) as neutralizer, the spectra were calibrated using the C1s line (BE = 284.8 eV) of the adsorbed hydrocarbon on the sample surface (C–C or $(CH)_n$ bondings).

3 Results and discussion

The BET measurements confirm the mesoporosity for the calcination temperature, with high surface area - S_{BET} ~130 m^2/g. The shape of adsorption/desorption isotherm - type IV is typical for mesoporous material, with well-defined hysteresis loop according to the IUPAC classification (Figure 1). SnO_2 show a uniform pore size distribution with an average pore size diameter around 5 nm. The globular morphology of synthesized material is also characteristic for mesoporous materials with nanocrystalline framework. The XRD pattern of mesoprous material can be indexed as SnO_2 with rutile-type tetragonal symmetry, as depicted in Figure 2.

Fig. 1. Adsorption-desorption isotherms for SnO_2

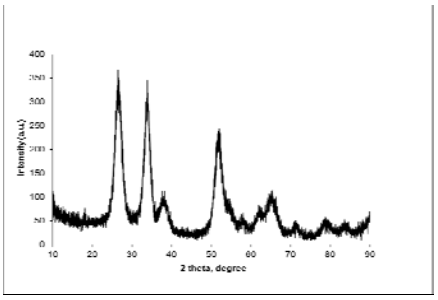

Fig. 2. X-ray diffraction pattern for SnO_2

The sample calcined at 600 ºC exhibited only the tetragonal phase with space group P42/mnm (JCDPS No. 77-0449) and the major peaks appear at 2θ = 26.8º, 33.9º, 38.6º, 51.9º, 62.1º and 65.5º. It is further observed that there is no indication of the presence of both low temperature monoclinic or high temperature cubic phases. Non-symmetrical peaks can be detected at 2θ = 62.1º and 65.8º and are indexed as (310) and (301) planes respectively. The estimated particle size of SnO_2 determined by the Scherrer equation is 9 nm. In order to determine the chemical states and to quantify the elements present on the surface and their quantification the XPS analysis was used. The characteristic BEs for Sn3d are typically assigned to +4 oxidation state. The deconvolution of the O1s photoelectron line shows a surface chemistry with the main lattice bound component (O^{2-}) as well as the OH groups and water confined on the outermost surface layer.

4 Conclusions

Mesoporous pure tetragonal SnO_2 was obtained by hydrothermal synthesis route. Surface chemistry investigations showed that oxidation state of Sn is only +4. The oxygen excess found on the surface comes from OH groups and water adsorbed from environment. The preliminary results obtained in this study show that this material is a good candidate for anode in PEMFC applications.

1 Introduction

Nowadays the use of CO_2 and CH_4 as chemical feedstock may contribute to reduce effectively such greenhouse gases in the atmosphere. Dry Reforming of Methane (DRM) has received considerable attention as an attractive route to produce syngas, CO + H_2, which main application is electricity generation and as intermediate in producing synthetic petroleum via Fischer–Tropsch synthesis. Nickel is the most frequently used metal in DRM because of its good catalytic activity and its cost-effectiveness as compared with Pt, Ru or Rh-based catalysts [1]. However, the formation of significant amount of carbon coke and the particle sintering at the high temperature limit its applications. The addition of second noble metals, such as Pt, Au, Pd may reduce poisoning and deactivation. Some of us have recently found for Ni-Au/$MgAl_2O_4$ catalysts that addition of gold lowered the amount of formed carbon during the DRM reaction [2]. Moreover, a trimetallic catalyst, NiAuPt/Al_2O_3, containing only 0.2wt% of Au and 0.2wt% of Pt showed improved catalytic activity and stability to carbon poisoning with respect to monometallic Ni and bimetallic Ni-Au and Ni-Pt systems [3].

Such promoting effect for the trimetallic catalyst was attributed to the formation of high active Ni-Au-Pt nanoparticles, synergistically interacting, where growth of small amount of bamboo-like carbon nanotubes occurs. Alloyed NiAuPt nanoparticles that could preferentially generate bamboo-like carbon were also postulated on the basis of XRD characterization.

In order to get more insights into the structural and surface properties of such NiAuPt/Al_2O_3 catalyst, EXAFS analyses and DRIFT investigations of CO chemisorbed species were carried out. Monometallic Ni and bimetallic NiAu, NiPt and NiPd/Al_2O_3 catalysts were studied for comparison. The DRM activity was tested in the range of temperature 400-800 °C and for the most active system, NiAuPt, a 5 days long run at 750 °C was registered.

2 Experimental

Monometallic Ni4wt%/Al_2O_3 and bi-trimetallic catalysts containing Ni4wt% and Au(0.2wt%), Pt(0.2wt%) or Pd (0.2wt%) were prepared and studied in the DRM reaction as reported elsewhere [3]. Fresh prepared and spent samples were characterized by XRD, TPR, TEM, EDX and TPO measurements. EXAFS analyses and DRIFT investigations of CO were also performed.

3 Results and discussion

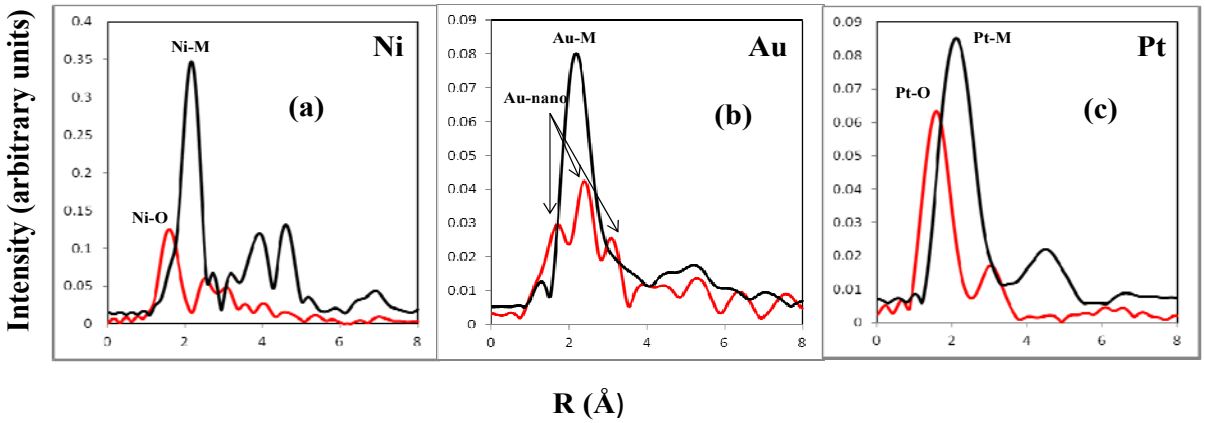

Fig. 1. Fourier transformed EXAFS spectra of (a) Ni-K edge, (b) Au-L_{III} edge and (c) Pt-L_{III} edge.

Figure 1 shows the Fourier transformed EXAFS spectra of Ni-K edge, Au-L_{III} edge and Pt-L_{III} edge in three adjacent plots. The red curves correspond to the calcined NiAuPt catalyst, while the black curve is related to the sample after reduction in H_2/Ar at 750 °C. In the Ni plot, the first peak corresponds to a Ni-O distance at □1.8 Å. After reduction, this peak is observed at a longer distance and with higher intensity suggesting Ni-metal coordination, which in turns points to nickel reduction and/or to Ni-Au/Pt alloy. In the Au plot the red curve shows three peaks at distances of 1.8, 2.5 and 3.2 Å suggesting that Au is distributed as small clusters on the surface. After reduction, a single peak with higher intensity appears suggesting local structural modification. In the Pt plot, a similar shift to that of Ni, was observed after reduction.
DRIFT spectra of adsorbed CO registered over Ni and NiAuPt catalysts evidenced for the trimetallic to a red shift of the linear carbonyl chemisorbed on nickel particles along with higher intensity of the band related to bridging carbonyls chemisorbed on the nickel particles.

4 Conclusions

EXAFS and DRIFT characterizations point out the occurrence of structural and geometrical effects induced by the addition of AuPt to Ni/Al_2O_3. The NiAuPt/Al_2O_3 catalyst demonstrated good catalytic stability during a 5 days long run at 750 °C.

Catalysts (Nimg)Alo_x + Ceo_2 Derived of Hydrotalcite Type Structures Applied to Dry Reforming of Biogas

Mansur A.J., Vallezi Paladino L.A.*

Federal University of São Carlos, Chemical Engineering Department, São Carlos, Brazil

* anandapaladino@gmail.com

Keywords: biogas dry reforming, syngas, hydrotalcites

1 Introduction

Biogas is a product of anaerobic fermentation of organic wastes (for example vinasse) and its main constitution is 60% CH_4 and 40% CO_2 (volumetric average), both greenhouse gases. In this context, dry reforming of biogas can be used to convert it to syngas ($CO+H_2$), which assumes industrial importance once it can be applied as raw material to produce environmentally friendly liquid hydrocarbons similar to diesel and gasoline by means of Fischer-Tropsch processes [1].

In general, dry reforming of biogas is catalyzed by nickel supported in Al_2O_3, especially because of costs issues. However, nickel based catalysts are deactivated during reforming due to formation of carbon deposits over the catalyst surface. Current literature has shown catalysts whose precursors are oxides derived from hydrotalcites applied to methane and biogas dry reforming [2,3]. Rare earth oxides associated to these structures, such as CeO_2, have also been studied in recent years, due to oxygen storage and transport capacities featured by this oxide, which can improve carbon removal [4]. In this work, catalysts whose precursors are oxides derived from hydrotalcites, promoted with CeO_2, were applied to dry reforming of biogas.

2 Experimental/methodology

Hydrotalcites were synthesized by coprecipitation technique, adding a solution containing nitrates precursors of Ni, Mg, Al and Ce ((Ni+Mg)/(Al+Ce) =3) to a basic solution constituted of NaOH and Na_2CO_3. Mixed oxides were obtained by calcinations of the hydrotalcites for 5 hours at 377 K, being referenced as $NiMgAlO_x$ + CeO_2, (x= 5, 10, 15 and 25%, nominal nickel content in weight), while Ce was fixed as 5% (nominal, w/w) in all this oxides. X-ray difraction was used to characterize hydrotalcites and mixed oxides. These last ones were also characterized by CO_2 temperature programmed desorption (after reduction *in situ*) to evaluate their basicity. Catalytic tests were carried at 377 K, with a load of 100 mg of the oxides, using a total flow of 118 mL/minute with $CH_4/CO_2/N_2$ = 48/32/38 (70800 $mL.h^{-1}.g^{-1}$) and CH_4/CO_2=1,5. Before reaction, the oxides were reduced *in situ* for 1 hour, at 477 K, under flow of 10 mL/minute of H_2 and 35 mL/minute of N_2. Carbon deposited over catalyst surface during the reaction was evaluated using thermogravimetric analysis.

3 Results and discussion

Figure 1 shows hydrotalcite phase, whose characteristic peaks are next to planes (003), (006), (110) and (113). Ceria (CeO_2) is also observed in both hydrotalcite and mixed oxide.

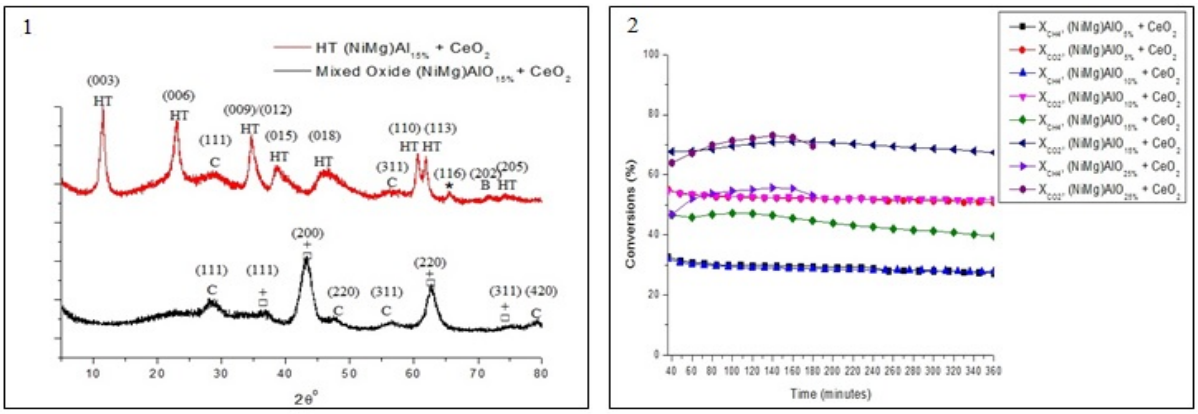

Fig. 1. Hydrotalcites and mixed oxides difratograms (HT-hydrotalcite; C-ceria; B- brucite; □- magnesium aluminium hydroxide carbonate; □- MgO; ⁺ NiO); Fig.2. Catalytic tests

Figure 2 shows that CH_4 and CO_2 conversions increased with nickel content. As detailed in Table 1, carbon deposition followed the same trend, probably because of sintering tendency of metal particles with higher nickel loads. Yet, all of them were stable, even in presence of CH_4 excess, except the one derived from $(NiMg)AlO_{25\%} + CeO_2$. Despite of this catalyst presents higher basicity (see Table 1) than $(NiMg)AlO_{5\%} + CeO_2$ and $(NiMg)AlO_{10\%} + CeO_2$ (after reduction process), this feature was not enough to ensure an extent removal of coke, most likely because of the highest active phase content. It can be said the best catalyst was the one whose precursor was $(NiMg)AlO_{15\%} + CeO_2$ mixed oxide, probably to the highest basicity presented after reduction.

Table 1. Catalysts basicity, carbon deposited after reaction H_2/CO molar ratios.

Structure	**CO_2 desorbed (μmol.g^{-1})/Carbon deposited (gC.h^{-1})/Average H_2/CO**
$(NiMg)AlO_{5\%}+CeO_2$	291/0,002/0,76
$(NiMg)AlO_{10\%}+CeO_2$	200/0,005/0,75
$(NiMg)AlO_{15\%}+CeO_2$	460/0,075/0,85
$(NiMg)AlO_{25\%}+CeO_2$	335/0,268/1,02

4 Conclusions

The catalysts presented here were all actives and stables, except the one derived from $(NiMg)AlO_{25\%} + CeO_2$ mixed oxide. H_2/CO ratios obtained make the syngas produced from biogas dry reforming able to be applied as raw material to Fischer-Tropsch processes.

Role of Rh as a Promoter on the Activity of Ni/Ceo_2-Zro_2 Catalyst for Oxidative Steam Reforming of Bio-Ethanol

Mondal T.[1], Pant K.K.[1*], Dalai A.K.[2]

1 - Indian Institute of Technology Delhi, Department of Chemical Engineering, Hauz Khas, New Delhi, India

2 - University of Saskatchewan, Department of Chemical and Biochemical Engineering, Saskatoon, Canada

Keywords: oxidative steam reforming, hydrogen production, bio-ethanol, Rh promoter

1 Introduction

Hydrogen production from renewable sources such as biomass, is gaining attention due to nearly CO_2 neutral energy supply. Hydrogen production from steam reforming of ethanol has attracted great attention owing to several advantages, such as neutral CO_2 emission, low toxicity, and high hydrogen content in ethanol [1].

2 Experimental/methodology

The catalytic oxidative steam reforming of ethanol (OSRE) for hydrogen production was studied over two selected catalysts Ni/CeO_2-ZrO_2 and Rh-Ni/CeO_2-ZrO_2. The catalysts were prepared by impregnation-co-precipitation method and characterized by BET, XRD, TPR, TPD, TGA, SEM and TEM techniques.

3 Results and discussion

Characterization results revealed that addition of ZrO_2 improves the oxygen storage capacity of CeO_2 which improves catalytic activity. TPR pattern revealed that the addition of noble metals (Rh) resulted in cutback in reduction temperatures probably due to H_2 spill over phenomenon [2]. The NH_3 TPD spectra of Ni/CeO_2-ZrO_2 shows the maximum desorption is occurring at low temperatures which confirms the presence of weak acidic sites.

The effects of temperature, steam to ethanol (S/E) molar ratio, and space time on conversion and product selectivities were investigated in a tubular fixed bed reactor at atmospheric pressure at an ethanol to water molar ratio of 1:9 and oxygen to ethanol ratio of 0.5 over a temperature range of 400 to 650°C (Fig. 1). It was found that conversion increased with temperature and complete conversion achieved at 600°C on $30\%Ni/CeO_2$-ZrO_2 with maximum hydrogen yield of 3.6 mol H_2/mol ethanol reacted. With increasing temperature hydrogen selectivity increased and the same decreasing trend found in case of CH_4 selectivity. Due to the contribution of the water-gas shift reaction below 550 °C CO_2 selectivity increased, while the role of reverse water gas shift reaction is exhibited by an increase in CO selectivity above 600 °C. By changing S/E molar ratio from 9:1 to 6:1 at 600 °C in the feed, the conversion and H_2 selectivity decreased from 99 to 96% and 65 to 60 % respectively. H_2 and CO_2 selectivity was decreased while CO and CH_4 selectivity was increased with decreasing space time. This is because of ethanol decomposion favours more than that of steam reforming reaction at lower space time. After impregnation of 1wt.% Rh on $30\%Ni/CeO_2$-ZrO_2 catalyst, H_2 selectivity increased upto 72% at the same reaction conditions (Fig. 2). Also CO selectivity drops from 14% to 4% on Rh supported catalyst on above reaction conditions. This result clearly indicates that impregnation of Rh on Ni/CeO_2-ZrO_2 catalyst improves catalytic activity by enhancing water gas shift reaction. $30\%Ni$-$1\%Rh/CeO_2$-ZrO_2 catalyst was found to have better catalytic activity than that of $30\%Ni/CeO_2$-

ZrO_2 catalyst. This indicates that addition of noble metal Rh improves the catalytic activity significantly for OSRE.

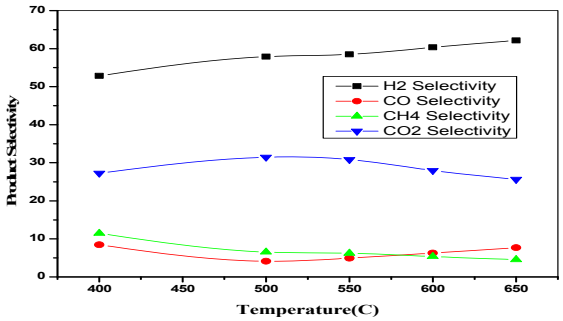

Fig. 1. Effect of temperature on product selectivity at P=1atm, T=600°C, molar ratio EtOH/H_2O/O_2 = 1:9:0.5, W/F_{AO} = 27.52Kgcat.h/Kgmol[EtOH] (Catalyst: 30%Ni-1%Rh/CeO_2-ZrO_2)

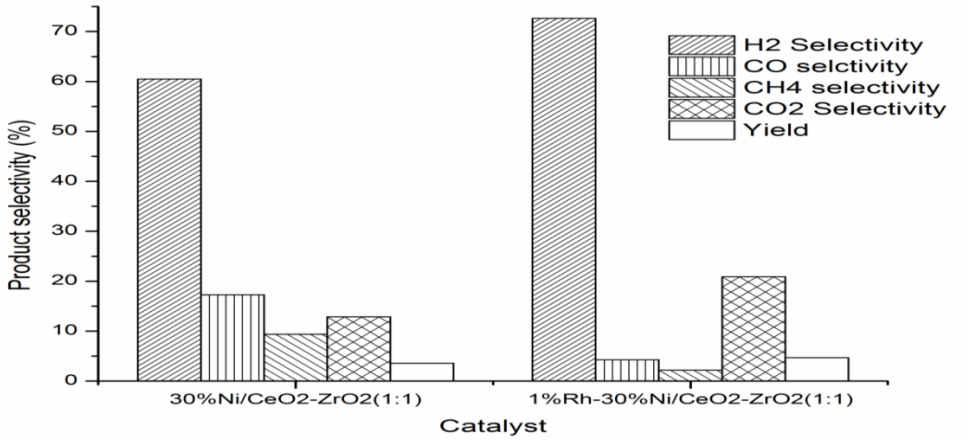

Fig. 2. Product distribution on 30%Ni/CeO_2-ZrO_2 and 30%Ni-1%Rh/CeO_2-ZrO_2 catalysts at T=600°C, P=1atm, molar ratio EtOH/H_2O/O_2 = 1:9:0.5, W/F_{AO} = 27.52Kgcat.h/Kgmol[EtOH]

4 Conclusions

Rh promoted 30%Ni/CeO_2-ZrO_2 catalyst exhibited better catalytic activity for OSRE than that of 30%Ni/CeO_2-ZrO_2 catalyst by enhancing water gas shift reaction.

Ethanol Steam Reforming over $Mn_xCr_{3-X}O_4$-based Spinel-type Oxide

Smal E.A.[1,2*], Mezentseva N.V.[1,2], Sadykov V.A.[1,2], Krieger T.A.[1], Rogov V.A.[1,2], Simonov M.N.[1], Larina T.V.[1]

Keywords: hydrogen production, steam reforming of ethanol, spinel-type oxide

1 Introduction

The rapid development of industry and transport in recent decades resulted in significant increase in energy consumption. According to estimates by the International Energy Agency (IEA) world energy consumption has increased by half from 1970 to 2008. IEA predicts that world energy demand will increase by 65-70% by 2030 compared to 2007 levels [1]. In order to ensure global energy and environmental security the international community is trying to reduce energy dependence on fossil fuels. Transformation of biofuels derived from the fast pyrolysis of biomass or bio-ethanol into syngas is one of the most important tasks of catalysis in the energy-related fields. [2]. Large-scale using of biofuels instead of the traditional hydrocarbon fuels can stabilize the current level of the accumulation of carbon dioxide in the atmosphere and prevent its growth. Bioethanol is the most common biofuel, accounting for 82% of all of the world's fuel from biomass. [3] Steam reforming is one of the most efficient processes for the hydrogen production from biofuels. Due to the high activity of biofuels the main problem of catalysts of steam reforming is their rapid coking that leads to deactivation. In this context it is required to design effective, inexpensive and stable catalysts for steam reforming process.

2 Experimental/methodology

Spinel-like mixed oxides $Mn_xCr_{3-x}O_4$ (x=0.3-2.7) were prepared via modified Pechini route [4]. Commercially available $Mn(NO_3)_2 \cdot 6H_2O$ and $Cr(NO_3)_2 \cdot 6H_2O$ were used as starting materials. Polymerizing agents citric acid, ethylene glycol and ethylenediamine were taken in 3.75 : 11.25 : 3.75 : 1 molar ratio to metal cations. Citric acid dissolved in ethylene glycol was added to aqueous solution of nitrate hydrates. This solution was stirred at room temperature for 2 h. After adding ethylenediamine the mixture was stirred again for 2 h and then kept at 100°C to evaporate water. The resulting gel precipitate was calcined at 500°C for 2 h in air obtaining oxide powder.

Ni or Ru (2 wt.%) were supported on oxides by the incipient wetness impregnation with $Ni(NO_3)_2$ or $RuCl_3$ solutions followed by drying and calcinations at 500°C for 2 h.

Also catalyst deposited on aluminum oxide was prepared by successive impregnation with water solutions of nitrates to obtain loading of 10 wt.% MgO, 10% $MnCr_2O_4$, 2% Ni and 2% Ru. After each coating step sample was dried in a microwave oven and calcined in air at 700°C for 2 hours.

Structural features and microstructure of the catalysts were analyzed by X-ray diffraction, TEM with EDX, UV-Vis and XPS. The reduction behavior was examined by temperature-programmed reduction (TPR H_2).

The catalytic properties of samples in ethanol steam reforming were studied by using flow reactor under atmospheric pressure in diluted (0.5% C_2H_5OH+ 2% H_2O in He, contact time 18-54 ms) and concentrated (10% C_2H_5OH+ 40% H_2O in N_2, contact time 70 ms) feeds.

To establish the route of reaction, one of the best samples was studied by in situ IR spectroscopy

during the reaction of ethanol steam reforming.

3 Results and discussion

According to XRD and UV-Vis data, as-prepared samples are comprised of several phases. Samples with a high Cr content contain cubic spinel $MnCr_2O_4$ and hexagonal Cr_2O_3. In samples with a high content of Mn phases of tetragonal Mn_3O_4 and cubic Mn_2O_3 are observed. Due to a low content of supported Ni and Ru and their strong interaction with oxides, they are not detected as separate phases. A high-resolution TEM shows nanocrystalline particles of chromium-manganese spinel with sizes up to 10 nm. In fresh sample no individual particles of RuO_2 or NiO are observed. They may be incorporated into the surface layers. In reaction conditions, Ni and Ru segregate to the surface forming metal alloy particles with sizes 2-10 nm.

According to H_2 TPR data, for all samples with supported Ru reduction of catalyst begins at lower temperatures than for unpromoted oxides. In the same time no TPR peaks of reduction of RuO_2 were observed indicating strong metal-support interaction.

All catalysts demonstrated a high efficiency and stability in the reaction of steam reforming. Sample 2%Ru+2Ni%/$MnCr_2O_4$, both bulk and supported, showed the best results. In dilute feeds evolution of hydrogen begins at 300°C and attained maximum - 2.5% - at 600°C. In concentrated feed hydrogen yield was 33% at 700°C and ethanol conversion was complete at 600°C. As by-products, methane and small (<1%) amounts of ethylene and acetaldehyde were observed at low temperatures. These results are better than previously obtained for fluorite and perovskite based catalysts earlier investigated in similar conditions in ESR [5]. Results of IR studies indicate that the rate-determining stage is transformation of ethoxy species via dehydrogenation followed by decomposition of acetaldehyde.

4 Conclusions

Highly active and stable to coking catalysts of ethanol steam reforming based on bulk/supported $MnCr_2O_4$ spinel promoted by Ni and Ru were elaborated. This is provided by a strong interaction between metal and oxide support and a high oxygen mobility and reactivity in spinel. According to *in situ* IR spectroscopy data, ESR on spinel-based catalysts proceeds via dehydrogenation route.

Keywords: porous ceramic converters, reforming, hydrogen, syngas

1 Introduction

Original porous ceramic membrane-catalytic Ni-Co-containing converters highly efficient in dry and steam reforming of methane and fermentation products into syngas and hydrogen were developed. The structural peculiarities of these converters and their impact on processes character were studied.

2 Experimental/methodology

Porous ceramic membrane-catalytic converters (PCMCC) produced by self-propagating high-temperature synthesis were used for investigation. The precursors included a Ni metal powder containing 5 mass % of aluminum and a cobalt oxide (II, III) powder. The ready PCMCC contained different amounts of the Ni(Al) and Co_3O_4 active components in the ratios (mass %) 100 : 0, 95 : 5, 80 : 20, 50 : 50, and 0 : 100. The PCMCC material also contained traces of carbon of the graphite press mold in which the PCMCC sintering took place. The PCMCC were porous gas permeable tubes with one end being sealed off and the other end having a round cap of larger diameter for being mounted inside the reactor. The length of the work area (tube) of the PCMCC was 80 mm, the outer diameter was 16 mm, the wall thickness was 3 mm, the average pore diameter determined by mercury porosimetry method and the bubble point method was 1–3 μm, and the material porosity was 40–60%.

The granular catalyst experiments were performed using 2–3 mm size grains obtained by crushing the PCMCC in a jaw crusher.

The dry reforming of methane (DRM) was carried out on a PCMCC in a flow type reactor with a mounted converter (or loaded grains) under the following conditions: $CH_4 : CO_2 = 1 : 1$, T = 400–800°C, W = 20–750 L/h, P_{inlet} = 1.1 atm, P_{outlet} = 1 atm.
The dry reforming of ethanol (fermentation products) or fusel oil (DRE/FO) were conducted on the same setup under the following conditions: EtOH(FO)/CO_2=1:5, T=150-650°C, W up to 1500 l/h, P_{in}=1.1 atm., P_{out} = 1 atm. The FO composition was vol. %: propanol – 19,1; iso-butanol – 17,5; iso-pentanol – 63,4.

The compositions of the initial gas mixture and the reaction products were determined on-line by gas chromatography on a CHROM5 chromatograph with a thermal conductivity detector, high purity argon as the carrier gas (99.998 vol %, flow rate of 30 mL/min), and two chromatographic columns packed by SKT activated carbon. The gas concentrations were determined using Ecochrom software.

The morphology, structure, composition, and particle size distribution for the synthesized PCMCC structures were studied by TEM (JEM 2010, resolving power of 0.14 mm, accelerating voltage of 200 kV) and EDAX analysis. The samples were crushed, and their suspensions in ethanol were deposited on nitrocellulose film substrates, which were placed on standard copper

holder grids, which, in turn, were mounted into the electron microscope chamber.

3 Results and discussion

A non-additive increase in the catalytic activity of PCMCC based on Ni(Al) and Co_3O_4 powders taken in 1 : 1 ratio in DMR in comparison with the sum of activities of Ni- and Co-containing PCMCC was found. It was demonstrated that the specific productivity of the bimetallic sample for synthesis gas reaches 85000 L/(h dm^3) being more than twice higher than these values for PCMCC with a different nickel to cobalt ratio. It was found that the specific activity of the PCMCC in the transformation of methane into synthesis gas substantially exceeds the activity of a fixed bed of granular catalyst of the same composition in a flow type reactor.

Transformation of ethanol in the process of dry reforming differs from the reforming of methane. Ethanol is less thermodynamically stable and more reactive substrate than methane. In this regard, the conversion of ethanol in catalytic channels of a converter is practically exhaustive at temperatures above 350 °C vs. 800 °C in case of methane. According to the programmed thermogravimetry data, the main difference is the reactions of dehydrogenation to form acetaldehyde and its subsequent decarbonylation to methane. The greatest contribution to the reaction of methane formation from ethanol in the DRE processes is made by nickel, the yield of methane increasing with the increase of nickel content. On the contrary, cobalt reduces the content of CH_4 in the reaction products. In the PCMCC the processes of ethanol reforming are intensified in comparison to the implementation of the process in a flow reactor with a fixed bed of granular catalyst of the same composition. However, due to the higher reactivity of ethanol, performance increase is not so high compared to the effect observed in dry reforming of methane.

Dry and steam reforming of organic fermentation products without their preliminary separation proceed efficiently over PCMCC, yielding hydrogen containing gas. Using as feed for dry reforming process the fossil oil essentially widen recourses of feed stock for hydrogen and syngas producing base on renewable raw. It was shown that mixture of organic alcohols have not ethanol as model of fossil oil is enhance feed for producing of syngas with composition close to one obtained from ethanol.

The PCMCC structure was found to contain nanosized Ni–Co alloy particles formed on the γ-Al_2O_3, which are, apparently, responsible for the non-additive increase in the catalytic activity of the nickel–cobalt converters.

4 Conclusions

It was found that PCMCC based on Ni(Al)-Co_3O_4 (1 : 1) demonstrates a non-additive increase in catalytic activity in DRM, DRE/(FO). The reason of such peculiarity might be a presence of Ni-Co-alloy nanoparticles distributed on the surface of a segregated γ-Al_2O_3. It was also established that the specific activity of the PCMCC in the transformation of methane into synthesis gas substantially exceeds the activity of a fixed bed of granular catalyst of the same composition in a flow type reactor what might be connected with a process character in a restricted volume of converter pores.

Dry Reforming of Propane over Ceo_2/Ni-Foam Catalysts

Karuppiah J., Mok Y.S.*

Jeju National University, Department of Chemical Engineering, Jeju, South Korea

* smokie@jejunu.ac.kr

Keywords: propane reforming, synthesis gas, catalysts, carbon deposition, nickel foam

1 Introduction

The catalytic C_3H_8 reforming with CO_2, in which the mixture gas being converted into synthesis gas with H_2/CO ratio of 1 has drawn great interest from the viewpoint of effective utilization of the greenhouse gases and petroleum. The synthesis gas is highly desirable for the production of value-added oxygenated chemicals and liquid fuels [1]. It is well known that the nickel metal is catalytically more active towards reforming reaction, but excess carbon deposition on the metal surface causes the deactivation catalyst. In selecting a catalyst, one needs also to consider other factors such as reactor design. Porous nickel foam (NF) templates are one of the most interesting microstructures and can be used as a catalyst support. The advantages of monolithic or foam reactors over conventional packed bed reactors includes high geometric surface area, low pressure drop when associated with high flow rates, efficient mass transfer, high thermal and mechanical stability [2]. Finally, the active site, especially novel metals can be dispersed uniformly onto the foams, and its confinement effect mainly leads to their activity and stability of supported catalysts, which is a key for the dry reforming reaction. With this background, in this work, we focused on the integration of CeO_2 on Ni-foam by single step wet impregnation method, and analyzing the catalytic activity of CeO_2 loaded Ni-foam for improving propane dry reforming reaction.

2 Experimental

Catalysts preparation

Integration of CeO_2 onto NF (2-4 wt.%) was prepared by impregnation of bare NF within cerium nitrate aqueous solutions of desired concentration. Followed by drying, the NF was calcined at 500^{o}C for 5 h in air to form the crystalline CeO_2 on NF.

Catalytic reaction and characterization

The dry reforming of propane with CO_2 was carried out in a thermo-catalytic reactor packed with 4 g of the catalyst made with cylindrical structures. The catalytic activity was studied in the temperature range of 520–600 °C for all the catalysts. The reactant gases were fed into the reactor at the proportion of 10:30:60 (C_3H_8/CO_2/N_2). The total flow rate was fixed at 300 ml min^{-1} throughout this work. During the reforming reaction, the concentrations of relevant components were analyzed by a gas chromatograph equipped with a thermal conductivity detector (TCD). Numerous techniques, such as N_2 adsorption–desorption isotherm, X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM) and transmission electron microscopy (TEM), and Temperature programmed reduction (TPR) and temperature programmed oxidation (TPD) were applied for characterization of fresh and spent catalysts.

3 Results and discussion

Towards the C_3H_8 and CO_2 conversion, the 4 wt.% CeO_2/NF showed (Fig.1) an improved catalytic activity when compared to 3 wt.%, 2 wt.% CeO_2/NF and bare NF. For 4 wt.% CeO_2/NF catalyst showed desired mass loading and optimal concentration of ceria over NF which favours

for the effective nanoconfinement of CeO_2 particles and superior metal-support interaction. Thereby it was observed the enhanced catalytic reforming efficiency for C_3H_8/CO_2. Typical H_2/CO ratios obtained with the different ceria loaded NF catalysts are illustrated in Fig. 2 as a function of reaction temperature. Over the observed temperature range, the 4 wt.% of CeO_2/NF and 3 wt.% of CeO_2/NF catalysts exhibited relatively higher H_2/CO ratio than the 2 wt.% of CeO_2/NF as well as pure NF.

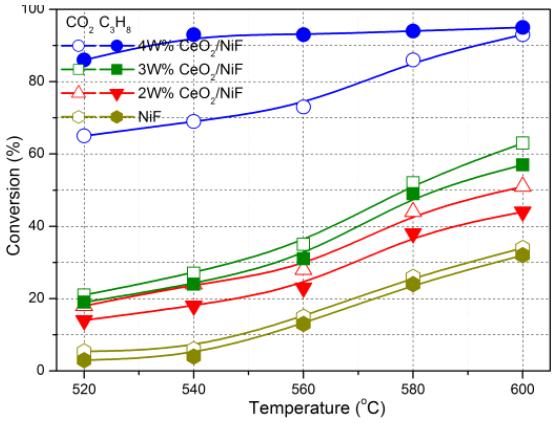

Fig. 1. Conversions efficiencies of C_3H_8 and CO_2

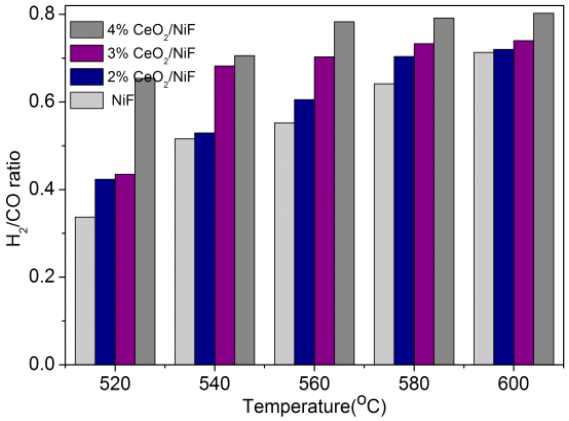

Fig. 2. H_2/CO ratios obtained with different catalysts.

The results of catalyst testing revealed that the catalysts with 4 wt.% CeO2 loading have showed the superior catalytic performance than 3 wt.% and 2 wt.% of CeO_2. After 24 h under stream at 560°C, CeO_2 catalysts showed a stable operation in presence of a deposited amorphous carbon. Carbon deposition on spent catalysts was analyzed by the temperature programmed oxidation (TPO). The structural and phase modification of the catalysts after the reforming reactions were further examined with XRD, SEM, TEM and TPO.

4 Conclusions

Nanocryatalline CeO_2 loaded NF catalysts were investigated in order to evaluate the effect of the support structure on the catalytic activity towards C_3H_8 dry reforming. It was observed the higher dry reforming activity of CeO_2-promoted NF and exhibited good stability against anti-sintering and coke resistance.

Keywords: syngas generation, catalytic heating element, natural gas conversion, external combustion engine

1 Introduction

In many types of heat engine devices a combustible fuel is employed and its heat of combustion is transferred to a working fluid for conversion. A common type in widespread current use employs an open plasma flame as the transfer medium. Another type employs a flameless combustion process that utilizes a catalytic coating at the surface area where heat is to be applied. In practice, an increase in the flow of thermal energy being transferred to the external heat engine is the primary mechanism for improvement of its performance. At the same time, it is known that syngas (mixture of H_2 and CO), which can be prepared by the conversion of natural gas, is catalytically oxidized very easily. We hereby propose a dedicated heating element that promotes the catalytic combustion of syngas, thus generating the primary source of thermal energy input for an external heat engine device.

2 Experimental methodology

A schematic diagram of the proposed catalytic heating element (CHE) design for the one-step process of the catalytic combustion of syngas is shown in Fig. 1. A detailed presentation of the CHE device can be found in Ref. [1], nevertheless, a brief overview of the proposed design is provided here for completion.

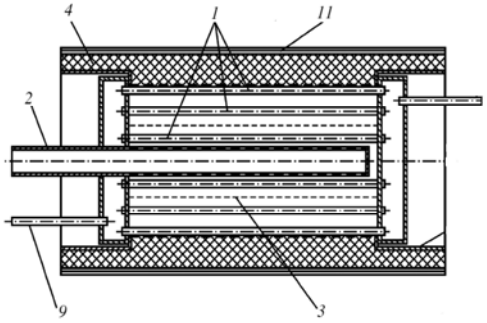

Fig. 1. Schematic diagram of the catalytic heating element (CHE).

The CHE is a cylindrical structure consisting of an annular tubular heat exchanger (1), which is located inside a gas distribution perforated tube (2) where the premixed air-fuel mixture is supplied to the element. In order to promote the uniform distribution of the fuel mixture and the extension of the mixture jets issuing from the holes around the gas distribution pipe, a perforated splitter (3) is introduced around the fuel mixture supply tube. The catalytically active layer (4) has a regular structure, and is composed of five flat and corrugated strips, wound on the tube heat exchanger (1) and sintered together. The thickness of the strips is about 1 mm with the winding pitch on the tube heat exchanger amounts to 27.5 mm. Tapes permeable to the gas form catalytically active channels with a diameter of 2.5 mm. The width of the tapes is 25 mm, and the spacing between adjacent rows of winding is 2.5 mm. The first and last rows are formed by flat ribbons, while the intermediate layers consist of alternating flat and corrugated

strips. To reduce the heat losses, the catalyst layer exceeds beyond the length of the heat exchanger. Furthermore, in order to reduce the start-up time of the heating element (11), the outer layer of the catalyst has a size larger than the critical size of ribbed channels for the penetration of flame into the porous structure.

In this work the CHE shown in Fig. 1 was tested experimentally. The concentrations of the components in the fuel mixture were measured by a GC (Crystal-2000M), and the concentrations of CO and NO_x in the exhaust gases were measured by a gas analyser (KM-900).

3 Results and discussion

The use of the aforementioned CHE device for the catalytic combustion of natural gas (here mainly methane, 86 – 98% by volume) allows the heating power and temperature to be regulated over broad ranges by suitable adjustment of the air-fuel ratio in the mixture. Table 1 shows the results of a comparison of different heat generation methods, while Table 2 shows additional analytical data for the catalytic combustion products.

This process is carried out on reinforced metal porous catalysts produced by self-propagating high-temperature synthesis. According to X-ray analysis, composite catalyst comprises the following phases: Ni, α-Cr_2O_3 and α-Al_2O_3. The specific surface area of 3.4 m^2/g; catalyst characterized by macroporous structure: a main pore volume in pores with a radius from 15 to 100 microns.

The use of such a CHE allows the generation of a high-intensity, uniform heat flux, and therefore, its employment acts to promote the intensification of the heat transfer process to the external combustion engine. In fact, it has been shown that the overall engine system efficiency can be increased to 30-35%, and by using thermochemical recuperation up to 41% [2]. Furthermore, it is evident from our current results that the syngas is generated at the desired ratio of 1:2 and that the concentration of CO and NO_x are within GOST levels.

Table 1. Comparison of different heat generation methods

Type of heating	Parameters
Flame heater 1	$T_{flame} = 1023$ °C; two propane burners: $Q_{pr} \approx 787$ W
Flame heater 2	$T_{flame} = 1847$ °C; acetylene burner: $Q_{ac} \approx 8787$ W
Catalytic heater	$T_{in} = 597$ °C; CHE: $Q_{in} = 3500$ W

Table 2. Analysis of catalytic combustion products

Inlet flow			Output data			
CH_4 (L/min)	Air_1 (L/min)	Air_2 (L/min)	CO (ppm)	NO_x (ppm)	CO_2 (vol %)	O_2 (vol %)
4	14	105	1	6	2.5	12.6

4 Conclusion

A catalytic heater was designed for external heat-engine applications. The high heat fluxes that be attained are highly beneficial for the performance of these heat engines. Tests reveal low emission levels, and a favorable ability to easily vary the output thermal power and temperature.

Keywords: hydrogen, ethanol steam reforming, CoNi catalysts, $MgAl_2O_4$

1 Introduction

Ethanol steam reforming (ESR) is one of the possible industrial processes for hydrogen production. As a transition metal, Ni-based catalysts exhibit high activity in reforming processes and are cost-effective in comparison with noble metal-based catalysts. However, the catalyst deactivation by carbon deposition is a general problem for ESR over supported Ni catalysts. Cooking of Ni surface is an important technological problem and many experimental studies have been addressed to this process. The objective of present work was to explore the structure, surface properties and catalytic performance of Co doped Ni catalysts supported on $MgAl_2O_4$ in ESR.

2 Experimental/methodology

The $MgAl_2O_4$ support employed in this study was prepared by sol-gel method [1]. The supported Ni, Co and CoNi catalysts were prepared by incipient wetness impregnation method of carrier with aqueous solutions of $Ni(NO_3)_2.6H_2O$ and $Co(NO_3)_2.6H_2O$. The obtained solids were dried and calcined under air flow at 110^0 and 550^0 C for 12 and 6 h, respectively. The samples were labeled as 8Ni, 4Co4Ni and 8Co, where the number is the nominal metal content. The samples were characterized by XRD, XRF, XPS, EXAFS, XANES and TEM. Catalytic tests were performed in a fixed-bed quartz reactor at atmospheric pressure and temperature range of 250^0 - 700^0C. Prior to each catalytic reaction the catalyst was reduced under H_2 stream at 750^0C for 1 h. Molar ratio H_2O/C_2H_5OH of 3 was kept. The effluent gaseous products were analyzed on-line by gas chromatograph.

3 Results and discussion

Figure 1 shows the evolution of ESR reaction (outlet composition and ethanol conversion) at different reaction temperatures from 250^0 to 700^0C. Ethanol dehydrogenation to CH_3CHO is observed for all catalysts at low reaction temperatures. Increasing the Co content leads to increase of CH_3CHO formation in a broader range of temperature, which means that this product is important intermediate in the ESR. However, the catalysts show different behaviour in the C-C breaking. A correlation between the cleavage of C-C bond, producing methane and CO, and the degree of reduction and metallic area (Table 1) is well visible for N catalyst at low temperatures. In opposite to that, Co catalyst did not promote the C-C bond cleavage efficiently due to the lowest degree of reduced species. The progressive reduction of Co^{2+} on Co catalyst during ethanol activation causes a progressive C-C bond cleavage at higher temperatures, producing CO, CO_2 and H_2. The high CO_2/CO ratio for Co catalyst at 450^0C suggests a promotion of water gas shift reaction (WGSR) in a higher extension compared to that for Ni-containing catalysts. The bimetallic CoNi catalyst presents behaviours between those of Ni and

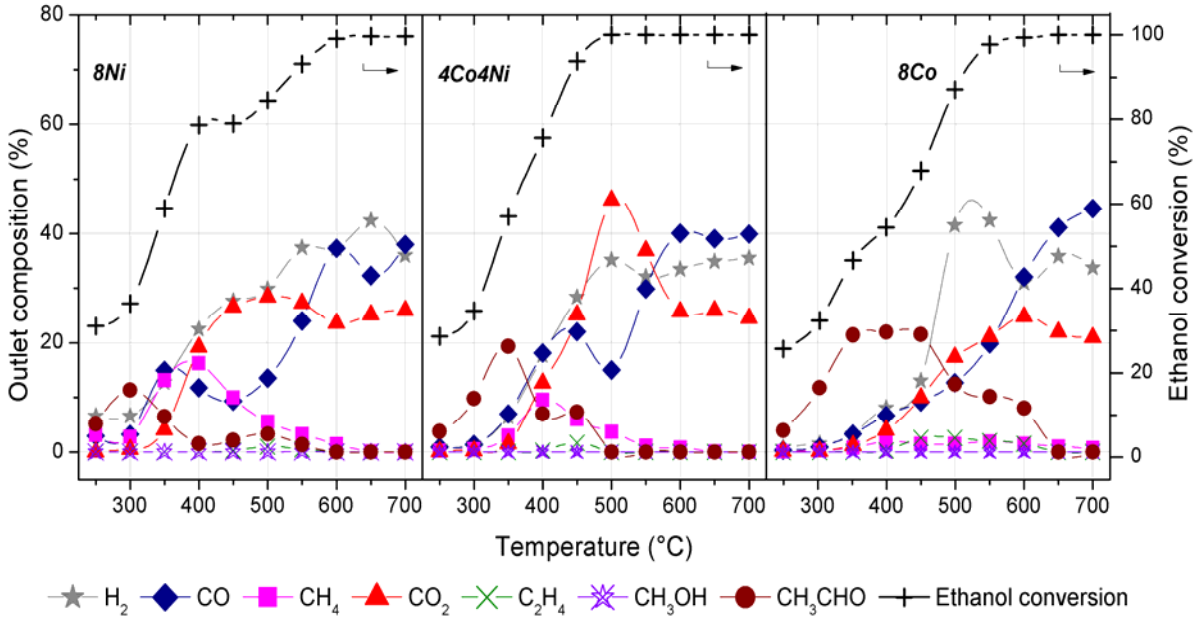

Fig. 1. Evolution of ESR as function of reaction temperature for Ni, CoNi and Co catalysts

Table 1. Physicochemical properties of catalysts

Sample	Reduction degree (%)	Metallic area ($m^2g_{cat}^{-1}$)	Carbon accum. rate ($mgCg_{cat}^{-1}h^{-1}$)
8Co	100	8.83	3.75
4Co4Ni	91	7.29	1.83
8Ni	84	0.75	2.01

Co catalyst. The lower extent of CH_3CHO formation on CoNi at low temperature compared to that of monometallic Co, due to the oxidative dehydrogenation of ethanol, suggests that CoNi catalyst is partially oxidized caused by H_2O activation. After 300^0C the lower extent of CH_4 formation for bimetallic CoNi compared to that for monometallic Ni means that the electronic modification caused by Co-Ni interaction influences the CH_x and HCO species adsorption on catalyst surface. The Co didn't promote the formation of CH_4. For all catalysts the CO_2 formation is increased at temperature > 400^0C, which means a better activation of water and promotion of WGSR, hence the H_2 is also increased. An inversion in the CO_2/CO ratio is observed after 500^0C, most probably, caused by $C + CO_2 \rightarrow 2CO$ (reverse Boudouard reaction).

4 Conclusions

It can be concluded that the different behaviours of $MgAl_2O_4$-supported Co, Ni and CoNi catalysts in ESR are related to the oxidation state of metallic components evaluated by TPR, XANES and EXAFS. Since the metallic sites are responsible for C-C bond breaking and further ethanol dehydrogenation, the Ni catalyst is the most active in ESR at low reaction temperatures (up to 350^0C). The bimetallic CoNi catalyst is more tolerant to carbon formation, showing better ability to oxidize the carbon, which is due to the alloy formation.

A Study on Kinetics of Methane Oxidative Steam Reforming (OSR) over Pt-Ni/Al_2O_3 Bimetallic Catalysts

Erdinç E., Aksoylu A.E.*

Bogazici University, Department of Chemical Engineering, Istanbul, Turkey

* aksoylu@boun.edu.tr

Keywords: catalytic hydrogen production, OSR of methane reaction, kinetics, heterogeneous catalysis

1 Introduction

A fuel processor (FP) is a catalytic system that produces CO-free hydrogen from a hydrocarbon having well established distribution network, like methane [1]. Oxidative steam reforming (OSR), which is a substantially preferred reforming reaction for FPs to be used in small scale applications, is the simultaneous steam reforming and partial oxidation. In OSR, exothermic total oxidation produces energy *(almost)* enough for endothermic steam reforming, which results in energy efficiency. OSR reduces coke formation, and increases stability and hydrogen yield at relatively lower temperatures. Moreover, OSR reactors are advantageous in reformer design due to their compact size, quick response feature, and inexpensive material requirement [2].

In order to design, construct and control an efficient reactor, reliable kinetic expressions must be known for the catalytic reaction of interest. Although power-law type of rate expression does not give a detailed idea about reaction mechanism, they are beneficial for prediction of system performance, comparison of different catalysts and designing reactors. In the previous studies conducted in our laboratory, several Pt-Ni/Al_2O_3 catalysts have been designed, prepared and tested by their propane OSR performance. We also have reliable kinetic expressions for propane OSR over the Pt-Ni system [3].

In the current work, power-law type of kinetic expression for methane OSR over Pt-Ni/Al_2O_3 catalyst is obtained as a function of temperature and partial pressures of methane, oxygen and steam.

2 Experimental

0.2Pt-10Ni/Al_2O_3 catalyst was prepared by sequential impregnation method. The catalyst was reduced *in situ* prior to each experiment. In the kinetic tests, the feed compositions were designed such that the upper-lower limits of the steam-to-carbon (S/C) and carbon-to-oxygen (C/O_2) feed ratios were 3.08-2.03 and 7.34-4.00, respectively. During the tests, conversion-residence time relation was kept linear for guaranteeing that the reactions were in kinetically controlled region. Experiments were conducted at 375 °C and atmospheric pressure for different partial pressure values for each reactant (i.e. methane, oxygen, steam) at two different non-zero residence time (W/F) values (Table 1). Rate orders with respect to methane, oxygen and steam were calculated by applying multivariable non-linear optimization function of MATLAB™ to the "methane conversion versus residence time" data. For the activation energy calculations, Set 4 in Table 1 was repeated at 350 and 400 °C. A power-law type rate expression as a function of partial pressures of reactants and temperature is proposed.

3 Results and discussion

The initial methane consumption rates were listed in Table 1 with corresponding partial pressures of reactants – methane, oxygen and steam. Methane consumption rates were obtained

from intrinsic kinetic data in the initial rate region by using differential method of analysis. Reaction orders with respect to methane, oxygen and steam partial pressures were estimated as 0.81, 1.60 and 0.44, respectively by non-linear regression analysis on 17 sets of "initial rate versus partial pressures of reactants" data (Table 1). Reaction rate showed positive dependency for all reactants with a decreasing order of oxygen, methane, and steam as expected.

Table 1. Initial rates of methane OSR reaction with varying feed compositions over the 0.2Pt-10Ni catalyst at 375 °C.

Set #	P_{CH4} (kPa)	P_{O2} (kPa)	P_{H2O} (kPa)	CH_4 Consumption Rate (μmol mg^{-1} s^{-1})	R^2
1	15.21	3.80	46.28	34.25	0.98
2	16.71	3.80	46.28	45.81	0.93
3	18.36	3.80	46.28	49.17	0.93
4	19.77	3.80	46.28	43.56	0.96
5	21.27	3.80	46.28	44.06	1.00
6	22.80	3.80	46.28	57.29	0.95
7	19.77	2.69	46.28	23.72	0.99
8	19.77	2.99	46.28	37.86	0.98
9	19.77	3.37	46.28	36.36	1.00

14	19.77	4.11	50.66	55.76	0.92
15	19.77	4.11	53.70	49.78	0.93
16	19.77	4.11	56.74	61.13	0.96
17	19.77	4.11	60.80	61.15	0.99

After reaction orders were determined, Set 4 in Table 1 was repeated at 350 and 400 °C. Temperature interval was kept narrow within ±25 °C in order to eliminate any possible effect of temperature on reaction path. The apparent activation energy and the pre-exponential factor were estimated as 0.956 μmol.mgcat^{-1}.s^{-1}.kPa$^{-2.85}$ and 39.05 kJ.mol^{-1}, respectively, by using Arrhenius equation.

4 Conclusions

Kinetic study was performed for determining intrinsic reaction rates of methane OSR over 0.2Pt-10Ni catalyst at 375 °C. Multivariable non-linear optimization function of MATLAB™ was utilized to estimate reaction orders. The proposed power-law type rate expression that is reliable in the range of $2.03 < S/C < 3.08$ and $4.0 < C/O_2 < 7.34$ feed ratios has reaction orders as 0.81, 1.60 and 0.44 in methane, oxygen and steam partial pressures, respectively. The apparent activation energy for methane OSR was calculated as 39 kJ.mol^{-1} and pre-exponential factor as 0.956 μmol.mgcat^{-1}.s^{-1}.kPa$^{-2.85}$ in the 350-400 °C interval.

Keywords: hydrogen, methane, isooctane, n-tetradecane, nickel, aluminate, oxidative steam reforming

1 Introduction

Natural gas and liquid fuels, derived from either fossil or renewable sources, represent an attractive source of hydrogen since their distribution infrastructure is readily accessible. Among the several reforming methods available (i.e. steam reforming (SR), partial oxidation (POX), and oxidative steam reforming (OSR)), OSR is most appropriate for minimising carbon deposition in hydrocarbon reforming. OSR has several advantages of both of POX and SR, such as rapid start-up, dynamic response, and relatively rich-hydrogen yields. Moreover, it is suited for heavier hydrocarbons, such as gasoline and diesel.

Noble metal-based catalysts are more efficient because of their long-term activity and coke resistance, but their cost is high. In contrast, nickel-based catalysts appear to be a good alternative although they may undergo severe deactivation due to carbon deposition. In our previous research it was shown that $NiAl_2O_4$ spinel can be a promising catalytic precursor to develop suitable Ni/Al_2O_3 catalysts with a high reforming activity and a marked stability [1,2]. In this work, the attention has been focused on the comparison of the reforming efficiency of various hydrocarbons such as methane, isooctane and *n*-tetradecane, selected as model compounds for natural gas, gasoline and diesel, respectively, in the oxidative steam reforming over a co-precipitated $NiAl_2O_4/Al_2O_3$ catalyst.

2 Experimental/methodology

The catalyst denoted as CP(17) was prepared by co-precipitation at pH = 8 using an solution containing a mixture of $Ni(CH_3\text{-}COO)_2{\cdot}4H_2O$ and $Al(NO_3)_3{\cdot}9H_2O$ in a Ni/Al = 0.5 molar ratio with alumina (γ-Al_2O_3, 133 $m^2\ g^{-1}$) to obtain 17wt.% nickel loading [1]. The catalytic tests were performed, on 125 mg of catalyst, in a flow reactor operating at atmospheric pressure at a constant temperature (600 ºC) for 31 h. The reaction mixture consisted of the selected hydrocarbon (15.6%CH_4, 1.95%*i*-C_8H_{18} or 1.1%*n*-$C_{14}H_{30}$) and O_2 and H_2O (with a O/C=1 and H_2O/C=3) diluted in N_2 and a total flow rate equal to 800 $cm^3\ min^{-1}$. Prior to the reaction, the catalyst was activated by reduction with 5%H_2/N_2 at 850 ºC for 2 h. The catalytic results were compared on the basis of an identical carbon-based volume hourly space velocity, namely 60000 $cm^3\ C\ g^{-1}\ h^{-1}$.

3 Results and discussion

Previous studies evidenced the potential of the CP(17) catalyst for methane steam reforming at moderate volume space velocity (38400 $cm^3\ CH_4\ g^{-1}\ h^{-1}$) due to the structural homogeneity of the Ni^{2+} species present in the calcined precursor [1]. This resulted in a low crystallite size, high dispersion and metallic surface area (9.5 nm, 33% and 40 $m^2_{Ni}\ g^{-1}$, respectively) after a high temperature reduction (850 ºC).

As a general behaviour, Fig. 1 showed that the higher reforming efficiency, with respect to the corresponding thermodynamic equilibrium values (squares), was obtained for CH_4 followed by *i*-C_8H_{18} and *n*-$C_{14}H_{30}$. As for the product distribution (H_2, CO, CO_2 and CH_4 as main products), the obtained H_2 yield in oxidative steam reforming of CH_4 and *i*-C_8H_{18} was quite similar (1.2 and 1.3, respectively). Interestingly, the H_2 yield in methane OSR accounted for the 96% of the equilibrium value while it was 81% in isooctane reforming. In addition, methane OSR led to the highest H_2/CO ratio (13). On the other hand, the CP(17) sample evidenced the poorest catalytic activity in *n*-tetradecane oxidative steam reforming with a 42% initial conversion which decreased gradually during the first 5 h to reach a stationary state (38%) with time on stream. This activity loss further impacted on the resulted $Y(H_2)$ (0.3).

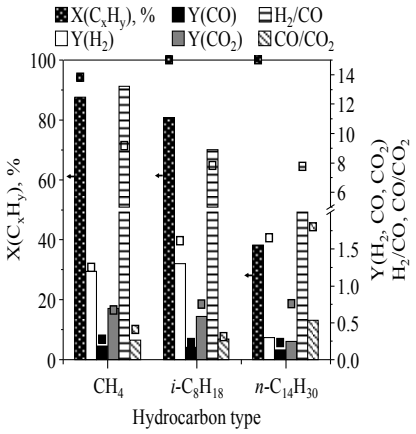

Fig. 1. Comparison of the oxidative steam reforming efficiency of various hydrocarbons.

The detected deactivation during the OSR(*n*-$C_{14}H_{30}$) could be related to several causes such as coke formation (mainly caused by catalytic decomposition of the hydrocarbon, the thermal cracking reactions or Boudouard reaction), nickel sintering and/or partial oxidation of the metallic nickel into NiO. In line of previous results [1], the OSR of CH_4 did not lead to coke deposition. In case of the heavier hydrocarbons, a notable amount of filamentous coke (24 and 37% for *i*-C_8H_{18} and *n*-$C_{14}H_{30}$, respectively) was noticed, as revealed by TPO and TEM analysis. It seems that the OSR(*n*-$C_{14}H_{30}$) is prone to form high concentration of ethylene (C_2H_4) which is a recognised coke precursor [3]. Moreover, the temperatures required for oxidation were remarkably higher than for *i*-C_8H_{18} indicating the presence of a well developed graphitic structure. Raman profiles also confirmed these results with two distinct bands D Band (amorphous coke) and G Band (graphitic coke) with clearly different I_D/I_G ratios, 1.2 and 0.8 for isooctane and *n*-tetradecane, respectively. This suggested that the nature of the deposited coke from isooctane OSR was less graphitic resulting in lower combustion temperatures.

4 Conclusions

This work confirmed the feasibility of the co-precipitated $NiAl_2O_4/Al_2O_3$ catalyst in the reforming of different hydrocarbons. It was found that the high stability of OSR of CH_4 and *i*-C_8H_{18} was related to a negligible or minor coke deposition in comparison with *n*-$C_{14}H_{30}$. In this way the effect of unavoidable filamentous coke formation on the performance of heavy hydrocarbons, with a less impact on the OSR(*i*-C_8H_{18}), could be minimised with higher reforming temperatures or higher H_2O/C ratios.

Keywords: LaNi1-xCoxO3, catalysts, methane, CO_2, reforming, methane, CO_2+H_2O, reforming

1 Introduction

Dry reforming of methane is a technology that allows the use of two of the major greenhouse gases: exploiting the greenhouse gas CO_2 as raw material could be more advantageous than its long-term storage. As the simulations of reforming equilibrium highlights the fact that water was always produced in the CO_2 reforming of methane and it is also present in NG or biogas composition. Therefore, CO_2 transformation conducted with water in the feed stream provokes H_2 selectivity changes at equilibrium and enable the coke gasification by catalysts with the water. The combination of CO_2+H_2O reforming of light hydrocarbons improves not only the H_2-selectivity but also modifies of carbon formation-deposition process. Nickel is mostly used for this reaction due to the availability and cost but it is rapidly deactivated by coke formation. Efforts have been made to avoid this deactivation by synthesizing Ni catalysts via introducing metal in the perovskite type oxide (ABO_3). So, in this contribution, a series of LaNi1-xCoxO3 perovskite-type oxides was well-characterized and tested in the dry and (C_2+H_2O) mixed reforming of methane with the aim to improve the H_2 selectivity and study the catalysts stability .

2 Experimental

The ternary oxides $LaNiCoO_3$ were synthesized via citrate method using metallic nitrate precursors. Catalysts were characterized before and after reaction by conventional methods. Steady state experiments were carried out at atmospheric pressure. A tubular fixed bed stainless steel reactor (i.d. 9 mm) with 100 mg of catalyst was employed. The total gas flow rate was kept constant at 0.8 Ncm^3s^{-1} with stoichiometric composition in He, $CH_4/CO_2/He$=20/20/60 for CO_2 reforming and $CH_4/CO_2/H_2O/He$=3/1/2/9 for the CO_2+H_2O reforming. The space velocity and the contact time were 6000 h^{-1} and 0.8 $ghmol^{-1}$ respectively; operating under plug flow conditions. The catalytic properties have been evaluated in terms of CH_4 and CO_2 conversions, H_2 and CO selectivity and H_2/CO ratio.

3 Results and discussion

TEM images recorded before reaction confirm the presence of Ni particles together with a phase corresponding to the lanthanum oxycarbonate in the $LaNi_{1-x}Co_xO_3$ catalysts. For $LaCoO_3$ the TEM micrographs have revealed the formation of $LaCoO_3$ particles with perovskite structure and their tendency to agglomerate. After reaction some particles appear to be aggregated, the nickel particle size being comprised between 5-15 nm and as were recorded by EDAX analysis correspond to Ni^0. Additionally, it can be observed carbon nanotubes formation, where a variable carbon content between 10-20% for the serie, were registered from the elemental analysis.

CH_4-conversion and H_2-selectivity for dry and mixed reforming for $LaNi_{1-x}Co_xO_3$ catalysts are displayed in the Figure 1. The results showed that the conversion rates of CH_4 increased in those catalysts with highest Ni content for the CO_2 reforming of methane. While the activity in terms of CH_4 conversion was similar for those Ni/Co mixed oxide catalysts by the presence of water vapor.

Hydrogen yields depend on metal and the ratio of Ni to Co. The best performance in terms of highest hydrogen yield was achieved with the $LaNiO_3$ and $LaNi_{0.8}Co_{0.2}$ catalysts for methane dry reforming. Otherwise, the positive effect of water vapor in the selective reforming of methane was also observed in the H_2-selectivity over $LaNi_{1-x}Co_xO_3$ serie, achieving similar H_2-values above 923K; as well as a significant reduction of the coke formation performed by Co incorporation in the mixed oxides.

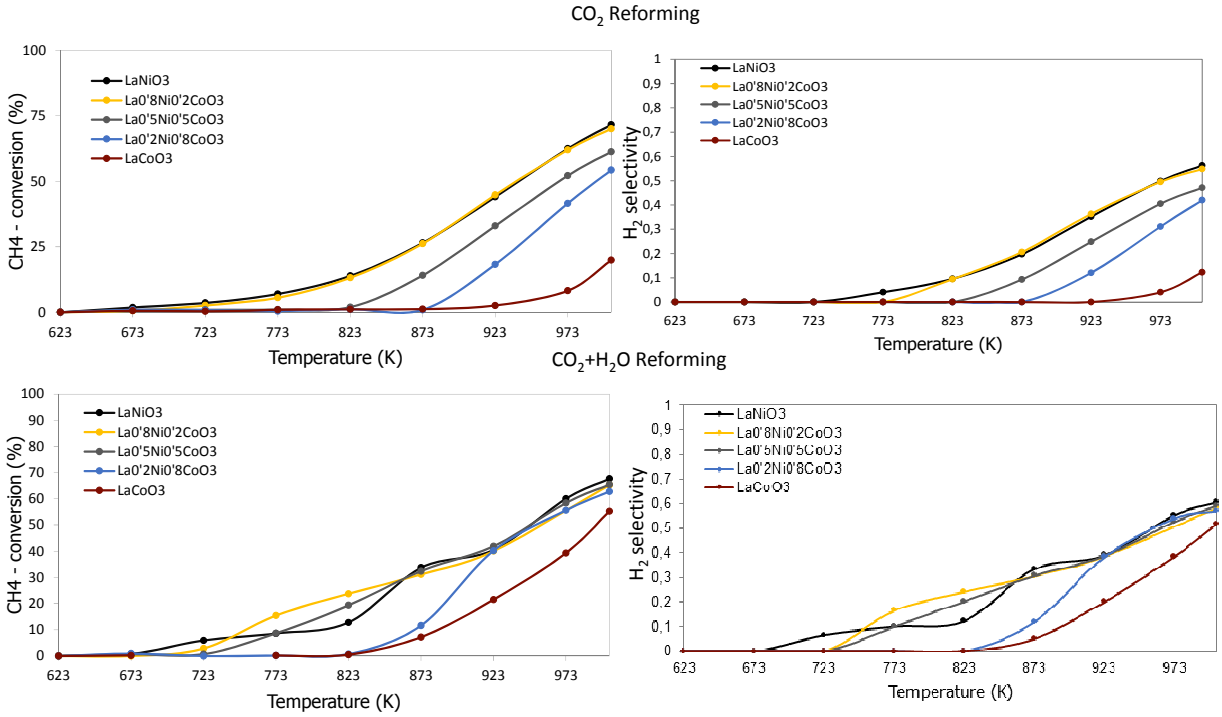

Fig. 1. Conversion/selectivity (%) vs.T (K) curves of methane CO_2 and methane CO_2+H_2O reforming over $LaNi_{1-x}Co_xO_3$

2 Conclusion

For the higher Ni content perovskite-catalysts, the Ni nanoparticles are apparently to be very sensitive to CH_4 activation in the CO_2 atmosphere; i.e., combination of CH_4 decomposition and CO_2 gasification. However, in the CO_2+H_2O reforming, methane conversions and H_2-selectivity were found to be similar at lower temperatures for this $LaNi_{1-x}Co_xO_3$ serie, because the activation of methane is mainly performed with steam while CO_2 could react eventually with H_2 and/or methane.

Development of Sulphur Tolerant Catalystsfor the Conversion of Carbon Dioxide to Methane

Kolb G.*, Neuberg S., Pecov S., Pennemann H., Zapf R., Ziogas A.

Fraunhofer ICT-IMM, Mainz, Germany

* gunther.kolb@imm.fraunhofer.de

Keywords: methanation, sulphur tolerance, microreactors, energy storage

1 Introduction

The increasing share of renewable energy generation sources in Germany creates a surplus of electric energy, when wind or sunlight is available. Therefore the storage of electric energy comes into focus to compensate the drawbacks of its irregular production by renewable sources. The chemical storage of electric energy seems to be a viable solution. One obvious solution is the electrolysis of water to hydrogen and oxygen. However, once the hydrogen is produced it needs to be stored. Alternatively it could be fed into the natural gas grid, which is well developed in Germany. The addition of hydrogen to natural gas is limited though, because the flame propagation properties of natural gas are affected by hydrogen.

The conversion of hydrogen with carbon dioxide from renewable or non-renewable sources such as biogas plants, power plants or steel fabrication to methane allows the unlimited addition of an energy carrier to the gas grid while the carbon oxides are re-utilized instead of being directly released to the atmosphere.

The methanation of carbon dioxide, also named as Sabatier process, is an exothermic reaction:

$$CO_2 + 4H_2 \Leftrightarrow CH_4 + 2H_2O \quad \Delta H = -165 \ kJ/mol \qquad (1)$$

High temperature not only reduces the maximum carbon dioxide conversion through the thermodynamic equilibrium but also favours the undesired competing reverse water-gas shift reaction (RWGS):

$$CO_2 + H_2 \Leftrightarrow CO + H_2O \quad \Delta H = +41 \ kJ/mol \qquad (2)$$

Owing to the Le Chatelier principle, the methanation reaction is favoured by elevated pressure. However, state-of-the-art electrolysers work in the pressure range above 10 bar and therefore it seems obvious to perform the reaction at similar pressure.

Carbon dioxide from biogas plants contains significant amounts of sulphur species, which tend to poison the catalysts. The focus of the current paper is on the improvement of the sulphur tolerance of ruthenium containing catalysts. Ruthenium is known to be a highly active catalyst for the methanation reaction, though its sulphur tolerance is quite low.

2 Experimental/methodology

The catalysts under investigation were introduced as coatings into microchannel reactors. The coatings were prepared by wet impregnation of a self-prepared ceria carrier with the active species prior to the wash-coating procedure which has been described previously .

The reaction was performed in small testing reactors, which have been described in detail elsewhere . The feed was provided by thermal mass flow meters and contained 80 Vol.% hydrogen and 20 Vol.% carbon dioxide apart from 1 ppm hydrogen sulphide, which was added to the hydrogen as readily prepared mixture. The feed flow rate was set in such a manner, that the Volume Hourly Space Velocity (VHSV) always amounted to 40 L/(h g_{cat}). An overpressure valve served as pressure actuator, which kept the operating pressure at 12.5 ±0.5 bar quite

reliably. The analysis was performed by an Agilent gas chromatograph, which worked on-line and with loop filling manager and separate analysis of water and permanent gases through different detectors.

3 Results and discussion

Fig.1 shows the carbon dioxide and carbon monoxide conversion and the selectivities as determined over different ruthenium containing catalysts. It is obvious from Fig. 1a, that the catalyst containing 5 wt.% Ru and 1 wt.% Rh deactivates rapidly and the deactivation is accompanied by an increasing selectivity towards carbon monoxide, which appears with a certain time shift. Addition of a higher amount of Rh (5 wt.%) slows the catalyst deactivation down (Fig.1b). The addition of 30 wt.% Ni to the catalyst formulation lead to similar initial activity as for the other samples, but further increased stability of the catalyst (see Fig.1c). The increasing selectivity towards carbon monoxide was observed after approximately 40 hours compared to 2 h and 26 h for the former samples respectively, which is attributed to the formation of nickel sulphide species, i.e. the nickel served as "sulphur trap". Ethane was found as only other by-product of the reaction system, which is formed with increasing selectivity with the course of catalyst deactivation, but only in the range of 1 %. The origin of the deactivation of the samples will be discussed applying different characterization techniques and further improved formulations will be presented.

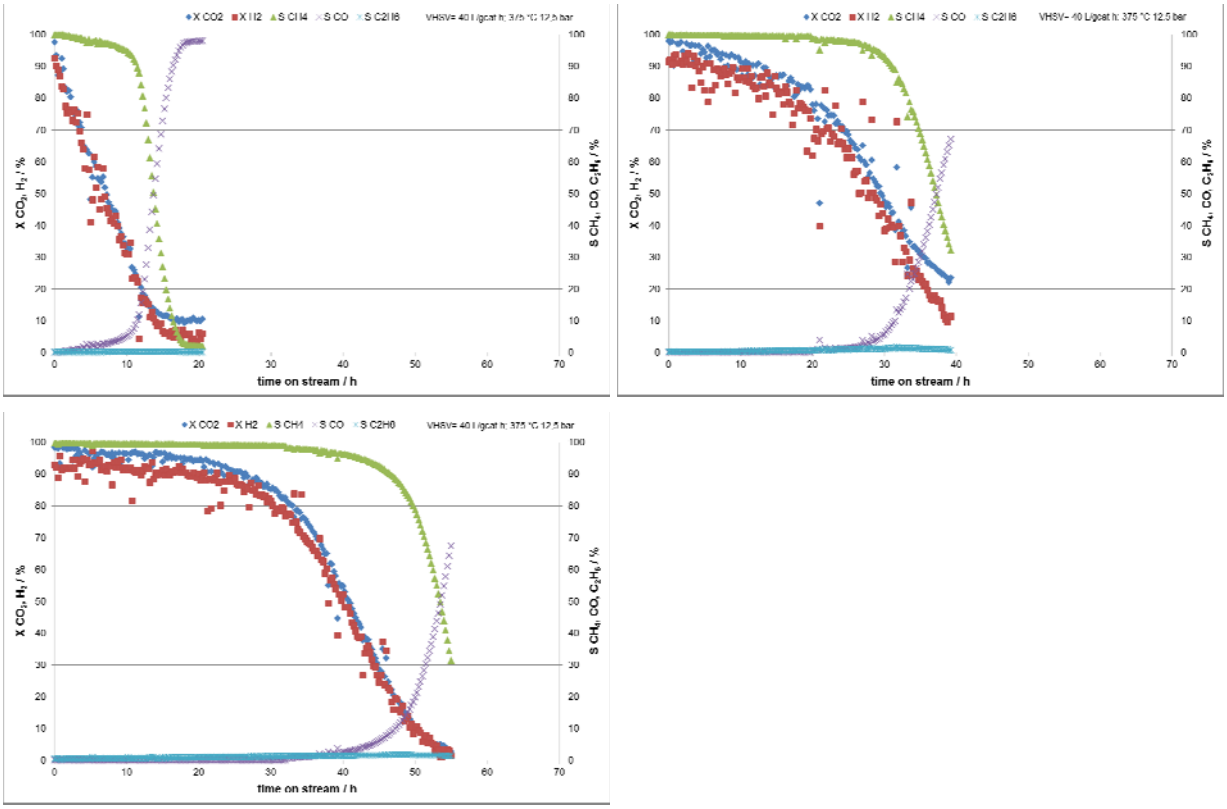

Fig. 1. Conversion of hydrogen and carbon dioxide and selectivitiy towards methane, carbon monoxide and ethane vs. time; 1a (top left): 5 wt.% Ru / 1 wt.% Rh on CeO_2; 1b (top right): 5 wt.% Ru / 5 wt.% Rh on CeO_2; 1c (bottom): 5 wt.% Ru / 30 wt.% Ni on CeO_2

Keywords: bio-syngas to SNG nickel, catalysts, poisoning, operando techniques, methanation, kinetics

1 Introduction

A major barrier in the commercialization of biomass gasification into biosyngas is the presence of impurities such as ammonia, HCl, H_2S, tars and alkali in the products that are detrimental to downstream processes like the conversion of bio-syngas to substitute natural gas (SNG). The exact role and the effects of these biomass-derived impurities on methanation catalysts are poorly known. Furthermore the way that such aging (or promoting) factors can combine with structural aging processes such as metal sintering under operating conditions is not clearly documented either. In the present study, we focused on the SNG process using Ni based catalysts in order to evaluate the kinetic sensitivity of various aging/promoting factors, combining the effect of model poisons such as (i) ammonia and acetonitrile for N containing compounds, (ii) heptane, toluene and benzene as tar representatives, iii) trichloroethylene for Cl containing compounds, v) H_2S for S containing compounds, vi) Na and K for alkali containing ashes, together with metal particle sintering occurring under SNG process conditions.

2 Experimental/methodology

In parallel with conventional ageing measurements in the presence or absence of poisons typical of biosyngas, a combination of operando techniques were used under methanation conditions: (i) DRIFT spectroscopy to check the nature of the main adspecies [1], (ii) magnetic measurements to follow the changes in Ni particle size distribution on stream and (iii) steady-state isotopic transient kinetic analysis (SSITKA) for quantitatively assessing the steady-state concentration of reversibly adsorbed CO and of the methane precursors from $^{12}CO/^{13}CO$ switch at reactor entrance [2].

3 Results and discussion

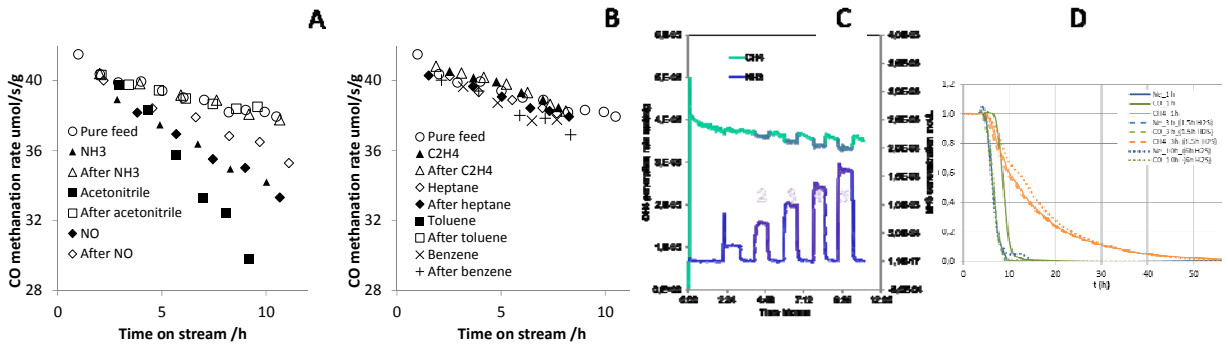

Fig. 1. A&B: Changes in methanation rate vs TOS, in the presence/absence of bio-syngas poisons; C: changes in CH_4 and NH_3 IR bands intensity; D: Changes in SSITKA curves after H_2S addition.

The main ageing effects, among which some are illustrated in Fig.1, have been analyzed by using the complementary information provided by the operando analyses:
(i) In the absence of added poisons, the CO carbonyl IR signal appeared to be correlated with the loss of activity. This irreversible ageing process is assigned, from operando analysis of Ni dispersion, to metal sintering and restructuring, as a consequence of metal carbonylation [2].
(ii) The effect of N containing poisons, superimposed with the previous irreversible Ni sintering, was totally or partially reversible. The degree of deactivation was ranked as acetonitrile> ammonia> nitric oxide, suggesting that various poisoning modes (e.g. competitive adsorption, coking, electronic effects) might be present.
(iii) Adding hydrocarbon compounds representative of tar by-products revealed that ethylene, heptane and benzene did not show obvious poisoning effects.
(iv) The addition of alkali compounds (Na^+ and K^+), present in the ashes formed during the biomass gasification, tended to decrease the inhibiting effect of CO carbonyl concentration on the methanation rate, and therefore might be classified as promoters rather than poisons.
(v) Chlorine contained in C_2HCl_3 was ranked as a strong poison but partly reversible. From its marked impact of bridged and/or multi carbonyls concentration, chlorine is assumed to act via site blocking and by decreasing electronic density at the metallic centers.
(vi) H_2S addition provoked a linear and irreversible deactivation, typical of a front catalytic bed poisoning. The carbonyl pool was decreased linearly with H_2S addition while the CH_4 transient kinetics were only weakly affected, discarding electronic effects by S deposits.
A tentative rationale of these complex aging processes is proposed on the basis of a kinetic study of the methanation reaction, based on the changes in carbonyl and CH_x active intermediates concentrations, directly measured by DRIFT and SSITKA [3]. Thus, the reversible poisoning effect of N and Cl containing species would affect essentially surface controlling steps such as hydrogenation of CH_x reacting intermediates deriving from carbonyls decomposition. It would proceed via a reversible electronic transfer from Ni to the electrophilic additives, evidenced by carbonyl bands shifts typical of electronic back-donation weakening from nickel to the CO π^* anti-bonding orbital. A reverse effect would characterize the promoting effect of alkali addition. For the added hydrocarbons, the absence of electronic effects would explain their negligible toxicity, unless surface coking might lead to diffusion limitation. S containing molecules would neutralize part of the catalytic bed without changing the reactivity of the unpoisoned active sites.

4 Conclusion

From a combination of state-of-the-art operando techniques, unique information was brought on complex surface processes under SNG reaction conditions. Strategies for improving the resistance of methanation catalysts to various types of bio-poisoning can be proposed from this mechanistic and kinetic re-investigation of one of the oldest catalytic reaction studied up to now.

Keywords: Fischer-Tropsch, iron, cobalt, support carbon

1 Introduction

Fischer–Tropsch (FT) is an attractive route for the synthesis of non petroleum carbon sources like coal, biomass, and natural gas into wide range of hydrocarbons through intermediate synthesis of syngas (CO +H_2) through gasification or reforming. Cobalt and iron are the widely accepted catalysts for the FT synthesis. However, the efficiency of these catalysts in terms of activity, selectivity and stability is still not high enough for wide implementation in industry. Our recent studies have shown that interaction of Co and Fe with conventional inorganic supports leads to significant deactivation of the catalysts due to the formation of inactive silicates (Co-O-Si and Fe-O-Si), segregation and low contribution of the active phase (χ-Fe_5C_2) [1-2].

This work aims at developing of new catalytic systems for FT synthesis by interaction of metals with carbon on the surface of conventional silica support. It should combine the advantages of high dispersion of cobalt and iron on the surface of support with their low deactivation due to the presence of carbon.

2 Experimental/methodology

Two different approaches have been used for the synthesis of composites on the basis of Fe and Co. Iron nitrate has been mixed with fructose solution with subsequent treatment at 80°C under stirring in the presence of different amount of silica during 24 h with subsequent drying and calcination in inert atmosphere. Silica support has been preliminary impregnated by different content of fructose with subsequent calcination in inert atmosphere to deactivate the surface groups for preparation of cobalt catalysts. The final catalysts have been prepared by impregnation of cobalt nitrate with and without Pt as promoter. The materials were thoroughly characterized by elemental analysis, XPS, Mossbauer spectroscopy, magnetization, XRD, TEM, nitrogen adsorption and SSITKA analysis.

Catalytic experiments were carried out on the REALCAT platform in a Flowrence high-throughput unit (Avantium®) equipped with 16 parallel milli-fixed-bed reactors (d=2 mm) operating at a total pressure of 20 bar, 220 or 300°C , H_2/CO= 2 molar ratio. The gas and liquid products have been analyzed after the test by GC analysis for evaluation of the activity and selectivity to hydrocarbons.

3 Results and discussion

Catalysts prepared with participation of carbon present significantly higher dispersion of the metal on the surface. Fig. 1 shows that conventionally prepared cobalt catalyst over silica

contains particles with the sizes in the range 50-100 nm. At the same time, in the presence of carbon on the surface the size of cobalt nanoparticles decreases to 5-10 nm. It results in increase of the activity by up to 2 times over carbon treated catalysts in comparison with the carbon free sample. The stability of carbon containing catalyst is higher due to the suppression of metal deactivation by interaction with support.

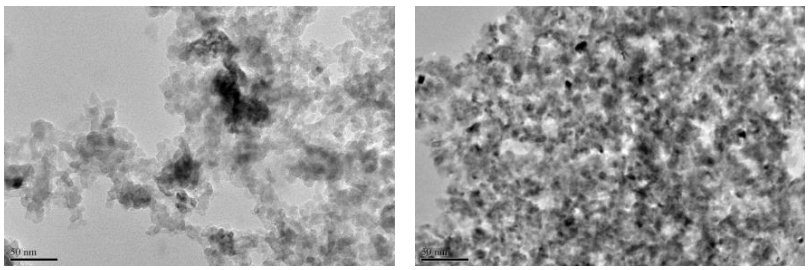

Fig. 1. TEM images of Co supported over silica and carbon-silica supports

Hydrothermal treatment during preparation of Fe based catalysts leads to condensation reaction with formation of humins stabilizing Fe species. The main effect of carbon addition during the preparation of iron catalysts for high temperature FT synthesis is in increase of the contribution of active χ-Fe_5C_2 carbide phase in the catalyst determined by analysis of magnetization (Fig. 2). At the same time, high surface area of silica support provides high dispersion and accessibility of carbide. It leads to increase of the activity by 2-3 times at the optimum composition of support (C/SiO_2 = 0.6-0.8) in comparison with silica and pure carbon supported catalysts (Fig. 2).

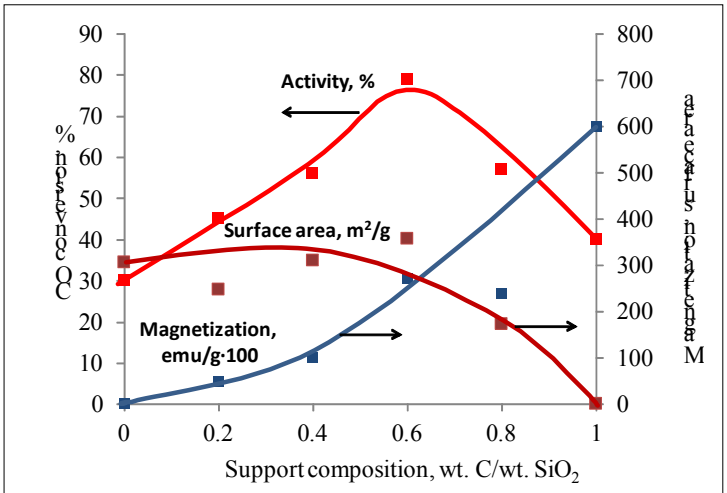

Fig. 2. Catalytic activity in FT, magnetization and surface area of the Fe catalysts with different contribution of carbon

4 Conclusions

Thus, our results show that the presence of carbon in inorganic support significantly improves the catalytic performance of the Fe and Co based catalysts in the Fischer-Tropsch synthesis. The main effect is due to the significant increase of the dispersion of metallic nanoparticles, suppression of metal deactivation by formation of silicates and increase of the contribution of the active phase by interaction with carbon.

Keywords: glycerol steam reforming, Ni/Al_2O_3, La_2O_3, B_2O_3, coke

1 Introduction

Biodiesel is by far the most common biofuel used in the EU, produced via vegetable oils transesterification [1]. About 10 wt % of the vegetal oil processed in biodiesel manufacturing is converted to crude glycerol, which cannot be absorbed by the current markets [2-4]. An interesting idea is the utilization of this crude glycerol as a raw material for the production of hydrogen or other energy carriers, with both economic and environmental advantages due to waste minimization and valorization [2-5]. In this context, steam reforming of glycerol has gained attention in recent years. As a reforming reaction, it is catalyzed by transition or noble metals and several catalytic schemes have been investigated [2, 4]. Ni-based catalysts have been proven to be active for the steam reforming of various compounds and biomass derivatives (including ethanol) and they are much more cost-effective for industrial applications than noble metals [4]. The aim of the present study is the investigation of the effects of B_2O_3 and La_2O_3 on the performance of Ni/Al_2O_3 catalysts.

2 Experimental/methodology

The catalysts were prepared by wet impregnation, using a commercial alumina. Nickel nitrate, lanthanum nitrate and boric acid were the precursor compounds. Ni content is 10 wt % in all catalysts, while La_2O_3 loading is 17 wt % and B_2O_3 is 5.6 wt %. All prepared materials and there notations are presented in Table 1. Physicochemical characterization includes N_2 adsorption-desorption (BET, BJH), XRD, DRS TPR and HR-TEM. Catalytic behavior was investigated in the temperature range 400-800 °C using a feed consisting of 20% He, 1% Ar, 75% H_2O και 4 % glycerol. In addition, catalytic tests were performed at 600, 500 and 400 °C for 3 h, with a new batch for each temperature in order to evaluate coking at each temperature. TPH, TPO, XRD and HR-TEM were applied for the assessment of the carbonaceous deposits on the spent catalysts.

3 Results and discussion

γ-Al_2O_3 is an active glycerol reforming catalyst even at 400 °C, with a 24 % conversion to liquid products (mainly acrolein, acetaldehyde and acetol). Glycerol conversion increases to 85 %, with the addition of La_2O_3, while with BAl a 100 % conversion and 39 % yield of acrolein was achieved. Conversion to gas was less than 15 % for all supports. These results show that modifiers enhance mainly dehydration reactions while for dehydrogenation and C-C bond cleavage the presence of a metal is required.

All Ni-based catalysts are more active than the corresponding supports, with an almost 100 % total conversion at 500 °C. Yet, there are differences depending on catalyst composition. Conversion to gas products and hydrogen yield are shown in Fig. 1. A 97 % conversion to gas and 83 % hydrogen yield is obtained by NiAl at 500 °C. Addition of lanthana deteriorates the textural properties but has no significant effect on Ni^0 dispersion. However, it improves the catalytic performance, increasing considerably the gas products, hydrogen yield at 400 °C and

the resistance to coking (Fig. 2, Table 1). On the contrary, B_2O_3 improves the textural properties and the dispersion of the nickel phase but decreases the yields of H_2 and other gases, while more coke is formed on this catalyst (Fig. 2, Table 1).

Table 1. Materials and their notation, S_{BET} after reduction, average nickel particle size after reduction and catalytic tests at 500 °C and 600 °C and carbonaceous deposits after testing for 3 h at 500 °C.

Catalysts	Notation	$S_{BET, R}$ (m^2/g)	$d_{Ni,R}$ (nm)	$d_{Ni,U500C}$ (nm)	$d_{Ni,U600C}$ (nm)	$C_{500°C}$ (mg C/g_{cat})

Ni/La_2O_3-Al_2O_3	NiLaAl	79	9.7 ± 0.6	10.7 ± 0.7	10.6 ± 0.5	39

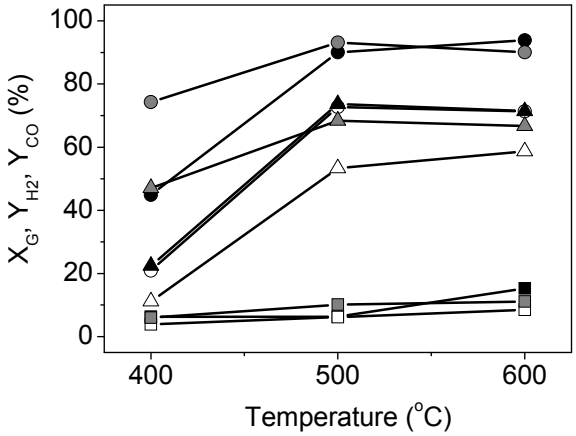

Fig. 1 Catalytic performance of NiAl (black), NiBAl(white) and NiLaAl (gray): ● conversion to gas, ▲H_2 yield, ■ CO yield.

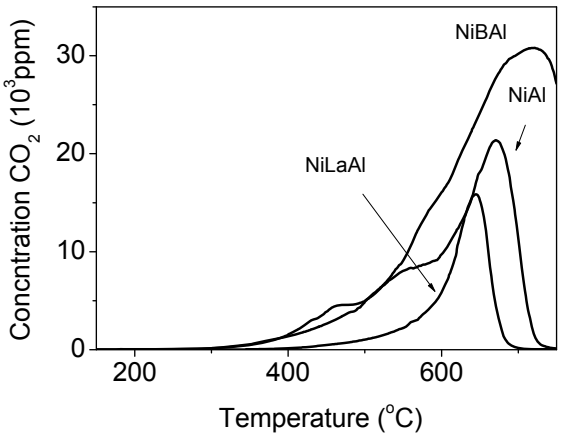

Fig. 2 Temperature programmed oxidation of carbonaceous deposits on the Ni-based catalysts.

4 Conclusions

The presence of a second oxide on Ni/Al_2O_3 catalyst has important effects on the catalytic behaviour and the resistance to coking. However, this is not due to changes in the texture and/or nickel dispersion, but must be related to the different metal-support interface and/or to a synergy effect.

Keywords: ORR, PEMFC, RDE, carbon nanotube, carbon nanofibers, platinum

1 Introduction

One of the promising approaches to reduce the content of platinum in the Pt/C catalysts for the oxygen electroreduction reaction (ORR) in polymer electrolyte fuel cells (PEMFC) is to increase the activity and Pt utilization by optimizing the morphological properties and the structure of the porous carbon supports. In recent decades, nanostructured carbon supports - carbon nanotubes and nanofibers received much attention because of the higher electrical conductivity and the effective mass transport properties. In this work we synthesized a series of Pt/C electrocatalysts based on commercial carbon blacks and nanostructured carbon supports: the original and the modified multiwall carbon nanotubes (CNTs) and catalytic filamentous carbon (CFC). The resulting catalysts were investigated in the ORR by rotating disk electrode (RDE) method as well as in PEMC. The higher performance of the Pt/CNT catalysts is shown.

2 Experimental/methodology

Pt/C catalysts were prepared by deposition of platinum oxide on the surface of carbon support under hydrolysis of Pt (IV) chloride complexes using Na_2CO_3 as a reducing agent. The conditions of the preparation can be found in ref. [1]. The original (CNT) and a modified with carbon (CNT-gr) multiwall carbon nanotubes and catalytic filamentous carbon of “fishbone” (CFC1) and "card deck” (CNF2) types were used. Commercial 20% Pt / Vulcan XC-72 catalyst was used for comparison.

Electrochemical measurements were performed using a rotating disk electrode in a thermostated three-electrode glass cell at a temperature range of 10 - 35 ° C in 0.1 M $HClO_4$. The Pt wire and Pt foil were used as a reference and auxiliary electrodes respectively. The electrode potentials were controlled by potentiostat Autolab PGSTAT 100. All potentials are given with respect to the reversible hydrogen electrode.

Membrane-electrode assemblies (MEA) were prepared using Nafion® 212 NRE (Sigma-Aldrich Co) membrane, commercial 20 % Pt/Vulcan XC-72 (0.2 mg_{Pt}/cm^2 of Pt load) as anodic catalyst, Carbon Toray paper (TGP-H-120) and Sigracet 25BC as cathodic and anodic gas-diffusion layers, respectively. The studied sample was mixed with Black Pearls carbon black and used as cathodic catalyst with Pt load of 0.05 mg_{Pt}/cm^2. Polarization curves were obtained at 80 °C in galvanostatic mode with a scan rate of 1 mA/s (in the 0 - 0.02 A/cm^2 current density range) and of 10 mA/s (for current density higher than 0.02 A/cm^2). The hydrogen and oxygen were humidified and supplied at a fluxes of 2.4 cm^3/s and 4.8 cm^3/s, respectively. The measurements were performed using Autolab PGStat302N potentiostat equipped with a buster BSTR20A. The ohmic resistance of MEAs and hydrogen crossover currents were obtained as described in ref. [1].

3 Results and discussion

The results presented in Table 1 show that the Pt nanoparticle sizes of the Pt/CNT catalysts are in the 2.8 - 3.4 nm range. The data are in agreement with those obtained by TEM and chemisorbed CO electrooxidation. The similarity of the Pt dimension indicates the good reproducibility of the method of platinum deposition on the surface of carbon nanotubes. In order to synthesize Pt/CFC catalysts, the support was oxidized under mild conditions. This leads to a noticeable oxidation of the CFC surface and increase the average size of the platinum nanoparticles (6-12 nm). Both mass and surface activities of Pt/C catalysts in the ORR obtained by RDE method were found to be higher than those of commercial 20% Pt/Vulcan catalyst. Most likely this is due to the influence of the properties of the carbon support. Carbonization of CNT surface (20% Pt/CNT-gr) as well as higher Pt content (40% Pt/CNT) leads to higher activities of the catalysts. The performance of the catalysts in PEMFC are correlated with those obtained by RDE. The use of the nanostructured carbon supports (such as CNT) improves the efficiency of Pt/C catalysts in the ORR.

Table 1. Pt nanoparticle size (d_{Pt}) according to gas-phase CO adsorption data, mass (A_{mass}) and surface (A_{surf}) activities at 0.9 V RHE obtained in the electrochemical cell (EC) and in PEMFC.

Catalyst	d_{Pt} nm	A_{mass}^{EC}, A/g_{Pt}	A_{sur}^{EC}, $\mu A/cm^2_{Pt}$	A_{mass}^{PEMFC}, A/g_{Pt}
40%Pt/CNT	3.4	129	278	186
20%Pt/CNT-gr	3.2	81	303	
20%Pt/CFC-2	12	60	236	66
20Pt%/CFC-1	6.2	16	145	
20Pt%/CNT	2.8	18	36	
20Pt%/Vulcan	3.2	44	61	71

4 Conclusions

In this work a series of Pt/C catalysts obtained on the nanostructured carbon supports (carbon nanotubes and catalytic filamentous carbon) was studied in the ORR in the electrochemical cell as well as in the PEMFC. It was found that the use of carbon nanostructured supports such as multiwall carbon nanotubes improves the efficiency of Pt/C catalysts in the ORR.

Mathematical Modelling Method Application for Catalytic Reforming Catalyst Operating Conditions Optimization in Industrial Reactors

Sharova E.S., Ivanchina E.D., Yakupova I.V.*

National Research Tomsk Polytechnic University, Tomsk, Russia

* yakupovaiv@tpu.ru

Keywords: catalytic reforming, Pt-catalyst, monitoring, mathematical model, optimal activity, coke, accumulation

1 Introduction

Optimization of industrial processes is one of the most important stages of mathematical modeling. The modern modifications of Pt-Re-catalysts of catalytic reforming process allow obtaining high – octane product with 96-98 octane number and selectivity can achieve 87-90 % mass. However, there is a question about their stability during the operating process, which is determined by carbon composition of raw material, technological operating condition and characteristics of reactor unit. It is only possible to solve catalyst work prediction problem by using kinetic model, which takes into consideration complex influence on deactivation of coke formation processes, poisoning and aging.

2 Experimental/methodology

The existence of formation and hydrogenation of unsaturated intermediate products of compaction is possible (Fig.1). Under certain conditions coke formation doesn't occur, because resins and asphaltenes (previous substances of coke) can hydrogenated to hydrocarbons or be in equilibrium with gas-phase reaction medium. Thus, controlling of feed temperature in reactor, it could be possible to provide process operation mode with the existence of equilibrium of formation and hydrogenation of coke structures.

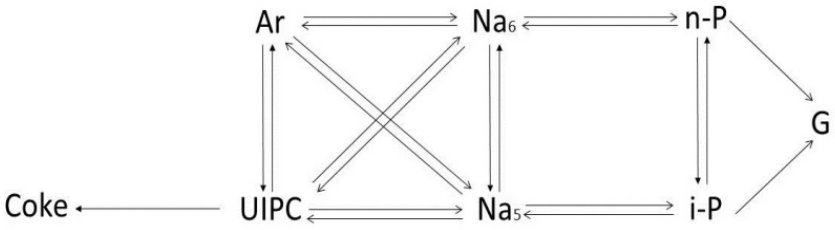

Fig. 1. Formalized scheme hydrocarbon conversions $C_8 – C_{12}$: G – gas; n-P – normal paraffins; i-P – izoparaffins; Na_6 – cyclohexanes; Na_5 – cyclopentanes; Ar – aromatic hydrocarbons; UIPC - unsaturated intermediate products of compaction

Catalyst Operating Condition Control System was designed for complete monitoring of the reforming catalyst operating condition. The system is based on the mathematical model of the naphta catalytic reforming which takes both the physical and chemical mechanisms of hydrocarbon mixture conversion reaction as well as the catalyst deactivation. The mathematical model of catalytic reforming [2] is performed as system of physical and heat balance:

$$G\left(\frac{\partial C_i}{\partial z}-\frac{\partial C_i}{\partial V}\right)=\sum_{j=1}^{n} W_j$$

$$G\left(\frac{\partial T}{\partial z}-\frac{\partial T}{\partial V}\right)=-\frac{1}{C_p^{mix}}\sum_{j=1}^{n} Q_j W_j$$

The initial conditions: Z=0, C_i=0, T=0, V=0, C_i=C_{en} (at the reactor entrance), if Z=0, T=T_{en}, where C_i - a concentration of i-th component, mol/m3; T – temperature; Z – a raw material volume, m³; W_j – j-th reaction rate, mol/(m³•h); V - a volume of the catalyst layer,m3; G - a raw material flow rate, m3/h; Q_j – j-th reaction heat, J/mol; - a heat capacity of mixture, J/mol.

Using computer modelling system the monitoring of catalytic reforming installation L-35-11/450K was done. Technological conditions: entrance temperature is 470˚C, pressure is 1.6 MPa, consumption of raw materials is 63.8 m²/hour. The catalyst used is PR-9 (Pt:Re = 0,25:0,25). The monitoring of installation was performed within the seventh work period – since 22.05.2012 to 18.03.2014. Such catalyst work indicators as “current” and “optimal” activity were determined. The chromatographic analyzes results of raw material and outlet substance compositions were used as initial data.

The monitoring of each catalytic reforming installation is concluded in determination of such catalyst work indicators as “current” and “optimal” activity. The catalyst activity [1] is defined as:

, W_k, W_0 - the chemical reaction rate, mol/sm³·s, with and without catalyst respectively; φ - the part of volume, occupied by catalyst and inaccessible for reacting mixture.

The optimal activity is defined by optimal process operation. Work at the "optimal" activity provides maximum duration of catalyst work cycle.

3 Results and discussion

The results which are presented at Fig.2 show that the amount of current activity during this work period is 0.7-1.0 points. However, a deviation from the optimal activity of 0.6 points in total can be observed. This deviation influences the accumulation of coke. For example, the total amount of coke in the catalysis is 87.73 % weight higher than the one, which could be observed during optimal operation.

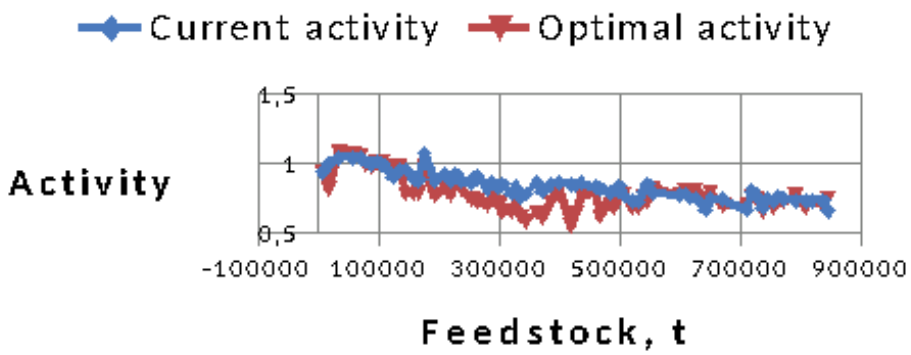

Fig. 2. The comparison of current and optimal activities of the PR-9 catalyst

Fluctuations of the catalyst’s activity during the entire work period can be associated with changes in the rate of technological regime: the feed temperature to the reactor, hydrogen gas circulation rate and the variability of the composition of the hydrocarbon feedstock.

4 Conclusions

1. The installation work is relatively close to optimal. Insignificant deviation from the optimal and current activity was observed at the end of the work period (0.6 points) which may be associated with change in the feedstock composition.

2. The amount of coke deposited at the catalyst during the current activity is 87.73 % weight higher than the optimum value.

Keywords: CO_2 uses, methanol synthesis, citrate route

1 Introduction

Methanol is an important commodity, which might be produced directly from CO_2 and H_2. We investigated Cu/ZnO catalysts in methanol synthesis, applying different Cu contents, calcination temperatures and two different synthesis methods: a modified citrate route [1-2] and coprecipitation [3]. Using the different synthetic methods, it was possible to vary copper crystal size in the 12-32 nm range and to investigate its effect on the catalytic performance. Mechanical mixtures of separately prepared CuO and ZnO were also studied. The catalysts were tested for methanol synthesis in mild conditions (7 bar, 140-250°C, GHSV 40 ml/min/g_{cat}).
Results provides insight to the synthetic approach of catalysts using copper and zinc oxides and in the study of the mechanistic aspects of work of catalysts containing these oxides.

2 Experimental/methodology

For the synthesis of the CuO/ZnO catalyst, a variant of the citrate method, which makes no use of nitrates as starting salts and decomposes the organic substance at mild conditions (~ 350°C 1%O_2 in N_2) was used. Coprecipitation method here utilized is performed with ammonium carbonate at 80°C and pH 6.5. This method has no necessity for a washing step to get rid of the sodium cation. Pure CuO and ZnO were synthesized separately. Mechanical mixtures of CuO and ZnO were prepared mixing both oxides in n-pentane at room temperature. Catalysts were characterized by X-ray diffraction, specific surface area, X-ray photoelectron spectroscopy and by N_2O chemisorptions.

3 Results and discussion

All synthesized Cu/ZnO catalysts are formed by CuO and ZnO phases. No mixed phase was observed. After reduction only Cu and ZnO species are present. Coprecipitation method leads to smaller CuO crystal size, higher Cu on the surface and higher Cu dispersion than citrate method. Methanol selectivity can attain 100% at temperatures lower than 180°C for catalysts prepared by coprecipitation with a small copper content, while for every catalysts prepared by citrate method, the selectivity is 100% up to 160°C. CO formation is highly favoured at high temperature and for small CuO crystal size. Large size of CuO particles favour methanol formation (Fig. 1). The apparent activation energy for methanol formation is in the range 30-52 kJ/mol, whereas that of CO formation is much higher (111-139 kJ/mol). For pure CuO, the apparent activation energy for methanol formation is about 70 kJ/mol and that of CO formation is more than 150 kJ/mol. Methanol yield, strongly depends on the amount of copper in the catalyst. The methanol formation rates and the CO formation rates depend linearly on the amount of surface exposed copper atoms. Lower the amount of surface copper atoms higher the turnover frequency (TOF) and selectivity to methanol. The reverse is observed for CO formation. TOF for methanol formation is inversely proportional to the Cu dispersion. The

turnover frequency of the CO formation is higher for small copper particles. Larger particles copper particles (20-32 nm) are much more selective to methanol than smaller ones (12-19 nm).

Pure copper is low active and ZnO is not active at all. The catalysts prepared by mechanical mixture is significantly more active than pure CuO. A synergy between CuO and ZnO is observed. These results suggest that the high activity of the CuO/ZnO catalysts prepared by cooprecipitation and citrate method is explained by the presence of CuO and ZnO, which are segregated during the calcination of the catalysts. The activity and the selectivity of CuO/ZnO catalys depends on the presence of ZnO and CuO in the mixtures and more precisely on the crystal size and the surface atoms of copper.

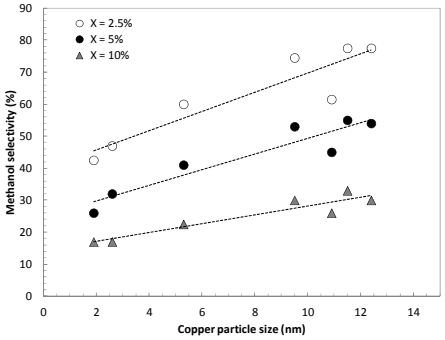

Figure 1. Correlation of Copper particle size and methanol selectivity via different synthesis methods

4 Conclusion

The optimal reaction temperature is in the range between 180°C and 200°C, because at lower temperatures there is a higher selectivity in methanol but coupled with a very low STY in methanol. At higher temperature, the STY in methanol is the highest at 225°C, but at this temperature the CO production is strongly enhanced.

The size of copper particles and the amount of surface copper atoms are crucial parameters for methanol and CO formation. Very small crystal sizes of copper boost the CO formation. On the contrary, large copper crystal sizes are highly active for the methanol synthesis. The citrate method at calcination temperatures between 400 and 500°C leads to the optimal Cu crystal size (about 20 nm). This copper crystal size, displays the lowest activation energy in the methanol synthesis and the highest selectivity to methanol. The coprecipitation method leads to smaller copper crystal size that is correlated to a low selectivity to methanol.

Catalysts synthesized by citrate and coprecipitation methods show always the phases CuO and ZnO, suggesting that the activity of the Cu/ZnO system is directly related with the presence of these two oxides. This has been demonstrated by the mechanical mixtures, which present a higher methanol formation than CuO alone. Pure ZnO is inert. These results underline the importance of the segregation of CuO and ZnO during the synthesis.

Results indicate that the best catalyst for a high formation of methanol and a low CO formation can be obtained when the catalysts present an adequate size of CuO particles, with a low copper surface atoms and an optimal interdispersion between CuO and ZnO particles.

Active Site Analysis of Sulfided $NiMo/Al_2O_3$ Catalyst for Hydrodesulfurization of 4,6-Dimethyldibenzothiophene

Nguyene T., Adachi Y., Kobayashi K.*, Nagai M.

Tokyo University of Agriculture and Technology, Tokyo, Japan

* mnagai@cc.tuat.ac.jp

Keywords: site-type analysis, transient response, HDS, 4,6-DMDBT, P-doped, $NiMo/Al_2O_3$

1 Introduction

Recent environmental concerns require an ultra-low sulfur transportation fuel which requires an extensive investigation to develop a highly-active catalyst for the hydrodesulfurization (HDS). The two-site mechanism is well known for the HDS on Mo-containing catalysts HDS [1-4]; one site for the hydrogenation and the other site for the desulfurization. However, a simultaneous rapid desulfurization and hydrogenation reactions of the intermediates, such as the hydrogenated 4,6-dimethyldibenzothiophene (DMDBT) to 3,3-dimethylbicyclohexyl (DMBCH) and 3-methylcyclohexyl-toluene (MCHT) during the HDS of DMDBT and of octahydrodibenzothiophene to bicyclohexyl during the dibenzothiophene HDS and the denitrogenation of *o*-propylaniline to propylcyclohexene during quinoline HDN, are still debated. In this study, a new approach to the site-type analysis of the active sites of the sulfided $NiMo/Al_2O_3$ catalyst for the HDS of DMDBT was studied based on the transient response of the poisoning of carbazole, acridine and quinoline during the HDS. A stereotypically-hindered DMDBT is among the most refractory sulfur-containing molecules in gas oils and low-rank oils. A third active site on the sulfided $NiMo/Al_2O_3$ catalyst was proposed for the simultaneous desulfurization and hydrogenation of DMDBT.

2 Experimental

The phosphorus-doped $NiMo/Al_2O_3$ was prepared using aqueous solutions of $Ni(NO_3)_2 \cdot 6H_2O$, citric acid, MoO_3 and 3.5 wt% H_3PO_4 and impregnated on alumina and loaded at 5.2 wt% NiO and 9.8 wt% MoO_3 by an incipient wetness method. The precursor was dried and oxidized at 723 K for more than 12 h. One gram of the oxidized catalyst was placed in the reactor of a high-pressure flow system. After the catalyst was calcined at 723 K for 1 h, the catalyst was sulfided from 573 to 623 K at the rate of 60 Kh^{-1} in a stream of 10% H_2S/H_2 at 4 Lh^{-1} and subsequently maintained at 623 K for 3 h. The transient response study of carbazole during the HDS of DMDBT was performed at the LHSV of 10 h^{-1}, 493-553 K and a total pressure of 2.5 MPa. After the reaction had reached a steady state in about 4 h, the solution containing the mixture of the 0.2 wt% DMDBT and carbazole (or acridine and quinoline; molar ratio to DMDBT at 1:1 and 1:2) in xylene was introduced into the reactor. The reaction products were quantitatively analyzed using an FID G.C. and identified by GCMS. The catalysts were characterized by XPS, TEM and NO adsorption measurements.

3 Results and discussion

The transient response of the carbazole addition to the DMDBT HDS on the sulfided $NiMo/Al_2O_3$ catalyst for the ratio of DMDBT to carbazole at 1:1 at 493 K is shown in Fig. 1. The carbazole addition increased the concentrations of MCHT and the isomers, decreased and attained constant values, then gradually increased that of 4,6-dimethyltetrahydro-dibenzothiophene (DMthDBT) and became constant, while those of 3,3-dimethylbiphenyl

(DMBP) and DMBCH and the isomers slightly increased. The addition of acridine underwent a similar trend based on the results of the carbazole addition. These results suggested three groups of behavior of the HDS products during the competitive adsorption of the transient response. The denitrogenated compounds and the hydrogenated carbazole compounds except for tetrahydrocarbazole were not observed during the reaction at 493 K. The carbazole was competitively adsorbed on the hydrogenation site, but did not prevent the desulfurization. The competitive adsorption of the HDS products and the nitrogen compounds was considered based on the transient response of the carbazole addition for elucidation of the active sites for the HDS of DMDBT. For the adsorption and the products on the direct desulfurization site, the following equation was obtained: $(C)_{HDS}=(B)/(A)=p_{DMBP12}/p_{DMBP11}=[K_{11}/K_{12}]\ [\theta_{DMBP12}/\theta_{DMBP11}][\theta_{V11}/\theta_{V12}]$

fLayoutInCell1fAllowOverlap1fBehindDocument0fHidden0fLayoutInCell1

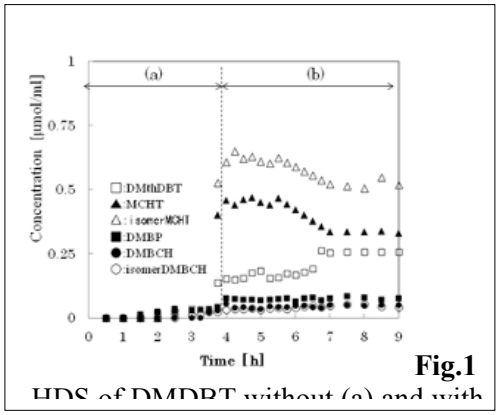

Fig.1 HDS of DMDBT without (a) and with

where θ_{DMBPi}, θ_{vi}, Ki, p_{DMBPi} are the coverage of DMBP, vacant, rate constant and i is the molar ratios of DMDBT to carbazole at (A) 1:1 and (B) 1:2. The (C) values of the other HDS products were also calculated at 493 K and are shown in Table 1. The values of (C) for the addition of carbazole to the HDS of DMDBT had similar values for the addition of acridine and qunoline. The greater increase in DMBP was observed for the addition of acridine probably due to the fact that acridine had a stronger adsorption than carbazole and quinoline. Furthermore, the inhibition order of the three nitrogen compounds underwent the same trend as the HDS products with increases in the DMBP, DMBCH and the isomers together with decreases in DMthDBT, MCHT and the isomers as listed in Table 1. As a result, three types of active sites were classified as follows: the direct desulfurization site for DMBP, the hydrogenation site for DMthDBT, MCHT and the isomers, and the simultaneous desulfurization and hydrogenation site for DMBCH and the isomers. The desorption amounts from the three active sites for the carbazole addition were calculated to be 0.077, 1.111 and 0.097 $\mu molL^{-1}g^{-1}$, respectively, for the desulfurization, hydrogenation and simultaneous desulfurization and hydrogenation sites, corresponded to the distribution of 6, 87, and 7 %, respectively. Thus, the sulfided $NiMo/Al_2O_3$ catalyst had the greater hydrogenation site than the others.

Table 1. The ratios (C) of reaction products for the molar ratios of DMDBT to the added compounds.

Product ratio for added nitrogen compound	DMBP	DMthDBT	MCHT and isomers	DMBCH and isomers
Carbazole	1.2	1.0	1.0	0.45
Acridine	1.3	0.98	0.87	0.58
Qunoline	1.4	1.1	1.0	0.45

4 Conclusions

A new approach to the site-type analysis of the active sites for the HDS of DMDBT using the transient response method proposed the presence of a third active site for the simultaneous desulfurization/hydrogenation of DMDBT to DMBCH as well as the two-sites for the hydrogenation to MCHT and the desulfurization to DMBP.

Keywords: Pt/Al_2O_3, metal oxide, NH_3 combustion

1 Introduction

Recently, NH_3 has been regarded as a renewable and carbon-free energy source due to the high energy density and ignorable thermal NO_x. In comparison with fossil fuel, however, NH_3 fuel has following problems: (1) the high-temperature for ignition, (2) the low combustion rate and (3) a production of fuel NO_x. In this study, the catalytic activity and selectivity of Pt/Al_2O_3 and metal oxide catalysts were evaluated to understand the catalytic behaviour and develop novel catalysts for NH_3 combustion. Our interest was also extended to a dependence of the catalytic performance on partial pressure of O_2.

2 Experimental/methodology

1.0 wt% Pt/γ-Al_2O_3 catalyst was prepared by a conventional wet-impregnation process using an aqueous solution of $[Pt(NH_3)_2(NO_2)_2]$ (Tanaka Kikinzoku Kogyo) and subsequent calcination in air at 600 °C for 3 h. As-prepared Pt/Al_2O_3 and commercial metal oxide catalysts were characterised by XRD, XRF and gas adsorption.

Catalytic NH_3 combustion was carried out in a flow reactor at atmospheric pressure (10 °C·min^{-1}, 1.0% NH_3, 0~18% O_2, He balance and W/F = 5.0×10^{-4} g·min·cm^{-3}). Dependence of NH_3 combustion activity and product selectivities on partial pressure of O_2 (λ), λ: $(pO_2/pNH_3)_{exp.}/(pO_2/pNH_3)_{stoichiom.}$, were also studied.

3 Results and discussion

Figure 1 shows NH_3 conversion, and N_2, N_2O, NO and NO_2 selectivities of as-prepared Pt/Al_2O_3 catalyst observed in the light-off curves of NH_3 combustion under excess O_2 (λ=24). The light-off of a stream of NH_3 conversion was obtained at approximately 270 °C. On the other hand, non-catalytic combustion initiated from approximately 500 °C, which is considered that NH_3 hardly ignites without catalyst. The maximum N_2O, NO and NO_2 selectivities of Pt/Al_2O_3 showed approximately 40%, 20% and 20%, respectively. In contrast to the thermodynamic expectation of NH_3-O_2 reaction to N_2 ($NH_3 + 3/4O_2 \rightarrow 1/2N_2 + 3/2H_2O$), N_2O and NO_x were kinetically-yielded from NH_3 combustion over Pt/Al_2O_3 catalyst.

To study NH_3 combustion activity of metal oxide at λ=24, the catalytic test was performed. NH_3 combustion activity (T_{10}: temperature at which NH_3 conversion reached 10%) of metal oxide showed following order: $MnO_2<Co_3O_4<Pt/Al_2O_3<Fe_2O_3\approx CuO<V_2O_5<NiO<ZnO$. Figure 2 shows the correlation between T_{10} of metal oxide and the enthalpy change ($\Delta H°$) of following reaction: $M_xO_y \rightarrow M_xO_{y-1} + 1/2O_2$, i.e., one molar oxygen desorption from metal oxide with the formation of its lower oxide phase. The plots tend to show that the high active

metal oxide has the low value of $\Delta H°$, indicating that NH_3 combustion activity of metal oxide associates with its oxygen bond energy. Therefore, the catalytic NH_3 ignition is expected to react with the oxygen of metal oxide.

NH_3 combustion activity (T_{10}), and N_2, N_2O, NO and NO_2 selectivities at 600 °C for Pt/Al_2O_3 and CuO as a function of λ were studied (Figure 3). In case of Pt/Al_2O_3 (Figure 3a), T_{10} for NH_3 combustion activity under stoichiometric to lean-burn conditions (24>λ≥1) showed low-temperature of approximately 270 °C, which dramatically increased under rich condition (1>λ). Although NO selectivity tends to decrease with an increase of partial pressure of O_2, NO_x ($NO + NO_2$) selectivity showed approximately 40% on each λ. Similar behaviour of high NO_x and N_2O selectivities could be found in MnO_2 and Co_3O_4 catalysts showing high catalytic activity for NH_3 combustion. CuO catalyst also exhibited high N_2O and NO selectivities under lean condition, but the formations of N_2O and NO were reduced in the stoichiometric reaction (λ=1) (Figure 3b).

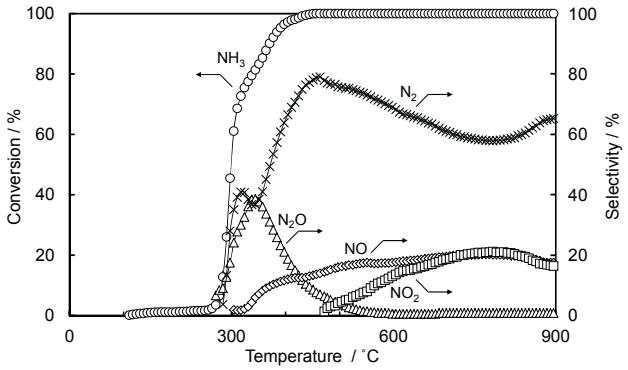

Figure 1 NH_3 conversion, and N_2, N_2O, NO and NO_2 selectivities of NH_3 combustion over Pt/Al_2O_3. Reaction conditions: 1.0% NH_3, 18% O_2, λ=24, He balance.

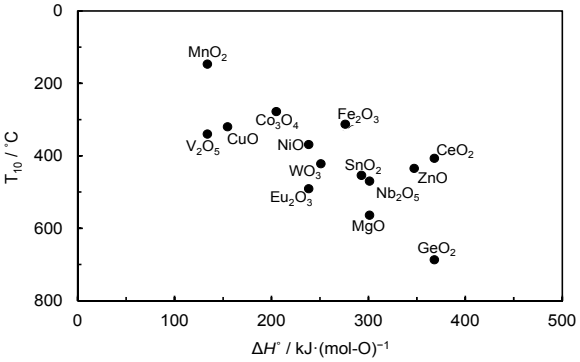

Figure 2 Correlation between NH_3 combustion activity (T_{10}) of metal oxide at λ=24 and enthalpy change ($\Delta H°$) of following reaction: $M_xO_y \rightarrow M_xO_{y-1} + 1/2O_2$.

4 Conclusions

Catalytic activity and product selectivities of Pt/Al_2O_3 and metal oxides for NH_3 combustion have been studied. Pt/Al_2O_3 showed high catalytic activity for NH_3 combustion, but N_2O and NO_x selectivities of that catalyst were high. In case of metal oxide catalysts, MnO_2 and Co_3O_4 also exhibited the higher activity than the other metal oxides, which implied that the catalytic activity of metal oxide correlates with its oxygen bond energy. On the combustion under both excess O_2 and stoichiometric condition, Pt/Al_2O_3 and metal oxide catalysts showed the high selectivities of N_2O and NO_x. However, CuO catalyst exhibited the high N_2 selectivity on the stoichiometric reaction.

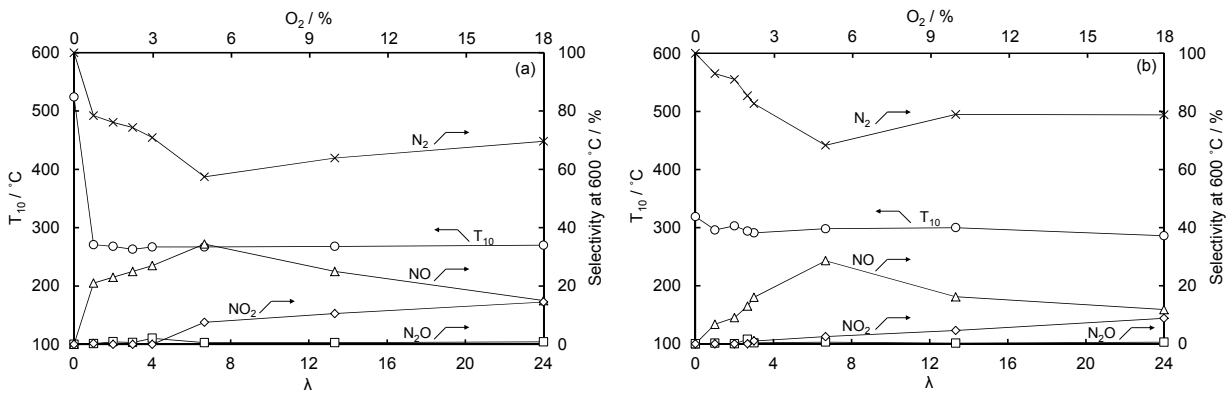

Figure 3 NH_3 combustion activity (T_{10}), and N_2, N_2O, NO and NO_2 selectivities at 600 °C for (a) Pt/Al_2O_3 and (b) CuO as a function of λ. λ: $(p_{O2}/p_{NH3})_{exp.}/(p_{O2}/p_{NH3})_{stoichiom.}$.

Keywords: water gas shift, Cu-catalysts, amines, methanol, reaction parameters

1 Introduction

H_2 is an important raw material in chemical and petrochemical industry [1] and one of most promising fuel option for the future. Steam Reforming (SR) of natural gas is currently the main source of H_2, feeding CH_4 and steam to produce H_2 and CO (Syngas). The CO may be further converted by means of the Water Gas Shift (WGS) reaction to increase the H_2 yield of ~ 2-5 % and decrease significantly the CO content such as required for polymeric fuel cell applications. Considering the SR-WGS integrated process, in the SR reactor small amounts of NH_3 forms from N_2 present in natural gas, that in the WGS step may give rise to amines [monomethyl (MMA), dimethyl (DMA) or trimethyl (TMA)]. These amines, due to their high solubility, fully dissolve in condensed unconverted water, recycled for economic reasons to the pre-reforming reactor, leading, to the formation of coke on the catalyst and, consequently, to its deactivation [2-3]. Aim of this work was to shed light on the role of the reaction parameters on the by-product formation in a WGS reactor operating at Medium Temperature (MTS), i.e. in just one step, allowing to decrease significantly the operational costs.

2 Experimental methodology

The Cu/Zn/Al (20 wt.% of Cu) catalyst (CAT A) was obtained by coprecipitation at 60°C and pH = 9.0 of a hydrotalcite-type (HT) precursor from the corresponding nitrates, followed by calcination at 550 °C for 6 h and reduction in programmed temperature by a H_2/N_2 gas mixture [4]. To collect data of more wide interest, the behaviour of a commercial Cu/Zn/Al catalyst (26 wt.% of Cu) was also investigated (CAT B). The tests were performed in a bench-scale plant equipped with a INCOLOY reactor, controlling the temperature by a J thermocouple sliding inside the catalytic bed. 2 mL of each catalyst were used, with 30-40 mesh particle size. A $H_2/CO/CH_4/CO_2$ gas mixture was fed, controlling the flow by mass flowmeters, while the NH_3 water solution was fed using a HPLC pump. The reaction condition used are summarize in Table 1, in which in bold are reported the values typical of industrial plants. After reaction, the gas were analysed *on-line* after H_2O condensation, using a gas chromatograph, equipped with two HWD detectors, while the by-product water solutions were analyzed *of-line* using a gas chromatograph equipped with a FID. As an internal standard, 250µL of isopropylamine were added to each 2mL sample.

Table 1. Summary of the operating conditions employed (NH_3 molar ratio calculated for the wet gas). The **bold** values are those used in the reference test

Dry Gas [v/v]	$H_2/CO/CH_4/CO_2$ = 72.0 / 18.8 / 4.6 /4.6
Pressure [bar] (P)	**15** - 20
Exit temperature [°C] (T_{out})	**320** - 340
Steam/Dry Gas [v/v] (S/DG)	**0.30** - 0.40
Contact time [s] (τ)	**3** - 6

NH_3 [molar ratio]	$\mathbf{2 \cdot 10^{-4}}$

3 Results and discussion

Both catalysts reached the equilibrium values for CO conversion regardless of the temperature; furthermore, only the thermodynamically favoured TMA was detected (>150 ppmw). The amount of by-products [methanol (MeOH) and amines] detected as a function of the reaction parameter are summarized in figure 1. CAT A gave rise always to significantly higher methanol amounts than CAT B. The increase of pressure favoured for CAT A and B the formation of methanol and amines, while increasing the temperature both catalysts showed a slight decrease in MeOH formation, while TMA content increased. It is noteworthy that Cat B in the reference test showed an amine amount lower than the detection limit, as well as in the test at 340°C.

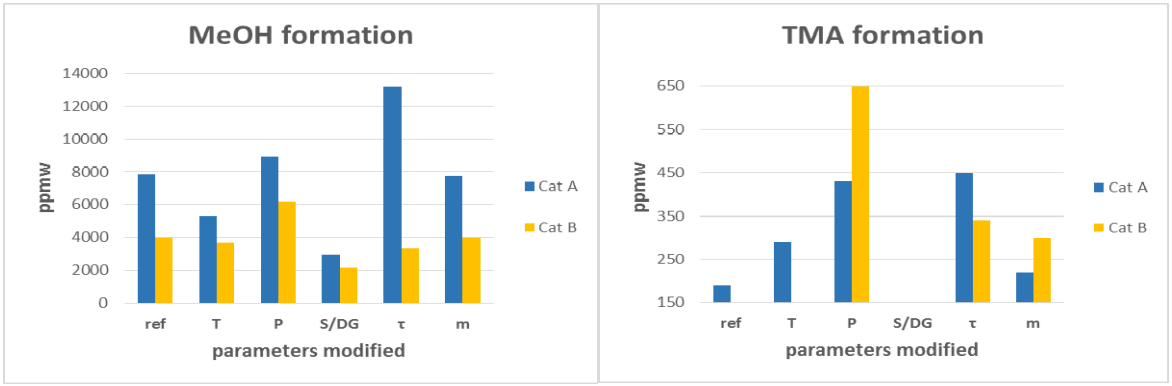

Fig. 1. Formation of MeOH and TMA for Cat A and Cat B in the reference conditions (ref) and changing the reaction parameters (see Table 1); "m" means MeOH + NH_3 co-fed.

Moving the S/DG value from 0.30 to 0.40, a relevant decrease in MeOH and TMA formation was observed for both the catalysts. Finally, increasing the contact time (τ) a significant increase of TMA production was always observed, while MeOH increased only for CAT A. On the basis of the above data, a correlations between MeOH and amine formation may be hypothesized. Thus, to shed light on the mechanism of amine formation, a further test was performed, at 15 bar, feeding a water solution containing the same amounts of NH_3 and MeOH ($4.81 \cdot 10^{-2}$ mol/L) (letter **m** in figure 1). By comparison with results obtained in the reference tests, no change in the amounts of MeOH detected was observed, showing that it partially decompose, in agreement with reaction temperature and pressure. On the other hand, TMA formation increased significantly for both catalysts, especially for the commercial one (Cat B). These results suggest that unlike the literature [5], a correlation between MeOH and amine formation may be hypothesized

4 Conclusions

In presence of NH_3 in the feed, the reaction parameters strongly affected the formation of by-products, mainly amines, on Cu-containing MTS catalysts. The increase of P and contact time favoured the formation of both MeOH and amines, while a higher S/DG value had an opposite effect. A correlation may be hypothesized between MeOH and amine formation, suggesting that amines formed by reaction of NH_3 with surface intermediates in the MeOH synthesis.

Keywords: MFI, hierarchization, coke, ethanol, cracking, toxicity

1 Introduction

Many zeolite catalysts currently used commercially are already hierarchical: FCC, hydroisomerization and hydrocracking being the most important examples in oil refining. In these cases, hierarchization is brought by steam and/or acid treatments where Al is selectively removed from the framework. Recently, other methods have been rediscovered (caustic treatment where Si is removed to a greater extent than Al), studied in-depth by modern techniques and new methodologies created (fluoride treatment where Si and Al are removed at and equal rate). Moreover, the production of nanosized zeolite crystals is equivalent to hierarchization as a sizable (mesoporous) surface is developed on their external surface. This contribution focuses on the effect of hierarchization on coking and regeneration of ZSM-5 zeolite catalysts in hydrocarbon methylcyclohexane (MCH) and ethanol (EtOH) transformations. Two parent ZSM-5, one made of micron-sized crystals and the other containing nano-sized crystals were studied as well as their off springs produced by caustic and fluoride treatments.

2 Experimental

The starting material, NH_4-ZSM-5 (Si/Al=19), is a commercial micro-sized zeolite provided by Clariant. Two hierarchical ZSM-5 zeolites, A and B, were derived from P using acidic and basic post-synthesis treatments, respectively. For sample A, the fluoride treatment was performed as described by Qin et *al.*[1] For sample B, the alkaline treatment was performed as described by J.C Groen *et al.* [2]. A nano-sized commercial zeolite NH_4-ZSM-5 (noted N) with Si/Al = 41, from Clarian, was also used in this work.

3 Results and discussion

The effects of two different hierarchization procedures (alkaline and fluoride leaching) on the performances of ZSM-5 catalysts in the transformation of methylcyclohexane at 723K are highlighted and discussed in relation to their porosities. The hierarchical catalysts exhibit different porosities; namely, the fluoride treatment leads to a zeolite combining micropores and macropores while alkaline leaching adds mesopores interconnected with the native micropores.
While the initial activities and selectivities of catalysts derived from the P, A, B zeolites are very similar in the conversion of methylcyclohexane, the presence of mesopores (alkaline leaching), close to the active sites, greatly improves the stability of such a hierarchical catalyst by favoring the desorption of products. This behavior is similar to a reduction in zeolite crystal size. This increased stability is not due to a decrease of the coke toxicity, but rather to an inhibition of the growth of coke precursors, in turn related to the shorter diffusion paths of reactants and products. Two types of coke are present on the meso-/micro-porous zeolite: (*i*) a "light coke" composed of alkylbenzenes strongly adsorbed on Lewis acid sites and silanols, (*ii*)

a “heavy coke” (alkylphenanthrenes and alkylpyrenes) trapped at the intersection of the zeolite channels. While the light coke has no impact on the catalyst stability, the heavy coke poisons active sites, most probably remote from the mesopores.
During the ethanol-to-hydrocarbons (ETH) transformation at 623K and 3.0 M Pa on HZSM-5 zeolites, unwanted side reactions occur and lead also to the formation of coke. Its composition is strongly related to the dimensions and shape of the ZSM-5 pores; the structures of molecules trapped are similar than these found in MCH. The coking rate depends on the textural properties of materials and more particularly on the diffusion path length. But the catalyst lifetime is not correlated to the coking rate, it is related to the external surface, since the ethanol transformation occurs mostly by pore mouth catalysis. Additions of macropores (A) by fluorine leaching or mesopores by alkaline treatment (B) of micron-sized zeolite (P) are simple tools to increase the number of pore mouths. But, by far, the most efficient way to increase dramatically the number of pore mouth is to reduce their crystal size. The highest catalyst longevity (>100 h), is obtained in spite of a total poisoning of acid sites on hierarchical nanometer-sized zeolite (N).
The decrease in the diffusion path also offers a clear advantage in the catalysts regeneration by lowering the temperature of total coke removal.

4 Conclusion

The time on stream behavior of the various catalysts shows the advantages of hierarchization and particle size. The deactivated catalysts are extensively characterized by their residual acidity and pore volumes, nature and quantity of the carbonaceous residues and ease of decoking. One important feature is that nanosized and hierarchical zeolite crystals produce less of the very toxic coke molecules (located at channels intersections) because most coke precursors diffuse efficiently to the external surface where their deleterious effect is minimal. Nanosized ZSM-5 are systematically better than any hierarchical zeolites produced by post-synthesis treatment due, among other factors, to the much lower diffusion pathways molecules have to follow in the microporous channels.

Keywords: ethanolysis, sodium, ethoxide, biodiesel, ethyl, ester

1 Introduction

Using bioethanol for biodiesel synthesis it is possible to obtain a 100% renewable product. Although at present ethanol is more expensive than methanol, it presents many advantages. Among the basic homogeneous catalysts used for biodiesel production, the one with best performance so far is sodium methoxide. Therefore, if the objective is obtaining biodiesel entirely composed by ethyl esters, the methoxide catalyst must be replaced. In this work, the transesterification reaction was performed using ethanol as alcohol and sodium ethoxide as catalyst.

2 Experimental/methodology

Biodiesel production process

The experiments were performed in a 500 mL flask with magnetic stirring, at 55 ºC. Refined sunflower oil and ethanol 99.5% were used as raw materials. The catalyst was sodium ethoxide solution (21 wt.%) in ethanol. The ethyl esters rich phase was purified using two consecutive washing steps. In the first one, neutral water was employed, and in the second one, a CO_2 saturated aqueous solution. Finally, the biodiesel was dried by stripping with N_2 at 80 ºC.

Figure 1. Results and discussion

Figure 1 (A) shows the monoglycerides profile, during the course of the reaction when MeONa or EtONa was used as catalysts, and methanol or ethanol was used as alcohol. As it is shown, the monoglyceride evolution during reaction was very similar for both catalysts when the alcohol used was methanol. However, the maximum concentration observed at low reaction times, was higher for the case of EtONa (%MG: 2.6 wt.%) in comparison to MeONa (%MG: 2 wt.%) which implies that the rate of disappearance of these compounds was higher when the catalyst used was sodium methoxide. Similar behavior was observed when ethanol was used as transesterification alcohol. On the other hand, when MeONa was used to catalyze the ethanolysis, the maximum monoglycerides content obtained was 4.5 wt.%, whereas the concentration measured for EtONa was 5.5 wt.%. This implies that the sodium methoxide catalyst has higher activity both for methanolysis and ethanolysis than sodium ethoxide, being this difference more pronounced when the alcohol used was ethanol. This is because the longer the carbon chain of the alcohol employed, the lower the reactivity of the alkoxide ion [1]. According to Reeve and Erikson [2], methanol is 4.4 times stronger as an acid than ethanol in an equimolar mixture. However, methoxide is less nucleofilic than ethoxide (0.82 times). The combination of these effects gives as a result that methoxide is 3.6 times more reactive than ethoxide. On the other hand, better solubility of ethanol in oil enhances mass transfer as compared to methanol [3]. Moreover, the phase distribution of the catalyst is more favorable for ethanol than methanol. As a consequence, the difference in reactivity is less pronounced than expected. In the same experiment it was observed that evolution of di- and triglycerides (not

shown) showed a similar pattern, but less marked than for the case of monoglycerides.

Catalyst consumption is shown in Fig. 1 (B). According to these results, there is a correlation between the moles of catalyst consumed due to saponification and the activity shown in Fig. 1 (A). The higher reaction rate was observed when MeONa was used as catalyst and methanol as alcohol. In this experiment, the percentage of catalyst that disappeared was only 30% of the initial concentration, this being the smallest value observed among the experiments carried out to compare different catalysts and alcohols. When EtONa and ethanol were used, the percentage of unreacted glycerides was the largest, which implies the lowest reaction rate. This correlates well with the results presented in Fig. 1 (B), which shows that 69% of the sodium ethoxide catalyst disappeared during the reaction with ethanol. This demonstrates that the reaction rate is not only affected by steric hindrance for the longer chain alcohol, but also is greatly affected by the catalyst disappearance. This is due to the less polar character of ethanol, which favors the saponification reactions during the transesterification to a greater extent than methanol. It can also be seen that using the same alcohol, either methanol or ethanol, sodium ethoxide showed greater tendency to form soaps than sodium methoxide, which is in agreement with its lower activity under identical conditions.

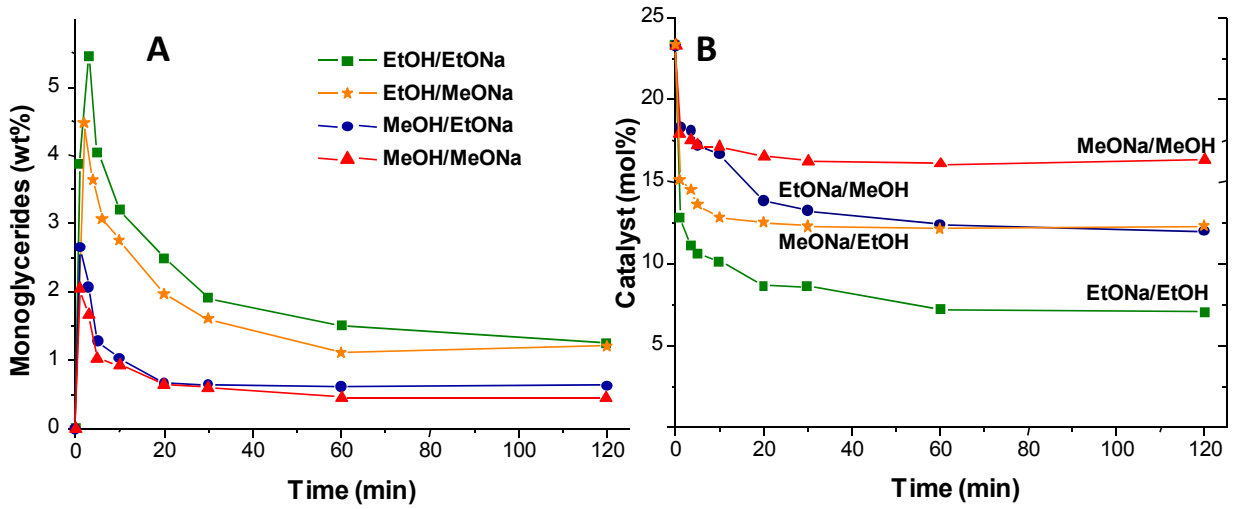

Figure 1. (A) Monoglycerides, and (B) catalyst concentration vs time using different alcohols (methanol and ethanol) and catalysts (sodium methoxide and ethoxide).

4 Conclusions

It was concluded that the methanolysis reactions are faster than the ethanolysis and sodium methoxide catalyst is more active than the corresponding ethoxide. This is due to two factors: first, the steric hindrance and secondly, that the saponification of EtONa in ethanol medium is greater than when using methanol, causing a decrease in the catalyst concentration and leading to lower conversion.

Biogas Steam Reforming for Syngas Production with Structured Catalyst

Álvarez A., Martínez T. L.M., Centeno M.A.*, Odriozola J.A.

ICMSE, University of Seville-CSIC, Seville, Spain

* centeno@icmse.csic.es

Keywords: biogas steam reforming, syngas production, H_2/CO, ratio, micromonolith

1 Introduction

Fischer-Tropsch technology has become a key strategy to overcome the actual petroleum scarcity. It allows the synthesis of liquid fuels similar to the ones derived from fossil sources but much more cleaner. However, one of the main requirements is the use of syngas with a H_2/CO ratio of 2. Therefore, finding viable and cheap ways to obtain syngas with this precise ratio would increase the viability of the process at industrial scale. In this way, the use of biogas, specially the one produced by rubbishes as a syngas source, is a very attractive option since it removes two household gases, and gives an added value to wastes.

Conventional packed-bed reactors have been mostly used for the syngas production from biogas reforming. In these systems, the use of small catalyst particles could cause high-pressure drops, flow misdistribution and even, hot spots that could alter the selectivity of the process [1]. Structured catalysts overcome these drawbacks. The employ of metallic monolithic catalysts allows the use of very small parallel channels, well below 1 mm, resulting in process intensification on favoring heat and mass transfer during reaction.

The present work describes the synthesis and structuration of a modified Ni/Al_2O_3 catalyst in order to produce syngas with the desired ratio from a mixture of CH_4, H_2O, and CO_2.

2 Experimental

Powder catalyst synthesis.

The support was synthesized by impregnation of Mg(NO3)2·6H2O (Aldrich) on γ-alumina powder (Sasol) in order to obtain a 10 wt % of Mg (calculated as MgO). This support was calcined at 850ºC for 12h. The catalysts was prepared by simultaneous impregnation with a solution containing both Ni(NO3)2·6H2O (Aldrich) and Ru(NO)(NO3)3 (Johnson Matthey) in ethanol. After drying at 60ºC for 12h, the solid has a final calcination at 500ºC for 3h in order to eliminate the precursor residues. The wt% of Ni is intended to be 15%, and that of Ru wt%, 0,5%.

Slurry catalyst synthesis.

The first step for washcoating the metallic substrate is to prepare stable slurry of the previously prepared catalyst. Particle size, solid content and pH are parameters that influence the slurry stability. In this work, the as prepared powder catalyst was milled until obtaining an average particle size of 10µm. Also, since the ZPC (zero point charge) of the catalyst was 10,5, the slurry pH was adjusted to 7,1 to ensure the stabilization of the slurry through high repulsions between the particles. Finally, colloidal alumina (Nyacol, 6% Wt) and Polyvinyl alcohol (PVA, 1,14 % wt) was added to improve the catalyst adherence and the washcoating drying process. The solid content of the slurry was 18,2%. After the deposition of the catalysts, the excess of slurry was dried and calcined at 500ºC 3h.

Micromonolith preparation.

Cylindrical monoliths were prepared using 50µm thick FeCrAlloy® foils by rolling around a spindle alternate flat and corrugated foils. Prior to washcoat, the metallic monoliths were calcined in air at 900ºC for 22h in order to generate an adherent α-Al2O3 scale. The metallic monoliths were dipped into the slurry for 60s, withdrawn at constant speed and then the excess suspension eliminated by centrifugation at 600rpm for 10min. This procedure was repeated three times with intermediate drying steps at 120ºC for 30min between coatings until 167mg of the catalyst were deposited. Finally, the coated structured supports were calcined at 500ºC for 3h.

3 Results and discussion

The powder catalyst characterization showed: (A) the desired metal incorporation into the support was achieved. (B) The addition of Ni and Ru barely changes the textural properties of the modified alumina and (C) A high Ni-Ru interaction evidenced by TPR and Raman spectroscopy. The slurry and the structured monolith were also characterized. No differences were detected regarding the textural properties after structuration. However, XRD analysis showed a clear presence of RuO_2 in the slurry sample (although no Ru species were found in the powder sample) implying a modification of the catalyst structure when preparing the slurry.

The catalytic activity of the powder sample, the calcined slurry and the micromonolith were performed at 750ºC with a CH_4:H_2O:CO_2 molar ratio of 1:0,56:0,4 with a WHSV(mg/g.h)=117000 for 100h (Figure 1). All samples showed the same activity at the beginning of the reaction. Nevertheless, the slurry gets deactivated after 5 hours. This late behavior could be achieved to the presence of RuO_2, which suggests a poor metal dispersion implying a minor Ru-Ni interaction. The powder sample, which has a better Ru dispersion, presents a better stability. On the other hand, the micromonolith presented the best activity and stability, and maintained a H_2/CO ratio of 2 for 100h. This great behavior can be explained based in the advantages of the catalyst structuration, where mass and heat transport processes are improved and the carbon gasification processes are enhanced, increasing the stability.

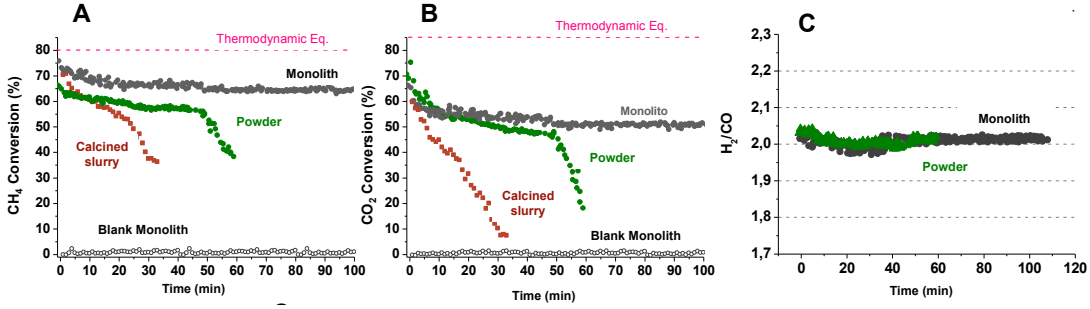

Fig. 1. (A) CH_4 Conversion. (B) CO_2 Conversion (C) H_2/CO ratio.

4 Conclusions

The catalyst structuration of a modified Ni catalyst in a metallic micromonolith allowed the syngas production with a H_2/CO ratio of 2 for at least 100h using the combined steam reforming of methane with a CH_4:H_2O:CO_2 molar ratio of 1:0,56:0,4 at 750ºC. Although the catalyst structuration generates a "less active" catalyst, the advantages of the catalyst structuration, where mass and heat transport processes are improved, increase the stability.

Cadmium and Tin Magnetic Nanocatalysts Useful for Biodiesel Production

Alves M.B., Medeiros F.C.M., Sousa M.H., Rubim J.C., Suarez P.A.Z.*

University of Brasilia, Brasilia, Brasilia

* psuarez@unb.br

Keywords: biodiesel, hydrolysis, esterification, transesterification, Ferrites

1 Introduction

In order to address the increasing demand for energy and growing ecological awareness, biofuels have emerged in the last decades as elegant alternatives to fossil fuels, since they are obtained from renewable sources. Therefore, improvements in the technology to produce renewable fuels, such as biodiesel, are needed to gracefully meet global demand for both food and biofuels, avoiding the food, energy, and environment trilemma. However, examples that can provide large amounts of raw-materials to produce biodiesel without competing with food production, such as the palm-tree oil called Macauba (*Acrocomia sclerocarpa* M.) that produce more than 4,000 liters per hectare when associated with cattle, usually contains high FA content (we have received a sample containing about 66 % of free fatty acids in its composition), making impossible their process using traditional transesterification technologies. The aim of this work was to identify new catalytic precursors with potential application in the preparation of biodiesel both using oils with high purity, as well as using a raw material with high free-FA contents. In this sense iron/cadmium and iron/tin magnetic materials were synthesized, which were tested as catalysts in the reactions of hydrolysis, esterification and transesterification of soybean oil and soybean FA. The catalytic activity of iron/tin catalyst was further investigated in the transesterification/esterification reaction of the crude acid oil from the Macauba palm-tree (*Acrocomia sclerocarpa* M.).

2 Experimental/methodology

Two aqueous metal solutions (M^{+2} and Fe^{+3}) were mixed with a hot sodium hydroxide aqueous solution, forming two precipitates: iron/cadmium (ICdO) and iron/tin (ISnO) oxides. The analysis of this solids by ICP, FT-Raman and DRX showed ferrite like solids ($MFe^{+3}{}_2O_4$, M= Cd^{+2} or Sn^{+2}). However, all these possible steps depend on the reaction parameters and may lead to different materials. Additionally, through the Scherrer formula, the broadening of the 311 main peak allowed calculation of the mean crystalline sizes of the grains of 3.5 nm and 34.8 nm for ICdO and ISnO samples, respectively. The magnetic properties of the samples were evaluated by recording the magnetic field (H) dependence of the magnetization (M) at 27 ºC. The ISnO sample presents a loop that shows a ferromagnetic-like behavior with saturation magnetization (M_s), remnant magnetization (M_r) and coercivity (H_c) values of ca. 12.8 emu/g (at H = 13 kOe), 3.1 emu/g and 86 Oe, respectively. On the other hand, the ICdO powder displays features of superparamagnetism, with negligible remanence and coercivity in low field regime. Moreover, the data indicate that ICdO does not saturate in the magnetic field interval investigated in this work, but reaching a magnetization of 22 kOe at the maximum value of magnetic field.

The catalytic activity of ICdO and ISnO were investigated in transesterification and hydrolysis of triacylglycerides, as well as in the esterification of fatty acids, which are useful reactions for biodiesel production. In this sense the experiments were carried out using soybean oil and fatty acids (previously prepared from soybean oil) as substrate. In 5 h, the reaction yields

for esterification, hydrolysis and transesterification, respectively, were up to: 98 %, 90 % and 84 % using ICdO and 98 %, 70 % and 30 % using ISnO (Conditions: 20 g soybean oil or soybean fatty acid, 6 g methanol or 20 g water and 1 g of ICdO or ISnO, at 200 ºC, 13.6 bar in hydrolysis and 18.6 bar in others). The catalysts are apparently more active for esterification than for transesterification and hydrolysis. It is important to highlight that there is a small contribution by self-catalysis promoted by fatty acids that act as catalysts of Brönsted. To evaluate the self-catalytic behavior of fatty acids we performed an esterification reaction at 200 ºC for 2 h in the absence of catalyst that resulted in 41 % yield. Thus, these results suggest that the main catalytic activity is due to the magnetic materials. Indeed, the increasing activity during hydrolysis observed for ICdO and ISnO may also be understood as a result of the catalytic activity of the formed fatty acids.

3 Results and discussion

In sequence, crude Macauba oil containing 66 % of free fatty acid was reacted with methanol in the presence of ISnO (Conditions: 20 g oil, 6 g methanol, 1 g catalyst, at 200 ºC, 18.6 bar). Note that only the ISnO catalyst was used because its performance was superior when compared to the ICdO in the recycling experiments. It is noteworthy that both esterification and transesterification reactions take place in this experiment, given that the substrate contains, in addition to glycerides, a high content of fatty acids. During the reaction there is a decrease in acidity value, sharper at the first 2 h, reaching a low acidity, which indicates that free fatty acids were esterified producing biodiesel. On the other hand, up to 90 % of FAME was obtained after 3 h of reaction, as a result of acyl-glycerides transesterification and fatty acid esterification. After the reaction, the ISnO catalyst was recovered by magnetic separation and was reused four other times with new charges of substrate with no significant loss of activity.

Keywords: glycerol, biodiesel, dry reforming, hydrogen, rare earth, oxide, fixed bed reactor

1 Introduction

Glycerol, a byproduct derived from transesterification of biodiesel is currently experiencing an oversupply crisis due to the higher biodiesel demand worldwide. Utilization of glycerol as feedstock helps to resolve this oversupply problem and directly rise up the price of crude glycerol and lowers the production cost of biodiesel plant [1]. Dry reforming of glycerol is aims as it offer a better pathway for the production of hydrogen and greener process as it used carbon dioxide as reactant and release water as their by-products [2]. Nickel (Ni) based catalyst has been widely used in reforming process due to its low cost as compared to noble metal catalyst. On other hand, cobalt (Co) based catalyst was selected as it provides similar activity to noble metal catalysts in the C-C bond cleavage, even at low operating temperatures. Therefore, in this study the H_2 production by glycerol dry reforming was evaluated using Ni and Co catalyst with different percent metal loading impregnated on La_2O_3 as support. The catalytic reaction was conducted in a fixed bed reactor where the reaction studies (i.e. hydrogen yield, glycerol conversion) and characterization of both catalyst was studied.

2 Experimental/methodology

Catalyst of 10 wt% Ni/La_2O_3 and 10 wt% Co/La_2O_3 were prepared via wet impregnation method. Initially, La_2O_3 support was calcined at 1073 K for 6 hours in a furnace. After that, an accurately weighted calcined La_2O_3 was mixed with $Ni(NO_3)_2.6H_20$ aqueous solution and magnetically-stirred for 3 hours. Then, the slurry was dried overnight in an oven at 383 K for 12 hours to remove excess water. The product was crushed and calcined again for 6 hours at 1073 K. It was then cooled down and sieved to a particle size of 90-200 μm for characterization and reaction studies. Catalyst characterization was performed using N_2 physisorption for Bruanaur-Emmett-Teller (BET) surface area, Scanning Elemental Analysis (SEM) and X-Ray Diffraction (XRD) analysis. For dry reforming experimental work, glycerol was flow through fixed bed reactor system via HPLC pump at a fixed temperature of 973 K. Flow of nitrogen gas to the reactor was set at 0.1 L/min flow rate at 1 bar while flow of carbon dioxide gas to the reactor was set at 9.9 ml/min at 1 bar. The composition of syngas produced was determined using online Agilent gas chromatography (GC) with TCD capillary columns and HP-Plot/Q column (30.0 m X 530 μm X 40.0 μm)

3 Results and discussion

Table 1 shows the comparison of BET surface area between 10 wt% Ni/La_2O_3 and 10 wt % Co/La_2O_3. It was found that the 10 wt% Ni/La_2O_3 exhibit large specific area and smaller metal

crystallite size as compared to 10 wt % Co/La_2O_3 which provides higher metal dispersion and larger surface area for the catalyst. These findings are co current with the results from the SEM where the morphology shows that there is presences of Ni species accumulate on the surface of La_2O_3 support.

Table 1: BET Analysis

	10 wt% Ni/La_2O_3	10 wt% Co/La_2O_3
BET specific surface area (m^2 g^{-1})	28.29	13.032
Cumulative pore volume (m^3 g^{-1})	0.0574	0.0211

FTIR analysis shows the same pattern of result for Ni and Co catalyst. Figure 1 (a) shows the XRD pattern for both Ni/La_2O_3 and Co/La_2O_3. The presence of La_2O_3 species in 10 wt% Ni/La_2O_3 was undetectable due to an increase in level of La_2O_3 dispersion that indicates formation of smaller crystallite. In contrast Co revealed additional peaks showing the formation of Co_3O_4 phase in the system resulting larger Co crystallite form. Figure 1 (b) shows yield of hydrogen for both catalyst and it shows Ni/La_2O_3 achieved 11.8 % of hydrogen which is the highest compared to Co and this can be supported by XRD and BET results.

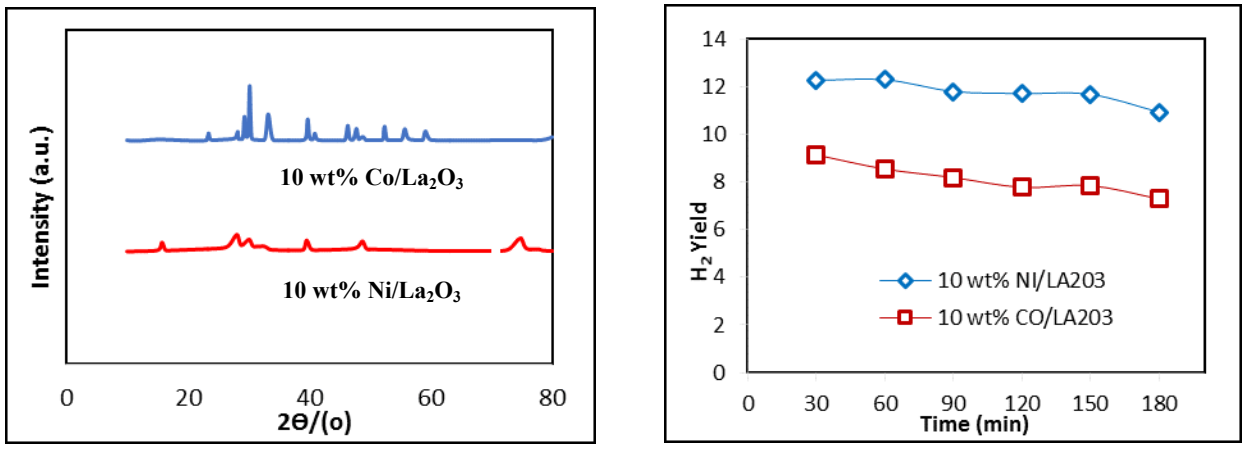

Fig. 1. (a) XRD patterns analysis of catalyst and **(b)** Yield of hydrogen of 10 wt% Ni/La_2O_3 and 10 wt% Co/La_2O_3

4 Conclusions

The Ni and Co catalyst supported by La_2O_3 have been investigated in glycerol dry reforming and both of the catalyst successfully produced hydrogen. From the results, 10 wt% Ni/La_2O_3 gives the highest H_2 yield and glycerol conversion. It is due to high activity of 10 wt% Ni/La_2O_3 towards hydrogen rich gas and great stability. Characterization analysis of XRD and BET results also revealed that 10 wt% Ni/La_2O_3 catalysts have smaller metal crystallite size which provide higher metal dispersion and larger surface area which is also proved by SEM analysis.

Keywords: ZSM-5, zeolite, acidity, modification, oligomerization, cracking propylene, coke, deactivation

1 Introduction

Acid MFI zeolite (HZSM-5) is used in catalytic processes linked with conventional and sustainable refining concepts. The outstanding performance of MFI zeolite is attributed to its unique acid and structural features, with very attractive shape selectivity for producing light olefins, and propylene in particular. The performance of MFI towards the production of propylene can be enhanced [1-4] by (i) selecting the proper SiO_2/Al_2O_3 ratio, (ii) calcinating with different protocols, (iii) using vapor at high temperatures, namely *steaming*, (iv) incorporating rare earth or transition metals, (v) exchanging hydroxyl groups by cations like Na^+, (iv) selecting a proper matrix of binders and fillers, and (v) by treatment with acids or bases, among others. In this work we have measured the correlations between the catalytic features (acid strength and porous structure) and its intrinsic performance (conversion, selectivity and deactivation) by a sensitivity and regression analysis, during the cracking of 1-butene to propylene using catalysts based on MFI zeolites of different SiO_2/Al_2O_3 ratio and modification degree with KOH and H_3PO_4.

2 Experimental/methodology

Catalysts were prepared based on commercial MFI zeolites (SiO_2/Al_2O_3 ratio of 30, 80 and 280), incoporating 1 and 3 wt% of K or P by incipient wetness impregnation at 70 ºC under vacuum using KOH (85 % purity) or H_3PO_4 (85 % purity) solutions, respectively. The catalysts were obtained by agglomerating 25 wt% of each zeolite with 30 wt% bentonite and alpha-alumina as catalyst inert matrix. The fresh and deactivated catalysts were characterized by elemenal analysis, XRD, ^{29}Si and ^{27}Al NMR, N_2 adsorption-desorption, adsorption-desorption of tert-butylamine (t-BA) and TG-TPO. The catalytic runs have been carried out in an isothermal fixed-bed reactor at 500 ºC; space time, 1.6 $(g_{catalyst}\ h)\ (mol_C)^{-1}$; WHSV, 8.75 h^{-1}; 1-butene (99 vol%, Air Liquide) partial pressure in the feed, 1.35 bar; time on stream, 0-5 h.

3 Results and discussion

The heat dissipated during isothermal adsorption of t-BA can be linearly correlated with the temperature of maximum t-BA desorption-cracking rate obtained in TPD of the same base. This result enables a fast characterization of the acid strength, which is a critical catalytic feature of the MFI zeolite that controls conversion and selectivity of propylene in 1-butene cracking. Thus, in accordance to previous literature [5], conversion increases and propylene selectivity decreases for zeolites with lower SiO_2/Al_2O_3 ratio, due to their higher acid strength.

On the other hand, zeolite crystal size and micropore volume are key factors controlling deactivation by coke deposition (Figure 1) and, consequently, the lifetime of the catalyst, as they favor the outward diffusion of coke precursors.

The modifications by KOH or H_3PO_4 of MFI zeolites affect their kinetic performance due to changes of these two catalytic features. On the one hand, these modifications lower acidity due to dealumination: K-modified MFI zeolites show significant drop of accessible framework Al, whereas P-modified MFI zeolites show a significant conversion of framework to extra-framework Al. On the other hand, these modifications cause desilication of the zeolites, which is greater for the MFI zeolites with the higher SiO_2/Al_2O_3 ratio, and is strongly correlated with the increase in mesoporosity and decrease in microporosity and crystal size

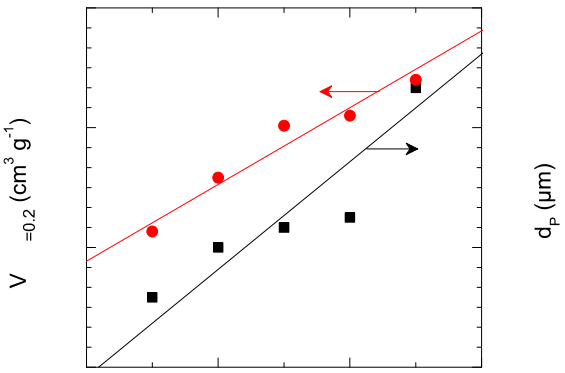

Fig. 1. Correlation between the coherent diffraction crystal size (d_P) and volume of N_2 adsorbed at $P/P_0 = 0.2$ with the amount of coke deposited after 5 h on stream.

Consequently, high propylene selectivity and slow deactivation rate by coke is obtained using high silica zeolites (SiO_2/Al_2O_3 ratio = 280) modified with of K or P, although the conversion of 1-butene is significantly decreased.

4 Conclusions

Acid strength as well as crystal size and mesoporosity are the features controlling the catalytic performance of high silica (SiO_2/Al_2O_3 = 280) MFI zeolites, which are the most promising catalysts for propylene production. Acid strength is the key factor controlling conversion of 1-butene and selectivity of propylene, whereas the diffusion length (size of the zeolite crystals and micropore volume) of the coke precursors is the key factor controlling coke deactivation and the lifetime of the catalyst. The modifications by KOH or H_3PO_4 of MFI zeolites lead to catalysts with lower activity but higher propylene selectivity and with extended lifespan due to its lower deactivation rate by coke deposition.

Catalytic Upgrading of Lignin Derived Pyrolysis Vapor via HZSM-5

Zhou G.[1], Jensen P.A.[1], Knudsen N.O.[2], Jensen A.D.[1*]

1 - Department of Chemical and Biochemical Engineering, Technical University of Denmark, Lyngby, Genmark
2 - DONG Energy, Fredericia, Genmark

* aj@kt.dtu.dk

Keywords: fast pyrolysis, lignin, HZSM-5

1 Introduction

Lignin is the second most abundant biomass component found in nature [1]. The estimated lignin production is 50 million tons/year from pulp and paper industry [2]. This number will increase with the development of new biomass utilizations, such as second generation bio-ethanol production. Hence the potential of lignin as a renewable source for chemicals and fuels should not be overlooked. By fast pyrolysis, lignin can be converted into a liquid fuel, known as bio-oil [3]. Due to its high oxygen content, a subsequent upgrading step is essential for using bio-oil as an engine fuel. In this study, lignin, obtained as a by-product from a second generation bio-ethanol plant, is pyrolyzed in a Pyrolysis Centrifuge Reactor. The pyrolysis vapor is directly upgraded catalytically using a HZSM-5 zeolite before product condensation.

2 Experimental/methodology

The lignin particles are conveyed by a screw feeder into the Pyrolysis Centrifuge Reactor that is kept at 500°C. The rotation of the blades in the reactor pushes the lignin particles onto the hot wall in order to obtain a high heating rate. The solid chars are separated from the gas by a change-in flow-direction separator (460°C), a cyclone (440°C) and a hot gas filter (300°C). The char free pyrolysis vapor is upgraded using a zeolite catalyst (HZSM-5) in a fixed bed reactor at varying temperatures from 350°C to 600°C. The liquid products are collected in a series of condensers placed in a cooling bath and a dry ice/ethanol bath. For each experiment, 30 g HZSM-5 (SiO_2/Al_2O_3=25) is used and about 30 g lignin is fed during 25 minutes.

3 Results and discussion

The product yields from fast pyrolysis and direct zeolite upgrading of the pyrolysis vapor are summarized in figure 1. Fast pyrolysis of lignin itself produces 25.8 $wt\%_{daf}$ of liquid organics. By upgrading the pyrolysis vapor over the HZSM-5 catalyst, the organic yield decreases significantly to less than 10 $wt\%_{daf}$, and a large amount of reaction water is produced. The organic yield reaches a peak at a catalyst temperature of 450°C and then decreases again at higher catalyst temperatures. At low temperature (350°C), the catalyst traps the pyrolysis vapor in the catalyst pores due to condensation and hence less organic liquid is collected. The desired organic products from the HZSM-5 upgrading are aromatics, such as benzene and toluene. The highest aromatic yield obtained is 4.0 $wt\%_{daf}$ at a catalyst temperature of 600°C.

Among the produced gases, CO and CO_2 are the major gas components. The yields of CO and CO_2 from the non-catalytic run are 4.1 $wt\%_{daf}$ and 11.4 $wt\%_{daf}$ respectively. The HZSM-5 zeolite promotes decarbonylation reactions to form CO over decarboxylation reactions to form CO_2. The yield of CO increases to 7.7 $wt\%_{daf}$ at a catalyst temperature of 600°C, while the CO_2 yield remains almost constant. The yields of valuable light olefins (including ethene and propene) increase with increasing catalyst temperature. The highest olefins yield is 4.3 $wt\%_{daf}$

obtained at a catalyst temperature of 600°C.

Via thermogravimetric analysis, the spent catalysts were heated up to 750°C under a N_2 flow. The catalyst used in the 350°C experiment, shows the highest weight loss (about 5 wt%) in thermogravimetric analysis. It verifies that the zeolite efficiently traps the pyrolysis vapor at low catalyst temperature. The trapped material does not form a graphite coke. Instead it is still reactive at elevated temperature.

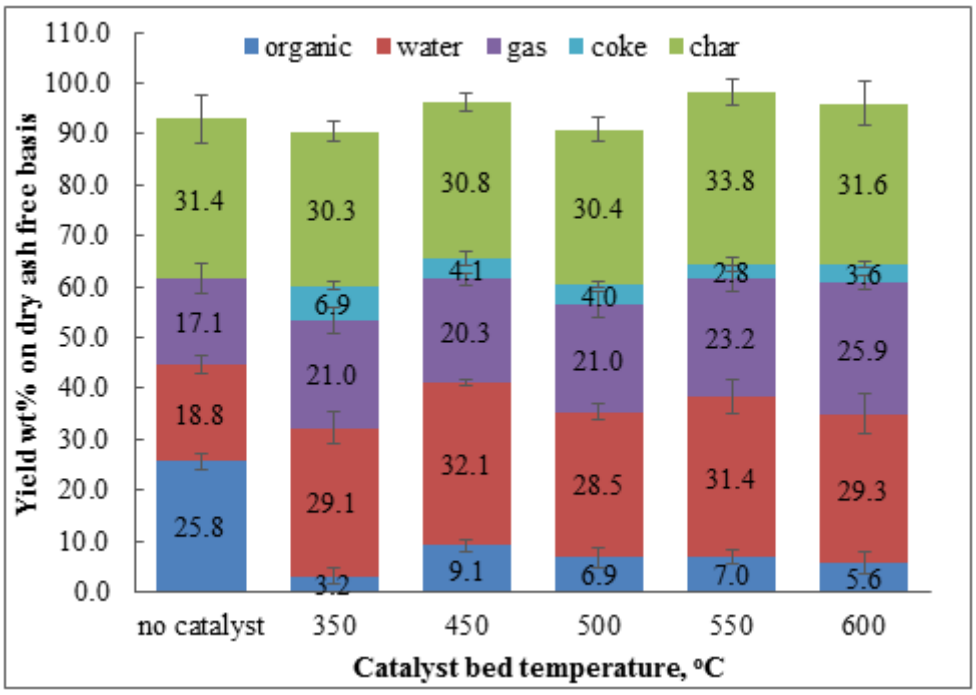

Fig. 1. Overall yields from fast pyrolysis of lignin and direct upgrading of pyrolysis vapor at catalyst temperatures from 350°C to 600°C

4 Conclusions

It is possible to convert lignin into bio-oil at an organic yield of 25.8 $wt\%_{daf}$ using a Pyrolysis Centrifuge Reactor. By direct upgrading of the pyrolysis vapor over a fixed bed of HZSM-5, the yield of organic liquid decreases significantly (<10 $wt\%_{daf}$) while the production of aromatics, such as benzene and toluene, is increased. The formation of aromatics is favored at high catalyst temperature. The highest yields of olefins and aromatics are 4.3 wt% and 4.0 wt% respectively at a catalyst temperature of 600°C. At low catalyst temperature, such as 350°C, HZSM-5 traps some of the pyrolysis vapor in the pores. However, the trapped reactant is still reactive at temperature >400°C. HZSM-5 rejects oxygen from lignin derived pyrolysis vapor mainly through the formation of H_2O and CO.

Keywords: fuel cell, oxygen reduction, alloy nanoparticles, chemical leaching, core-shell particles

1 Introduction

Pt-X alloy nanoparticles (X = Cu, Co, etc.) have received much attention because of their potential as cathode catalysts for the ORR in fuel cells. They form core-shell structures with a Pt skin covering an alloy core [1], which has been related to their superior ORR activity as compared to C-supported Pt nanoparticles. P. Strasser et al. found that the Pt shell can be made on purpose by electrochemical or chemical leaching protocols (EL, CL; [2, 3]). For particles below a critical size, EL was shown to result in shells of 3-4 layers of pure Pt covering alloy cores of approximately the initial composition (often PtX_3) [2, 4]. For layers of such thickness, electronic ligand effects could not explain the strong activity gains observed. Therefore, lattice strain, which has a longer range of influence [5], was proposed to cause the beneficial effects [4].

We have studied the effect of CL of C-supported $PtCu_x$ alloy particles (x_{av} □ 3) on their structure and ORR activity. CL, which was reported to be beneficial but inferior to EL [6], might limit the release of Cu onto electrodes activated by a final EL step. Moreover, it provides unlimited sample quantities for characterization studies, in our case by XRD, electron microscopy, XAFS, XPS, and Low-energy Ion Scattering (LEIS)

2 Experimental

$PtCu_x$/C was obtained by a reductive co-deposition with ethanol, with subsequent alloying by annealing in dilute H_2 at 800 °C. Following Strasser's procedures [6], EL was performed by 200fold potential cycling between 0.5 and 1.2 V in 0.1 m $HClO_4$, CL by refluxing in 1 M H_2SO_4 for 36 h. Activities were determined with the rotating-disc electrode and will be reported for a potential of 0.9 V, related to electrochemical surface areas (ECSA) determined by CO stripping.

3 Results and Discussion

According to XRD and electron microscopy, the alloy particles exhibited a distribution of sizes around 3.5 nm, and of Cu contents around $PtCu_{2.6}$. Superstructure signals indicated order in the alloy structure. The activity of the as-made catalyst (140 μA/cm^2 Pt) was twice that of a Pt/C reference. While direct EL improved the performance by just 25 %, 265 μA/cm^2 Pt were obtained after CL, which was further increased to 315 μA/cm^2 Pt by an additional EL step.

CL resulted in an average composition of Pt_3Cu. XRD showed a wide distribution of Cu contents, including small monometallic Pt particles, and the loss of superstructure. After annealing in H_2 at 800 °C, HAADF-STEM revealed a close metal-C interaction and the coexistence of individual atoms with the particles. CL produced hollows in large particles. Smaller particles were compact and surface-enriched in Pt within 3 atomic layers. The support was sprinkled with single Pt atoms, well-crystalline alloy particles had disordered overlayers (Fig. 1). XAFS confirmed the participation of the particle bulk in dealloying: Cu was found in a more Pt-rich environment. The average Pt-Pt distance was found to be 2.67 Å before leaching and 2.70 Å after CL while the peak activity of PtCu alloy particles was related to a Pt-Pt distance of 2.72-2.74 Å in literature [7]. Coordination numbers derived suggest a shell of 3-4 Pt layers over a $PtCu_2$ alloy core, but the abundance of Pt-Pt coordinations observed might also arise from segregated Pt particles present. While XPS confirmed Pt surface enrichment, the actual thickness of the Pt skin was assessed by quantitative dynamic LEIS. It was observed that the alloy core was covered by a single Pt monolayer containing almost no Cu (Fig. 2).

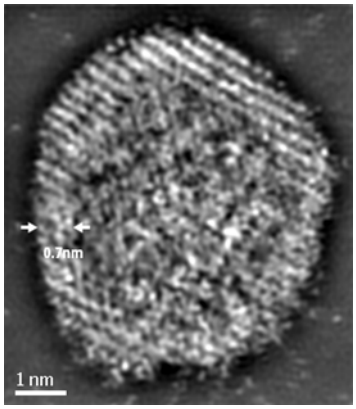

Fig. 1: HAADF-STEM image (Fourier filtered) of alloy particle after CL, with Pt enrichment in core ($Cu_{39}Pt_{61}$ vs. $Cu_{48}Pt_{53}$ in bulk), disordered surface structure, and individual Pt atoms nearby

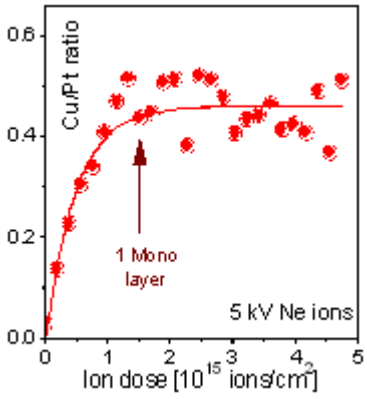

Fig. 2: Surface analysis by LEIS

This morphology is very different from that reported to result from EL (3-4 Pt layers on alloy core of original composition [2, 4]). The reason for this is unclear. The further improvement of electrochemical behavior by EL subsequent to CL may be due Pt-Cu distance further approaching the optimum value cited above.

Our observation that EL results in higher activity when starting from the CL sample with its Cu-depleted alloy core is, however, at variance with recent literature where activity after EL was described to be best for Cu-rich cores [4].

We found individual supported (Pt) atoms not only after CL but also after high-temperature alloying. This suggests that they are no intermediates of Ostwald ripening, but are strongly stabilized by the carbon support, with concomitant electronic effects. Therefore it should be examined if they can contribute to the catalytic activities observed.

4 Conclusions

Chemical leaching of carbon-supported $PtCu_3$ nanoparticles results in their significant activation for the ORR. The leached particles are covered by a monolayer of pure Pt, their cores are strongly depleted in Cu, which is different from morphologies reported in literature for alloy particles after EL. They can be further activated by electrochemical leaching.

Keywords: Hydroxyapatite, support, Palladium, WGS, COPROX

1 Introduction

The use of hydrogen as fuel is a promising alternative to produce clean energy. However, due to the H_2 production mainly via the reforming hydrocarbons its purification is necessary to eliminate the traces of CO in the hydrogen stream, especially, when the posterior use can only tolerate very low concentration of CO (< 100 ppm). For this purpose, the water gas shift (WGS) and CO preferential oxidation (COPROX) processes are applied as post-reforming stages for removing most of the CO and producing additional H_2. Palladium-based catalysts appear to be more efficient in both reactions because of their long-term activity and selectivity and their ability to operate at low temperature [1,2]. However due to their high cost the Pd active species should be highly dispersed on the support. In this sense, current research is dedicated to the synthesis of supports less sensitive to sintering and exhibiting suitable metal-support interactions. Hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, crystallizes in the hexagonal system and engenders two types of zeolite-like channels that play an essential role in its properties. Moreover, the structure of apatites allows different substitutions and ion exchanges which may modulate their surface chemistry [3]. In spite of the flexibility of their properties, hydroxyapatite supported palladium catalysts have never been used as support for WGS and COPROX applications.

The present work concerns the synthesis, characterization and the activity of palladium supported on these carriers. In order to examine their catalytic efficiency the prepared catalysts were evaluated in CO preferential oxidation in H_2-rich gas mixture and water gas shift reactions. Interesting conclusions are drawn from the correlation between the distribution of Pd active species and their performance in the two investigated reactions.

2 Experimental

Hydroxyapatite support (HAp) was synthesized adding drop wise a boiled aqueous solution of calcium nitrate to a solution of $(NH_4)_2HPO_4$. The precipitate was redissolved in a nitric acid solution and neutralized with ammonia at pH 10. The resulting mixture was maintained under stirring at 80 °C for 16 h. After filtration, the recovered solid was washed well with purified water then dried at 120 °C and finally calcined at 500 ºC for 4 h. The Pdx/HAp catalysts were prepared by impregnation of the corresponding support by tetraamminepalladium (II) chloride monohydrate where x is the Pd wt.% content. The prepared catalysts were calcined at 500ºC (4 h) and finally reduced under 5%H_2/Ar at 200 ºC for 2 h. The characterization of the oxidized and reduced Pdx/HAp involved mainly XRD, FTIR, UV-Visible-NIR diffuse reflectance spectroscopy, H_2-TPR, TPO, NH_3-TPD and TEM microscopy.

The COPROX catalytic tests were performed, with flow/mass ratio of 1320 cm3 min-1 g-1, in a tubular flow reactor operating at atmospheric pressure using 150 mg of the catalyst. Prior to running the catalytic experiments, the catalysts were submitted to a pre-treatment routine consisting on their reduction at 200 ºC (1 h) in a flow 5%H_2/Ar. The reaction mixture was

composed of 1% CO, 1% O_2 and 60 % H_2 (balanced with He) and a total flow rate equal to 200 cm^3 min^{-1}, which gives an oxygen excess parameter "λ" equal to 2. In the case of the WGS reaction, the composition of feed gas (in vol.%) was $CO/H_2O/H_2/CO_2$ = 4/9.4/37.9/3 balanced to He. The temperature of the reaction was increased from room temperature up to 360 °C with a heating rate of 5 °C min^{-1}. The reaction products were continuously analysed by Gas Chromatograph equipped with a TCD detector.

3 Results and discussion

Table 1 reports characterization results of the prepared Pdx/HAp catalysts. The FTIR spectrum and XRD diffractogram corresponding to the prepared HAp support were found to be identical to the reference spectrum and patterns reported in the literature. Moreover, the absence of pyrophosphate structure confirmed that the synthesized phosphate was pure apatite. Table 1 also shows the mean Pd particle size, determined by TEM microscopy, of reduced Pdx/HAp. The results revealed the presence of small Pd particles on Pd0.5/HAp (6.4 nm), whereas on Pd2/HAp the mean particle size was larger (12.1 nm). Moreover, the deposited Pd species were, generally, highly dispersed on the support surface (36-71%).

Table 1. Properties of the prepared Pdx/HAp catalysts

	Pd, wt.%	S_{BET}, m^2 g^{-1}	Pore volume cm^3/g	Pore size, nm	Pd particle size[(a)], nm	Pd[(a)] dispersion, %	S_M[(a)], m^2 g^{-1} Pd	H_2/Pd[(b)]

Values determined by (a) TEM and (b) H_2-TPR. (c) values corresponding to reduced catalysts.

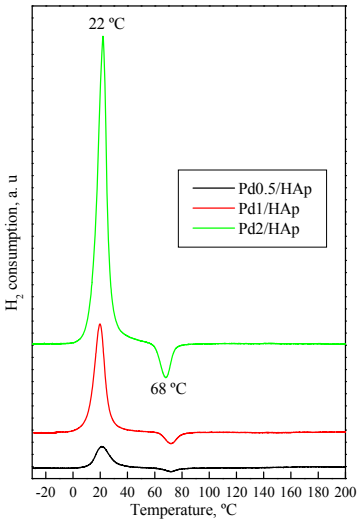

Fig. 1. H_2-TPR profiles of the Pdx/Hap catalysts

Fig.1 displays H_2-TPR profiles for the Pd(x)/CaHAp catalysts. Beside the reduction of PdO crystallites at around 22 ºC, the spectra showed a negative peak, centred at 68 ºC, which was associated with β-PdH decomposition. The determination of the Pd species, their surface chemistry and their interaction with HAp support were studied by means of UV-Visible and FTIR spectroscopy, TPO and NH_3-TPD techniques. The catalytic activity of the assayed Pdx/HAp catalysts in the COPROX and WGS reactions showed that they were active and selective (not shown). Moreover their activity was compared with classical Pd catalysts used in these types of reactions.

Interesting conclusions are drawn from the correlation between the distribution of Pd active species and their performance in the two investigated reactions.

Keywords: direct, methanol-dimethyl ether synthesis, CO_2 hydrogenation, zeolites, alumina, acidity

1 Introduction

Fossil fuels depletion and environmental protection imply new routes for energy production with low carbon dioxide emissions and high-energy efficiency. Electricity generation from renewable sources (wind, solar, geothermal and hydroelectric plants) presents a very satisfactory progress. Yet, electricity demand and supply do not always coincide. On the other hand, progress in alternative fuel production for the transport sector is slow, due to various reasons, among which the availability of raw materials. An interesting idea, addressing the above problems, is to store electric energy in the form of chemical energy. Hydrogen, (coming from water electrolysis during low electricity demand) and CO_2 (from flue gas and any other CO_2-rich stream) can be used for the synthesis of a mixture of methanol and dimethyl ether, alternative fuels for heat engines or Fuel Cells [1-4]. In the present work CO_2 hydrogenation for the production of methanol/DME has been studied over bifunctional catalytic systems comprising of a methanol synthesis and a methanol dehydration catalyst.

2 Experimental/methodology

A commercial $CuO/ZnO/Al_2O_3$ (CZA1) catalyst has been selected for the methanol synthesis reaction. A variety of commercial and home-made catalysts with different acidic properties and physicochemical characteristics have been used for the methanol dehydration reaction: γ-Al_2O_3 (Al4), WO_3/Al_2O_3 (WAl4) and various zeolites, Ferrerite(10) (FER(10)), Faujasite (USY6), HZSM-5(11.5) and HZSM-5(25). The investigated materials have been characterized with respect to their textural properties (B.E.T. and B.J.H. methods) and crystallinity (XRD). Methanol dehydration catalysts have been also studied regarding their acidity by TPD-NH_3 and FT-IR with in situ pyridine sorption. Furthermore, the adsorption/desorption properties of catalysts toward methanol and water as well as the dehydration reaction mechanism have been investigated with the use of transient-MS and in situ DRIFTS techniques. Catalytic tests were performed over mechanical mixtures (1:1) of the above materials, at 3.0 MPa and temperatures 180-250 °C and a gas mixture of CO_2/H_2.

3 Results and discussion

Regardless of the catalytic configuration used, CO_2 conversion increased with temperature (180-250 °C) but it is always lower than that predicted by thermodynamics, indicating that the reaction occurs under the kinetic regime (Fig. 1A). Although there are no significant variations in the activity, there are noticeable differences regarding the yields of reaction products over the various catalysts investigated. For the catalytic configurations containing alumina the main product is methanol, indicating that methanol, produced from CO_2 hydrogenation, is not consumed for the formation of DME (Fig. 1B and C). This may be due to the poor acidity of these samples, to the nature of acid sites (Lewis and Brönsted) or to the fast deactivation of acid sites by the adsorption of water formed. Catalysts containing zeolitic materials produce mainly

DME and lower amounts of methanol, showing that these are more active for the methanol dehydration reaction and/or more resistant to deactivation than alumina (Fig. 1B and C). Differences in DME yields are observed for the various zeolites, depending on parameters such as the micropore structure, the Si/Al ratio of the zeolite and the number, strength and nature of active acid sites. Catalysts deactivate with time on stream but, in most cases, catalytic activity is almost completely restored after regeneration.

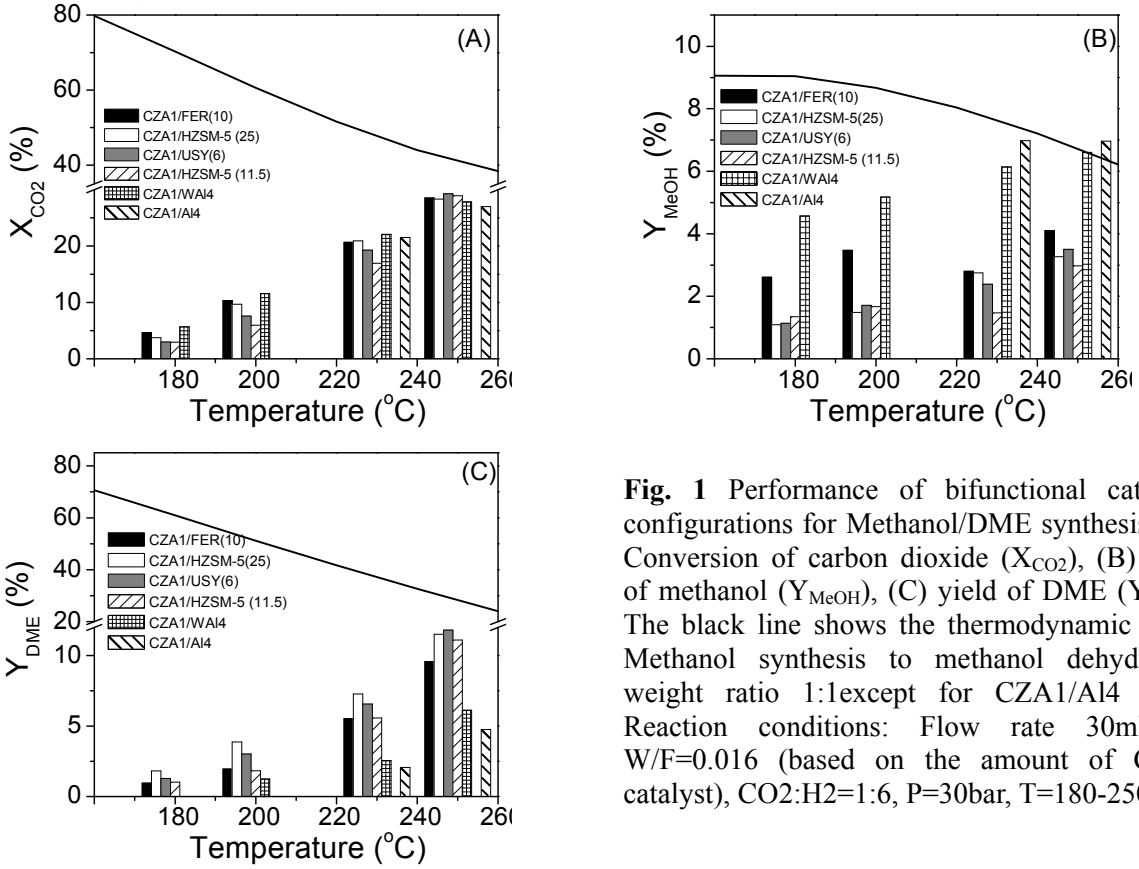

Fig. 1 Performance of bifunctional catalytic configurations for Methanol/DME synthesis: (A) Conversion of carbon dioxide (X_{CO2}), (B) yield of methanol (Y_{MeOH}), (C) yield of DME (Y_{DME}), The black line shows the thermodynamic limit. Methanol synthesis to methanol dehydration weight ratio 1:1except for CZA1/Al4 (1:2). Reaction conditions: Flow rate 30ml/min, W/F=0.016 (based on the amount of CZA1 catalyst), CO2:H2=1:6, P=30bar, T=180-250oC

4 Conclusions

The structure and the acidity (nature, number, strength, Lewis/Bronsted ratio) of the methanol dehydration component play a significant role on the selectivity of the catalytic systems for the direct hydrogenation of CO_2 to produce methanol and DME.

Keywords: dimethoxymethane, catalytic steam reforming, hydrogen, fuel cell

1 Introduction

Polymer electrolyte membrane fuel cells (PEMFC) are considered as an alternative environmentally sound source of electric power. Such fuel cells are usually fed by pure hydrogen or hydrogen-rich gas mixtures produced by catalytic conversion of hydrocarbons or oxygenated hydrocarbons.

Dimethoxymethane (DMM) is an easy to synthesize oxygenated compound of C_1 chemistry. DMM is a nontoxic and environmentally benign chemical. It is a liquid under normal conditions, and therefore can be easily stored and handled. DMM has a wide scope of applications. In particular, DMM can be used as an additive to diesel fuel to improve combustion and reduce pollutant emissions of diesel engines. These facts together with the recent data on DMM steam reforming (SR) reported in [1-4] predict increasing DMM demand that will become a promising feedstock for production of hydrogen-rich gas for PEM FC feeding.

Overall DMM SR is expressed by equation:

$CH_3OCH_2OCH_3 + 4H_2O = 8H_2 + 3CO_2$

Besides these reactions, a reverse WGSR may proceed to produce carbon monoxide:

$CO_2 + H_2 = CO + H_2O$

It is generally assumed [1-4] that DMM SR proceeds via a consecutive two-step reaction mechanism: the first step is hydration of DMM to methanol/formaldehyde over acidic catalysts (or acid sites of the catalyst); the second step is steam reforming of the produced methanol/formaldehyde over Cu-based catalysts (or Cu-based sites of the catalyst) to hydrogen-rich gas.

The present work reports the results of comparative study of alumina-supported bifunctional $CuO-CeO_2$ and CuO-ZnO catalyst in DMM SR to hydrogen-rich gas to be used for fuel cell feeding. To elucidate the role of each catalyst component in DMM SR, the data on the catalytic performance of γ-Al_2O_3, CuO/γ-Al_2O_3, ZnO/γ-Al_2O_3 and CeO_2/γ-Al_2O_3 are presented as well.

2 Experimental/methodology

$CuO-CeO_2/\gamma$-Al_2O_3 and $CuO-ZnO/\gamma$-Al_2O_3 catalyst samples were prepared by incipient wetness co-impregnating γ-Al_2O_3 (S_{BET} = 200 m^2/g, V_{pore}= 0.7 cm^3/g, granule diameter 0.25–0.5 mm) with aqueous solutions of copper (II) and cerium (III)/zinc(III) nitrates taken at the desired ratio. CuO/γ-Al_2O_3, ZnO/γ-Al_2O_3 and CeO_2/γ-Al_2O_3 were prepared by incipient wetness impregnation of γ-Al_2O_3 with aqueous solutions of copper (II), zinc (II) and cerium (III) nitrates, respectively. The samples were dried at 100°C in air and calcined at 400°C-500°C in air for 3h. The catalysts were characterized by BET, TPR, XRD, FTIR spectroscopy, HRTEM, EDX and HAADE-STEM techniques.

DMM SR experiments were performed in a fixed bed flow reactor at atmospheric pressure, GHSV=10000 h^{-1}, temperature 150-300°C and feed gas composition (vol.%): DMM/H_2O/N_2=14/70/16. Prior experiments, the catalysts were reduced in a flow of 5 vol.% H_2 + 95 vol.% N_2 at 350°C for 1h. The composition of the inlet and outlet gas mixtures was analyzed by a gas chromatograph.

3 Results and discussion

Table 1. Performance of alumina-supported CuO-ZnO and CuO-CeO_2 catalysts in DMM SR to hydrogen-rich gas

Catalyst	X (DMM), %	Outlet product concentration, vol.%					W(H_2), L H_2/g·h
		H_2	CO_2	CO	CH_3OH	CH_3OCH_3	
10%CuO-5%ZnO/γ-Al_2O_3	100	60	20	1	0.06	0.1	16.5
10%CuO-5%CeO_2/γ-Al_2O_3	100	59.5	19.5	0.5	0.7	0.6	15.5

The Table presents data on DMM conversion, outlet product concentrations and H_2 productivity at DMM SR over bifunctional catalysts at 300°C. Note that at this temperature both catalysts showed the maximum H_2 productivity (~16 L H_2/g·h) and complete DME conversion to hydrogen-rich gas with H_2 and CO contents of ~60 and ~1 vol.%, respectively. The latter fact is important as it allows using a simpler scheme for production of hydrogen-rich gas for PEM FC application that dictates strict requirements regarding the CO impurity. Indeed, the hydrogen-rich gas produced by DMM SR can be used for direct feeding of HT PEM FC without any further CO removal. For LT PEM FC feeding, the hydrogen-rich gas should be purified of CO to the level of 10 ppm, which can be achieved by selective oxidation or methanation of CO, bypassing the stage of the water-gas shift reaction.

Based on the data obtained, it is shown that the catalytic performance of CuO-CeO_2/γ-Al_2O_3 and CuO-ZnO/γ-Al_2O_3 in DMM SR is associated with the γ-Al_2O_3 acid sites and alumina-supported copper-cerium/zinc oxide species, which are responsible for, respectively, DMM hydration and methanol/formaldehyde SR.

4 Conclusions

Bifunctional CuO-CeO_2/γ-Al_2O_3 and CuO-ZnO/γ-Al_2O_3 catalysts containing on their surface both acidic and copper-based sites are active and selective for DMM SR to hydrogen-rich gas with low (1 vol.%) CO content. These catalysts provide for 100% DMM conversion with hydrogen productivity of ~16 L H_2/g_{cat}·h at GHSV = 10000 h^{-1} and T = 300°C. So, 50 g of the catalyst is sufficient to provide operation of 1 kW PEMFC-based power unit using DMM as the primary fuel.

Keywords: ketonization, liquid phase, prapanoic acid, catalysts, CeO_2, ZrO_2

1 Introduction

Renewable liquid fuels, as well as chemicals, derived from biomass resources are gaining significant attention as alternative to the existing fossil based resources [1-2]. Among various processes, fast pyrolysis and hydrolysis are the two main conversion routes for transforming biomass into liquid fuels. In both cases, carboxylic acids are formed as one of the major intermediates, being partly responsible for undesirable properties like low pH and high oxygen content of the derived bio-oils. Thus, upgrading of these carboxylic acids is required for obtaining quality fuels. In this context, ketonization reaction, which allows coupling two carboxylic acids to form a ketone, is a very convenient route for lowering the acid content as well as oxygen concentration of the derived bio-oils through the removal of oxygen as CO_2 and H_2O [3-5].

The conversion of these carboxylic acids to ketones in a condensed phase medium at lower temperature (<300 ºC) would be preferred than the vapour phase conversion (>300 ºC), because it is more practical for upgrading intermediate liquid biofuels like bio-oil [4,5]. Thus, the present work is focused on the study of liquid phase ketonization using a model bio-oil compound, propanoic acid, in presence of CeO_2 and ZrO_2 or their mixed oxide as catalysts.

2 Experimental/methodology

CeO_2, ZrO_2 and $Ce_{0.5}Zr_{0.5}O_2$ catalysts were prepared by thermal decomposition (TD) of corresponding $Ce(NO_3)_3.6H_2O$ and $ZrO(NO_3)_2.xH_2O$ precursors at 500 ºC for 6h in air. For comparison, commercially available CeO_2 (Acros Organic) and ZrO_2 (Sigma-Aldrich) were also used for the reaction. The samples were characterized in detail using N_2 adsorption-desorption isotherms, powder X-ray diffraction pattern and FT-IR spectral analysis.

The ketonization reaction was carried out in a 100 ml stainless steel high pressure batch reactor. 0.5 g of catalyst was added to 70 ml toluene and 1 ml of propanoic acid solution. The reactor was first pressurized up to 40 bar with N_2 and subsequently heated. The reaction was carried out at 290 ºC for 6 h with stirring at 800 rpm. The products were analyzed by GC. Prior to characterization and after reaction, the catalysts were dried at room temperature in air for 12 h.

3 Results and discussion

The catalysts obtained from the TD method show significant improvement in the surface area (CeO_2-TD: 70 m^2/g and ZrO_2-TD: 53 m^2/g) than the commercially available samples (CeO_2: 12 m^2/g and ZrO_2: 5 m^2/g). This property is even higher for the 1:1 combination of Ce and Zr (83 m^2/g) than their counter oxides. Cubic crystalline phase is observed for both commercial and prepared CeO_2 samples whereas different crystalline phases, monoclinic and tetragonal, are detected for commercial and prepared ZrO_2, respectively. The XRD pattern of $Ce_{0.5}Zr_{0.5}O_2$-TD catalyst maintains the cubic geometry of the CeO_2 phase.

In comparison with the commercial catalysts, synthesized materials (CeO_2-TD and ZrO_2-TD) perform better for the ketonization of propanoic acid (PA) in liquid phase at 290 ºC. This result is attributed to the improvement of their specific surface area. Among the prepared samples, CeO_2-TD shows much higher PA conversion than ZrO_2-TD. However, the 3-pentanone selectivity from converted PA is superior for the last one. According to Figure 1A, almost all (90%) the converted PA is transformed to the desired 3-pentanone over the ZrO_2-TD catalyst. An intermediate conversion and selectivity is obtained with the mixed oxide catalyst, no synergetic effects being, therefore, detected.

FT-IR spectral analyses (Figure 1B) of all the samples reveal that Ce containing catalysts, CeO_2 and $Ce_{0.5}Zr_{0.5}O_2$, form the metal carboxylate (ν_{asym}: 1545 cm^{-1} and ν_{sym}: 1373 cm^{-1}) on reaction with PA whereas this is not the case for ZrO_2 sample. This indicates different affinities of Ce and Zr centres to PA on its transformation to ketone, which probably control their observed catalytic activities.

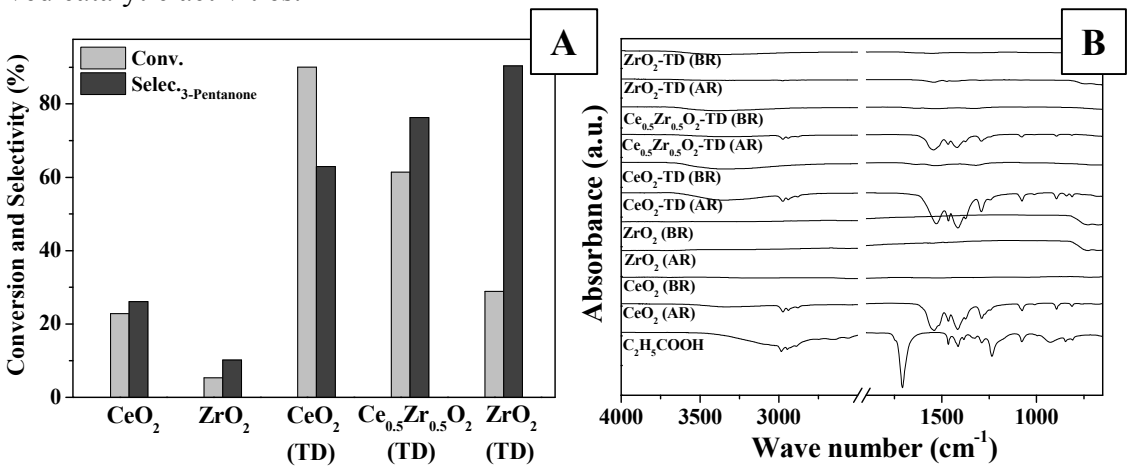

Fig. 1: A) Catalytic activity of the commercial and prepared samples in ketonization of PA and B) FT-IR spectra of the catalysts before and after the ketonization reaction.

4 Conclusions

The ketonization of propanoic acid has been studied in liquid phase and the CeO_2-ZrO_2 catalysts, active for this reaction, have been developed by thermal decomposition method. CeO_2 alone shows very good conversion, however, its modification with ZrO_2 in 1:1 ratio gives a better catalyst for this transformation in terms of 3-pentanone selectivity with high conversion rate. FTIR provides some insights on the different mechanism of ketonization on Ce and Zr sites.

Keywords: mesoporous WO_3, photocatalysis, metal doping, CH_4, conversion, methanol

1 Introduction

In the last few years there has been a growing interest in the production of methanol to be used as an alternative fuel [1]. An inexpensive way to obtain it is by photocatalysis which is a valuable technique that allows carrying out the selective oxidation of methane to methanol at ambient temperature and pressure [2].

Prior studies indicate that WO_3 is one of the most efficient catalysts for this type of photocatalytic reaction [3]. However, the total yield remains still low. In an attempt to improve its performance, an ordered mesoporous WO_3 was tested in this photocatalytic conversion and the changes in the catalyst during the reaction was monitored by in situ DRIFTS measurements. Additionally, the influence of metal doping M/WO_3 (M=Ni, Fe, Cu) was also studied.

2 Experimental

The Ordered mesoporous WO_3 was synthetized by a replicating technique using ordered mesoporous silica KIT-6 as the template. After impregnation, the sample was dried and then calcined for 4h at 350ºC to eliminate impurities. Later, the material was sintered for 6 h at 550 ºC to obtain the WO_3 inside the silica template. The KIT-6 was removed by HF (10 % wt) solution under stirring. Finally, the catalyst was separated by centrifugation, washed sequentially with water and ethanol and dried at room temperature.

M-doped WO_3 (M=Fe, Cu and Ni) was prepared by impregnation. Solutions of respective metal nitrates in ethanol were mixed with the appropriate amount of WO_3 suspended in ethanol. The slurry was kept under stirring at room temperature for 2 h. After being dried at 100ºC for 5 h, the obtained powder was calcined at 300ºC for 5 h to eliminate the nitrates and then, sintered at 500ºC for 2 h.

The photocatalytic partial oxidation of methane was carried out in a photochemical reactor of 500 mL volume. A medium pressure mercury lamp inside the reactor was used to provide UVC-visible light irradiation. The reaction temperature was maintained at ~55˚C. A mixture of CH_4/He was sparged continuously through the photocatalytic reactor. In a typical experiment 300 mL of water containing 0.3 g of catalyst were placed in the reactor. Gas samples were periodically analyzed by gas chromatography.

3 Results and discussion

The diffraction peaks of all samples indicated the presence of the monoclinic structure of WO_3 (JCPDS 43-1035), no crystalline phases related to Cu, Ni or Fe were detected, probably due to its low concentration. Additionally, the self-reduction process of the WO_3 by the electrons generated in the photocatalytic reaction was confirmed by real time DRIFTS experiments.

On the other hand, the comparison of the performance of a commercial WO_3 (Alfa-aesar) with the as-synthesized mesoporous WO_3 evidences an improvement in the photoreactivity which would be related with a remarkable increase in the surface area of the latter from 7.8 to

151.0 m^2 g^{-1}.

As shown in Figure 1, the Ni doped WO_3 exhibits the highest rate of methanol production with a low amount of CO_2. The Ni in this configuration would be in the form of NiO (p type oxide) resulting in n-p junction that improves the charge separation and thus, a higher amount of CH_3OH is generated. Moreover, since Ni has a suitable conduction band edge (-0.5 V) for the production of hydrogen, this metal oxide can capture the photogenerated electrons and protons to generate H_2, suppressing the self-reduction of WO_3 previously described (no changes in the color of suspension were observed). Therefore, the difference in the photoactivity of the doped samples is related to the ability of electron capture of these metals.

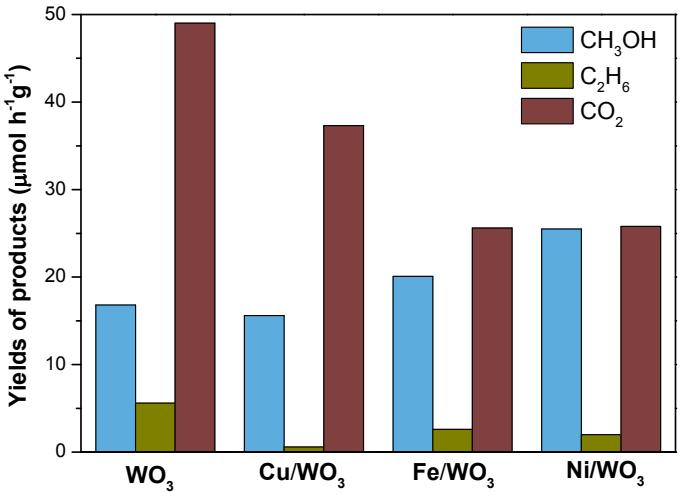

Fig. 1. Yields of products in the photocatalytic oxidation of CH_4.

4 Conclusions

The photocatalytic oxidation of methane to methanol over pure and doped WO_3 was examined. This study revealed that mesoporous catalyst can play an important role in the conversion of methane to high valuable compounds such as methanol, mainly due to its large surface area and ordered structure that increases the adsorption of the reactant molecules. On the other hand, the Ni doping markedly favoured the photocatalytic performance. For instance, selectivity toward methanol could be increased from 21.9% to 46%.

Keywords: dry-reforming, ferrierite, ITQ-6, Cs-promoted, Ni catalysts, syngas, carbon, deposition

1 Introduction

Dry-reforming process involves the conversion of main greenhouse gases, CH_4 and CO_2, responsible of global warming. This reaction has very important environmental implications because methane and carbon dioxide can be converted into syngas (H_2-CO) which, in turn, is transformed into dimethyl ether, methanol and other valuable products in several refinery GTL (gas to liquid) and Fisher-Tropsch processes.

Nickel is catalytically active in the reforming reaction, but carbon deposition on the metal surface causes catalyst deactivation. Nature of the support, preparation method and addition of promoters [1,2] strongly affect the metal distribution and its reducibility.
Recently, zeolites were reported to be suitable supports for nickel in the dry reforming of methane [2,3].

In the present work, we have investigated a lamellar zeolite (FER), still unexplored as support, and compared the performance of Cs- promoted Ni catalysts supported on both lamellar and delaminated (ITQ-6) forms in order to understand the effect of the different textural characteristics of the support in the dry reforming of methane.

The characterization of these materials by XRD, BET area, TPR, SEM-EDX and AFM has allowed to establish interesting relationships between their catalytic performance and physico-chemical properties.

The objective was to develop a catalyst able to overcome the long-standing carbon formation and thermal sintering problems.

2 Experimental

FER (Ferrierite type zeolite) precursor was synthesized starting from a gel having the following molar composition: 1 SiO_2– 1.46 NH_4F – 0.91 HF – 1 TMPP – 9.1 H_2O (TMMP is 4-amino-2,2,6,6-tetramethylpiperidine). Pure silica ITQ-6 material was prepared according to [4]. Cation exchange was performed with 1.0 molar chloride solution of Cs^+.

Ni catalysts (5% wt/wt) were prepared by incipient wet impregnation of the supports. After impregnation, the catalysts were reduced at 500°C in H_2 with a flow rate of 20 cm^3min^{-1} for 1 hour.

The CO_2 reforming reaction of CH_4 was carried out in a continuous flow quartz tube reactor at 1 atm pressure, varying the reaction conditions in order to optimize the catalytic performance. Reaction products were analyzed by on-line gas chromatograph (GC Agilent 6590) having FID and TCD detector and appropriate columns for the detection of gas on outlet current on stream.

3 Results and discussion

Some representative results of the 10-hours catalytic tests at 700°C with an equimolar CH_4/CO_2 feed are summarized in Table 1. It is observed that the CO_2 conversion is always higher than the CH_4 conversion, because of the simultaneous occurrence of the reverse water gas shift reaction (RWGS) [5]. For all catalysts the H_2/CO molar ratio is higher than one, most probably because, under the present reaction conditions, dry-reforming is accompanied by secondary reactions, such as CO disproportionation (Boudouard reaction) and steam reforming of methane [6].

Table 1. Catalytic behavior of catalysts after 10 h reaction at 700°C.(Values at steady-state).

Sample code	CH_4 [mole%]	CO_2 [mole%]	H_2/CO	C [mole%]
Ni-FER	75	90	1.40	0.88
Ni-CsFER	73	91	1.23	0.52
Ni-ITQ-6	77	90	1.39	2.1
Ni-CsITQ-6	75	92	1.14	0.76

According to Table 1, the peculiar lamellar structure of FER allows to carry out the reaction with a lower coke formation (ca. 60%) with respect to the delaminated structure (ITQ-6).

Cesium addition to FER does not affects the reforming activity but reduces again the coke formation by decreasing the amount of nickel ensemble necessary to the occurrence of undesired carbon deposition.

According to [6] the structure, morphology and formation rate of carbon deposits depend on the formation of intermediate Ni-carbide (Ni_3C) phase which, in turn, is affected by the dimension of Ni particles deposited on the support.

The AFM image of Ni-Cs-FER catalyst shows a homogeneous distribution with no metal agglomeration.

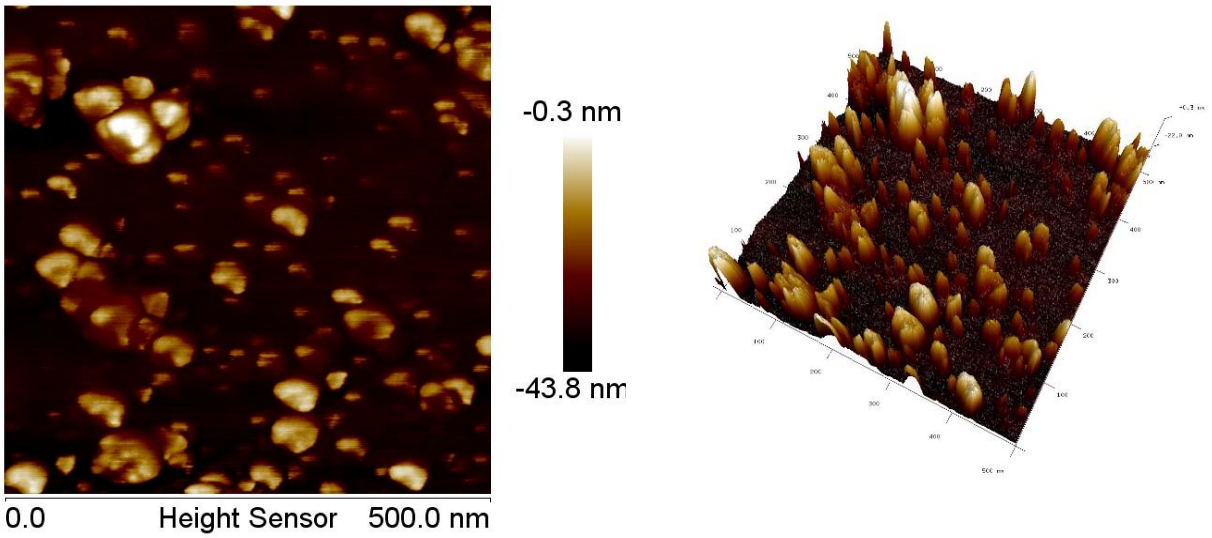

Figure 1. AFM images of Ni-Cs-FER

Keywords: anode electrocatalysts, CO-tolerance, controlled surface reactions, SnPt/C, electrocatalysts, Pt_3Sn, conducting, mixed oxides, support

1 Introduction

Reducing the amount of Pt along with increasing the metal dispersion is a key requirement for the implementation of fuel cells. CO tolerance and stability of the anode electrocatalysts also has to be improved, as the hydrogen fuel generally contains CO impurity that poisons Pt. In order to mitigate these issues, various approaches have been attempted.

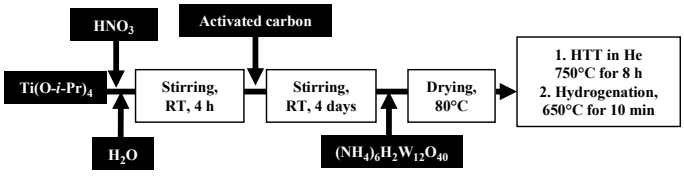
In this contribution our results in development of Pt-Sn alloys supported on active carbon and novel $Ti_{0.7}W_{0.3}O_2$-C composite supports for Pt-based electrocatalysts are presented.

2 Experimental/methodology

Sn-Pt/C electrocatalysts. A 40 wt% commercial Pt/C (Quintech) catalyst was modified by tin anchoring via Controlled Surface Reactions (CSR) using $SnEt_4$ as the tin precursor [1-3].

40 wt% Pt/$Ti_{0.7}W_{0.3}O_2$-C electrocatalysts. A low temperature sol-gel-based multistep synthesis route followed by high temperature treatment (HTT) in He and reduction was applied for the composite materials preparation (Scheme 1). 40 wt% Pt loading was achieved using $NaBH_4$ and ethylene glycol [4].

All electrocatalysts were characterized by XRD, TEM, EDS and XPS techniques. The activities of the samples were compared in both methanol oxidation reaction and CO_{ad} stripping with those observed on home made 40 wt% Pt/C or PtRu/C (Quintech, Pt= 20 wt%, Ru= 10 wt%) references. Details of *in situ* EC-IRAS measurements can be found elsewhere [2,3].



Scheme 1. Flow chart for preparing $Ti_{0.7}W_{0.3}O_2$-C composite materials.

3 Results and discussion

By means of CSR alloy-type SnPt/C electrocatalysts with wide range of the Pt/Sn ratios (Pt/Sn= 0.8-12.5) and exclusive Sn-Pt interaction were obtained. XRD demonstrated that the electrocatalysts contain a near-stoichiometric fcc Pt_3Sn alloy phase along with a certain amount of the Pt-rich $Pt_{(1-x)}Sn_x$ solid solution. The content and dispersion of the fcc Pt_3Sn phase can be controlled by tuning the reaction conditions of CSR. No evidence of the presence of SnO_2 phase was found by means of the XRD and EDS analysis. According to *in situ* XPS studies pre-treatment in hydrogen at 350°C resulted in complete reduction of the ionic tin to Sn^0. These

results demonstrate that the method of CSR is a powerful tool to create Pt-Sn bimetallic nanoparticles exclusively, without tin deposition onto the carbon support. It has been shown that the optimal balance between the Pt/Sn ratio, the amount of the fcc Pt_3Sn alloy phase and the metal particle size are responsible for the activity increase in both the CO and methanol electrooxidation. Increase of the tin content above a certain (optimal) amount gives rise to a negative effect on the catalyst performance in both reactions.

Another way for improving the CO tolerance of the electrocatalyst by the bifunctional mechanism is to create interfaces between Pt particles and an oxide-containing support which is (i) stable under the reaction conditions, (ii) electroconductive, (iii) generates OH groups as oxidants at low potential and (iv) stabilizes the small size of the Pt particles. Composites of activated carbon and $Ti_{(1-x)}W_xO_2$ mixed oxide are good candidates for this role. The challenge in the preparation of this material is that the preferable properties are linked to complete isovalent W incorporation into the rutile-TiO_2 lattice. XRD, EDS and XPS techniques confirmed the successful synthesis of the $Ti_{0.7}W_{0.3}O_2$-C composite. The uniform distribution of highly dispersed Pt particles with mean particle size of 2.3 ± 0.8 nm was verified via TEM technique.

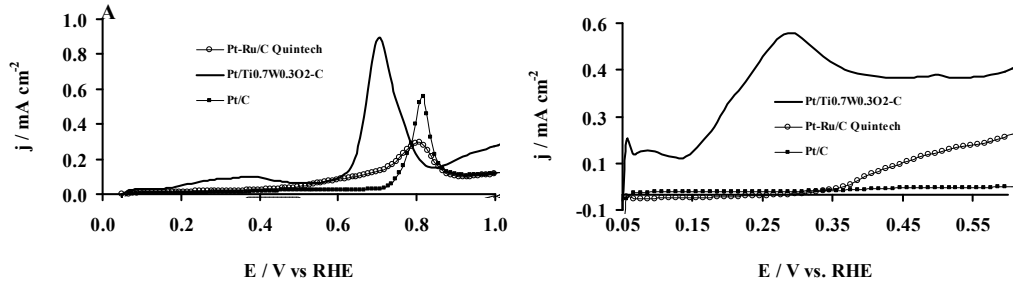


Fig. 1 CO_{ads} stripping voltammograms on home made Pt/C, PtRu/C (Quintech) and Pt/$Ti_{0.7}W_{0.3}O_2$-C catalysts (A) after Ar purging and (B) a part of the voltammograms in the "pre-peak" potential range after H_2 purging. Recorded in 0.5 M H_2SO_4 at 10 $mV \cdot s^{-1}$.

Enhanced CO tolerance of the electrocatalyst prepared using the $Ti_{0.7}W_{0.3}O_2$-C composite material is demonstrated in Fig. 1. In fact, performance exceeding that of the PtRu/C benchmark along with considerable stability during 5000 cycles for this electrocatalyst was observed.

4 Conclusions

A clear correlation between the amount of the Pt_3Sn phase and the electrocatalytic performance was established for Sn-modified Pt/C catalysts prepared by CSR. Enhanced CO tolerance along with considerable stability was achieved upon using a $Ti_{0.7}W_{0.3}O_2$-C composite material with high degree of W incorporation as a support for Pt-based electrocatalysts.

Direct Synthesis of Dimethyl Ether from Mixture of Carbon Dioxide and Carbon Monoxide over Copper Alumina Catalysts Prepared Using the Sol-gel Method

Takeishi Kaoru*

Graduate School of Engineering, Shizuoka University, Hamamatsu-shi, Japan

* tcktake@ipc.shizuoka.ac.jp

Keywords: dimethyl ether (DME), carbon dioxide, hydrogen, direct synthesis, copper alumina, sol-gel method

1 Introduction

We have developed the excellent DME direct synthesis catalysts using by the sol-gel method. The Cu-Zn/Al_2O_3 catalysts prepared using the sol-gel method have higher activity and selectivity for DME synthesis from syngas (mixed gas of H_2 and CO) than usual DME direct synthesis catalysts, mixed catalysts of methanol synthesis catalysts and methanol dehydration catalysts [1]. This time, these catalysts are applied for DME direct synthesis from carbon dioxide and mixture of CO_2 and CO. The chemical equation of the DME direct synthesis from CO_2 will be $6H_2 + 2CO_2 \rightarrow CH_3OCH_3 + 3H_2O$. This reaction works for utilization of CO_2 and reduces of CO_2 which is one of the greenhouse effect gases. If excellent catalysts will be developed and be used widely, the problem of global warming and problem of environments such as air pollution will be solved. If hydrogen will be produced using sustainable energies such as sun light power, window power, hydropower, and so on, the produced DME works as hydrogen carrier and energy carrier.

2 Experimental

Cu-Zn/Al_2O_3 catalysts prepared using the sol-gel method were used for hydrogenation of CO_2 and/or CO. Each catalyst was used alone, not mixed with an acid catalyst such as alumina. Patented catalyst developed by Kansai Electric Power Co. (KEPCO) & Mitsubishi Heavy Industries (MHI); one of the mixed catalyst of methanol synthesis catalyst and methanol dehydration catalyst; CuO-ZnO-Al_2O_3-Ga_2O_3-MgO (100:25:15:5:1) & Al_2O_3-ZrO_2 (100:10) was prepared depending on the patent [2]. The reactions were carried out with pressurized fixed bed reactor, and the usual reaction pressure was 0.9 MPaG (absolute pressure 1.0 MPa). Reactant gas flow was H_2/(CO_2+CO)/ /Ar = 15.0/5.0/2.0 ml min^{-1}, and catalyst weight was 0.5 g. Online gas chromatographs (TCD, FID) were used for the analysis of reactants and the products, and Ar gas was used for the internal standard gas.

3 Results and discussion

First, I checked the influence on DME production activity by Cu loading percent in Cu/Al_2O_3 catalysts prepared using the sol-gel method on the DME production by CO_2 hydrogenation. The Cu(30 wt%)/Al_2O_3 catalyst produced DME fastest among the all Cu/Al_2O_3 catalysts. It is speculated that 70 wt% of Al_2O_3 in the catalyst is the best percent of Cu(active sites for methanol synthesis)/Al_2O_3(active sites for methanol dehydration). Therefore, the Al_2O_3 percent in the Cu-Zn/Al_2O_3 catalysts prepared by the sol-gel method was kept 70 wt%, and several Cu-Zn/Al_2O_3 catalysts that had different ratios of Cu/Zn were prepared using the sol-gel method. The catalysts were tested for CO_2 hydrogenation, respectively. The Cu-Zn(15-15 wt%)/Al_2O_3 catalyst produced DME fastest among the all Cu-Zn/Al_2O_3 catalysts. The maximum of DME selectivity is 14 *C*.%. However, under the reaction temperature of 160 ^oC, CO

production was reduced and DME selectivity became larger, and the biggest value was 65.8 *C*.% by the Cu-Zn(15-15 wt%) /Al_2O_3 catalyst. On the other hand, the DME production rate became slower with 15 μmol g_{-cat}^{-1} h^{-1}, and its rate was less than 1/3 of the DME production rate under 180 °C, 200 °C, and 220 °C. However, these data are much better than those by the patented catalysts developed by KEPCO & MHI [2]. For better DME selectivity, it is clarified that lower reaction temperature makes DME selectivity higher; however, the DME production rate becomes lower, so other compositions of Cu-Zn-Al_2O_3 should be developed. After many catalysts were prepared and the catalysts were tested for DME direct synthesis from CO_2, I have developed more excellent catalysts, Cu-Ga/Al_2O_3. At present, the Cu-Ga(24-6 wt%)/Al_2O_3 catalyst prepared using the consecutive sol-gel method is the best catalyst for DME direct synthesis from CO_2. The DME selectivity increased to about 30 *C*.%, and DME production rate improved to 63 μmol g_{-cat}^{-1} h^{-1}.

Then, the Cu-Zn(15-15 wt%)/Al_2O_3 catalyst and Cu-Ga(24-6 wt%)/Al_2O_3 catalyst prepared using the sol-gel method were tried for hydrogenation of various ratio mixture of CO_2 and CO for DME direct synthesis, respectively. Fig. 1 shows a part of the results of the DME production and methanol production at 220 °C, 240 °C, and 260 °C of the reaction temperature. In the case of the Cu-Zn(15-15 wt%)/Al_2O_3 catalyst (Fig. 1), the DME production rate is increased with the increasing of the ratio of CO/(CO+CO_2). On the other hand, in the case of the Cu-Ga/Al_2O_3 catalyst, there is an optimal ratio around 0.8, but the DME production rate was much slower than the rate by Cu-Zn(15-15 wt%)/Al_2O_3. Ga is one of rare-metals and very expensive, therefore Cu-Zn(15-15 wt%)/Al_2O_3 catalyst is useful as practical catalysts. From these results, CO_2 should be reformed to CO by the reverse-water gas shift reaction, and then the reformed CO should be hydrogenated to DME. Two-step DME synthesis from CO_2 would be practical for the industrial. However, I have developed the significant catalysts using the sol-gel method for DME direct synthesis from CO_2 and CO compared with the mixed catalysts such as the patent catalysts of KEPCO & MHI

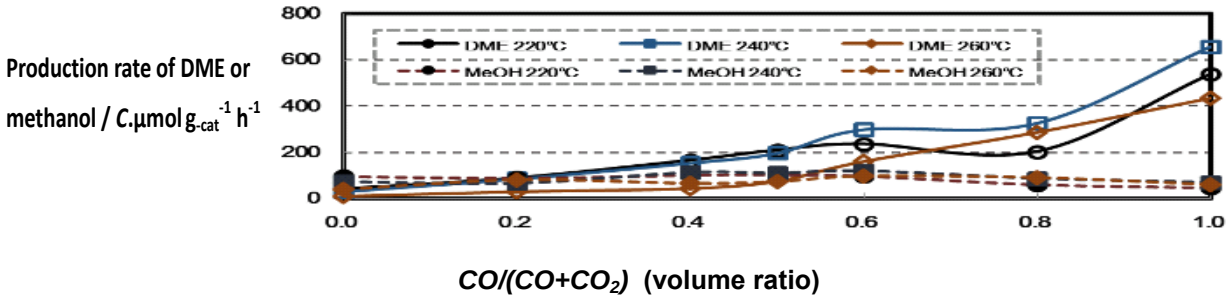

Fig. 1. Hydrogenation of CO_2 and CO mixture over Cu-Zn(15-15 wt%)/Al_2O_3 catalyst prepared using the consecutive sol-gel method. Catalyst weight: 0.5 g; reaction gas: H_2/(CO_2+CO)/Ar = 15.0/5.0/2.0 ml min^{-1}; reaction pressure: 0.9 MPaG.

4 Conclusions

I have developed the significant catalysts using the sol-gel method for DME direct synthesis from CO_2 and CO compared with the mixed catalysts.

Effect of Calcination Temperature on Stability and Activity of $Ni/MgAl_2O_4$ Catalyst for Steam Reforming of Methane

Katheria S.*, Gupta A., Deo G., Kunzru D.

Indian Institute of Technology Kanpur, Kanpur, India

* katheria@iitk.ac.in

Keywords: steam reforming of methane, nickel, catalyst, magnesium, aluminate, spinel

1 Introduction

Steam reforming of methane is a widely used conventional process for large scale production of hydrogen. Nickel as active metal and magnesium aluminate spinel ($MgAl_2O_4$) as catalyst support is widely used for this process. During preparation of $Ni/MgAl_2O_4$ catalyst, pretreatment of catalyst support and calcination temperature of nickel impregnated catalyst become important part of catalyst preparation as these can significantly influence the performance of $Ni/MgAl_2O_4$ [1]. In this work, we have demonstrated that high temperature calcination of $Ni/MgAl_2O_4$ not only enhances the activity of the catalyst but also the stability at elevated pressures.

2 Experimental

Magnesium aluminate (MG30) containing 30wt.% MgO and 70wt.% alumina, supplied by SASOL, Germany was used as the catalyst support. Three catalysts having composition of 15%$Ni/MgAl_2O_4$ were prepared for studying the effect of calcination temperature on catalyst activity and stability. First catalyst (Cat 1) was prepared by wet impregnation method in which the support (MG30) was calcined at 900°C for 4h before impregnating the required amount of $Ni(NO_3)_2.6H_2O$. The impregnated catalyst was then calcined at 500°C for 3h. For the preparation of second catalyst (Cat 2), the final calcination temperature was 850°C (instead of 500°C). The third catalyst (Cat 3) was prepared by impregnating $Ni(NO_3)_2.6H_2O$ on the as-received MG30 powder and then the impregnated support was calcined at 850°C for 3h.

Various characterization, such as BET surface area analysis, thermo-gravimetric analysis (TGA), X-ray diffraction(XRD), temperature-programmed reduction(TPR), temperature-programmed desorption(TPD), temperature-programmed oxidation(TPO) and UV-vis spectroscopy of fresh, reduced and calcined samples were done to examine the change in catalyst properties before and after use.

Steam reforming of methane was conducted in a ¼" o.d. Inconel 600 reactor which was placed in a tubular furnace. 300 mg of the catalyst (average size of 0.4 mm) was placed in the middle of the tubular reactor and the upper and lower part of catalyst tube filled with quartz chips. Prior to the activity test, the catalyst sample was reduced in H_2 flow of 60 ml/min at 850°C for 3h. All activity tests were performed at 600°C with CH_4:H_2O:N_2 molar ratio of 1:5:1 with W/F_{ao} (mass of catalyst/inlet molar flow rate of methane) of 0.95 g-h/mol. Product gases were analyzed on a gas chromatograph by a thermal conductivity detector using a 3m long Carbosphere column.

3 Results and discussion

Surface area of the as-received MG30 powder, which was 250m^2/g, reduced to 70m^2/g after

calcination at 900°C for 4h. The surface area further reduced when Ni impregnated catalysts were calcined. Formation of magnesium aluminate spinel phase was confirmed from the XRD plots of the calcined support. The diffraction patterns showed that, in all the three catalysts,the major phases were NiO and $MgAl_2O_4$. UV-vis spectroscopy analysis of the calcined catalysts confirmed the formation of $NiAl_2O_4$ after high temperature treatment of $Ni/MgAl_2O_4$ catalyst, in agreement with the earlier published results [1, 2].

Steam reforming of methane was conducted in the temperature range of 500-800°C and reactor pressure of 1-5 bar. It was observed that the activity of Cat 1 decreased with run time. At a pressure of 1 bar, the rate of deactivation was slow at 500°C but increased significantly with increasing temperature, most likely due to the carbon deposition on the catalyst.

The variation of methane conversion with run time for the three catalysts at 600°C and two different pressures (1 bar and 5 bar) is shown in Fig. 1 and 2.

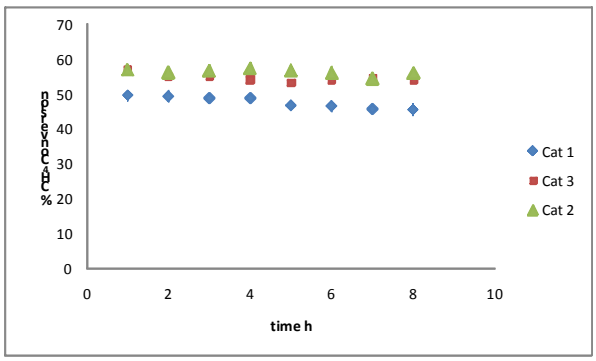

Fig. 1. Variation of methane conversion with run time for different catalyst (Temperature= 500°C and Pressure= 1bar

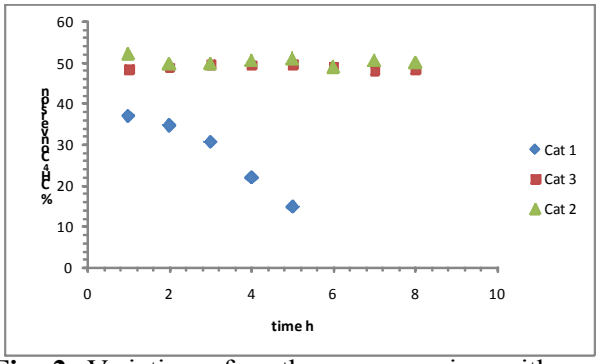

Fig. 2. Variation of methane conversion with run time for different catalyst (Temperature= 500°C and Pressure= 5bar

For Cat 1, the rate of deactivation significantly increased at higher pressure. In contrast, at identical conditions, the activity of Cat 2 and Cat 3 ,which were calcined at the higher temperature (850°C) remained stable over the duration of the run (~8h). As can be observed from Figs.1 and 2, Cat 2 and 3 were not only stable but also had a higher activity. From the activity test it was confirmed that precalcination of the catalyst support had no effect on the catalytic activity and its properties. The higher activity and stability of Cat 2 and Cat 3 catalysts can be attributed to a strong metal support interaction when the catalyst was calcined at 850°C. Stability of magnesium aluminate spinel phase and enhanced metal support interaction resulted in higher catalytic activity.

4 Conclusions

For the catalyst that was calcined at 500°C, the catalytic activity decreased significantly with increasing temperature and pressure. Calcination of the $Ni/MgAl_2O_4$ catalyst at higher temperature increases the activity and stability of the catalyst for steam reforming of methane. Precalcination of the magnesium aluminate support has no significant effect on the catalytic activity.

Effect of Nickel Complexes on the Metal Dispersion and Catalyst Activity of Ni/SBA-15 Catalyst for Methane Dry Reforming to Syngas

Hajimirzaee S.*, Iro E., Hodgson S., Olea M.

School of Science and Engineering, Teesside University, Middlesbrough, UK

* s.hajiimrzaee@tees.ac.uk

Keywords: nickel catalyst, methane, dry reforming, catalyst, life time, syngas

1 Introduction

The heavy reliance on dwindling fossil resource for fuel which generates high CO_2 emission has driving research into sustainable and environmentally friendly alternatives such as methane dry reforming reaction which has the advantage of utilizing two abundantly available green-house gases to produce syngas for fuel [1]. Nickel-based catalysts have been widely used for this reaction due to availability and low cost of nickel compared to noble metals; however, rapid coke deposition on nickel causes the catalyst to deactivate in a short time [2]. It has been shown that in addition to small nickel particles on the support, strong metal-support interaction and uniform dispersion of nickel on the support prevent the migration and coalescence of metal particles during the reaction and thus could prolong the catalyst life time and resistance against coking [3, 4]. By using the ordered mesoporous silica as support (SBA-15), which has high surface area, large pore sizes and thick pore walls for hydrothermal stability, nickel particles were confined in the channels of the mesoporous material, thus preventing metal sintering and promoting stability of the catalyst [3]. In this research, the nickel complexes $[Ni(H_2O)_6]^{2+}$, $[Ni(NH_3)_6]^{2+}$, $[Ni(en)_6]^{2+}$ where (en) is ethylenediamine, $NH_2CH_2CH_2NH_2$, and $[Ni(EDTA)]^{2-}$ EDTA is ethylenediaminetetracetic acid, $C_{10}H_{16}N_2O_8$, were synthesized and grafted onto the SBA-15 support to study how the chemical metal–support bonds affect the strength, dispersion and eventually the stability of Ni/SBA-15 catalysts in methane dry reforming in a gas mixture with three times more methane than CO_2 which only the most stable catalysts could be active for a long period of time as methane decomposition promotes faster coke deposition.

2 Experimental/methodology

SBA-15 powder was prepared through sol-gel method as described by Zhao et al.[5]. Ni/SBA-15 catalysts were prepared through incipient-wetness impregnation using different nickel complexes. Ammonium hydroxide, en and EDTA as well as deionised water were used to prepare the nickel complexes. Nickel acetate and SBA-15 were dissolved in water with weight ratio of 1/1.5/30. Then the nickel complex solution were added to SBA-15 and stirred. During filtration, two samples were prepared for each case, one without washing and another one with washing with deionised water to eliminate the counterions of the complexes. The samples were subsequently air dried at room temperature for 1 day and calcined at 550ºC for 4 h.

The catalyst activity in the dry reforming process was investigated in the Catlab system (Hiden Analytical Ltd) via temperature-programmed reaction using a fixed bed quartz reactor at atmospheric pressure. Catalyst sample was placed in a tube reactor and reduced in a 5% H_2 in argon stream at 800ºC for 1 hour prior to the reaction. Then the temperature was cooled and the reactor was flushed with pure argon. Then feed gas containing CH_4 and CO_2 with molar ratio of 2.7:1 and GHSV of 63,000 mL/(h·g_{cat}) was introduced to the reactor. The temperature of the reactor was raised linearly to 850°C at a heating rate of 10°·min^{-1}. The effluent gas was analysed on-line using a Hiden QIC-20 mass spectrometer.

Other characterisation techniques used include: Fourier Transform Infrared Spectrometry (FT-IR), Scanning Electron Microscopy (SEM)/ Energy dispersive X-ray spectroscopy (EDX), X-ray Diffraction spectroscopy (XRD), Transmission Electron Microscopy (TEM), N_2 adsorption-desorption at 77 K and Temperature Programmed Reduction (TPR).

3 Results and discussion

Methane dry reforming reactions of the six catalysts are shown in Figure 1(a) to 1(f). The Ni/SBA-15 catalysts (a), (c) and (e) which had the smallest sized nickel nano-particles as confirmed by XRD and TEM results with hydrogen reduction occurring at the higher temperature range above 500°C, had the most stable H_2 and CO yield over time and temperature up to 850°C with catalyst (e) having the earliest initial reaction at 250°C. The Ni/SBA-15 catalysts (b), (d) and (f) with bigger nickel particles, less uniform dispersion and most of the hydrogen reduction occurring at lower temperature range below 450°C had H_2 and CO yield reducing over time and temperature due to faster coke deposition.

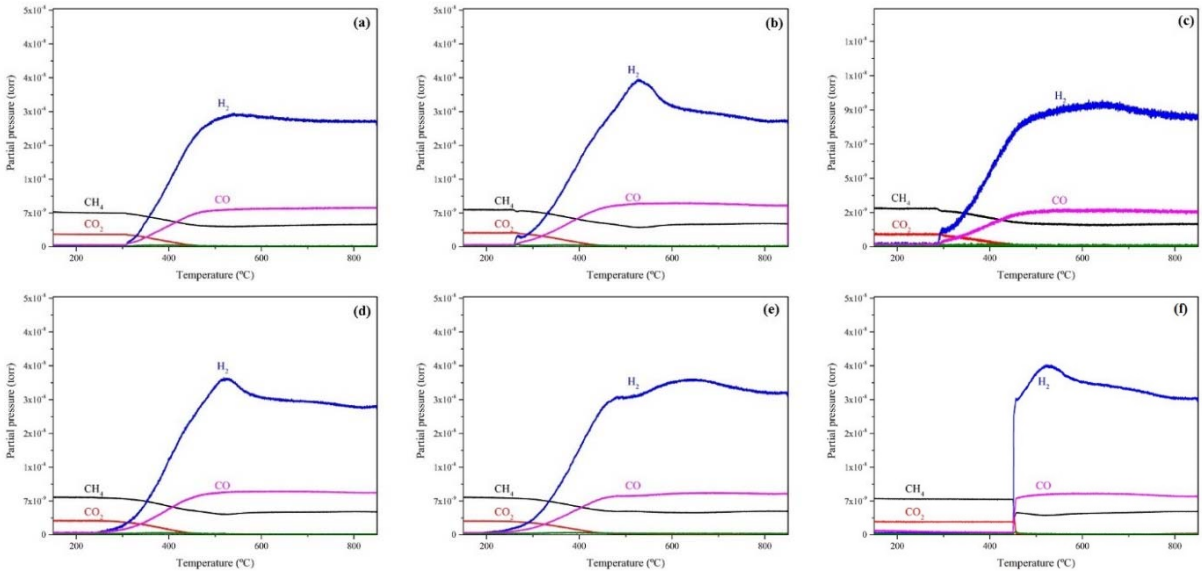

Fig. 1. TPRx of different Ni/SBA-15 samples in dry reforming of methane: (a) water -unwashed, (b)en-unwashed, (c) en-washed, (d) NH_4OH-unwashed, (e) NH_4OH-washed, (f) EDTA-unwashed

4 Conclusions

The nature of nickel complex and choosing to wash or not to wash the catalyst with deionised water after impregnation had pronounced effect on the metal-support interaction, nickel particle size, dispersion and as a result on the activity and stability of the catalyst.

Keywords: direct coal liquefaction, Mo-based catalyst, hydrogenation, dissolution, organic matters

1 Introduction

Hydrocarbon compounds are very valuable chemicals as fuel and base materials in petrochemical industry. Direct coal liquefaction is an available technology to produce the liquefied hydrocarbon fuels with the combined cracking and hydrogenation of organic matters of coal under high temperature and pressure. The various useful hydrocarbon compounds can be produced by the cracking and recombination through the catalytic hydrogenation of the organic materials of coal. However, it was known that the organic macromolecular compounds of coal have relatively low H/C ratio as compared with oil/petroleum from which the hydrocarbon compounds can be made. Therefore, the direct coal liquefaction including the catalytic hydrogenation process with H2 is necessary for the synthesis of hydrocarbon compounds from organic materials of coal. Coal is composed of fixed carbon, volatile matters, ash and moisture and the organic materials such as fixed carbon and volatile matters are the macromolecular compounds which consist of carbon, hydrogen, oxygen, nitrogen and sulfur etc.

In this study, the hydrogenation of coal using batch-type autoclave reactor was conducted under high pressure and temperature. In the reaction test, the ionic liquid was used as an additive to improve the cracking and dissolution of organic matter of coal and the reaction efficiency of the direct coal liquefaction process with catalyst. And then the effect of the ionic liquid on the catalytic effect of the cracking and dissolution of coal was investigated for the reaction characteristics. Also, the physic-chemical properties of the solid and liquid phase of reactant and product were characterized by X-ray diffraction, proximate analyzer, elemental analysis, FT-IR spectra etc.

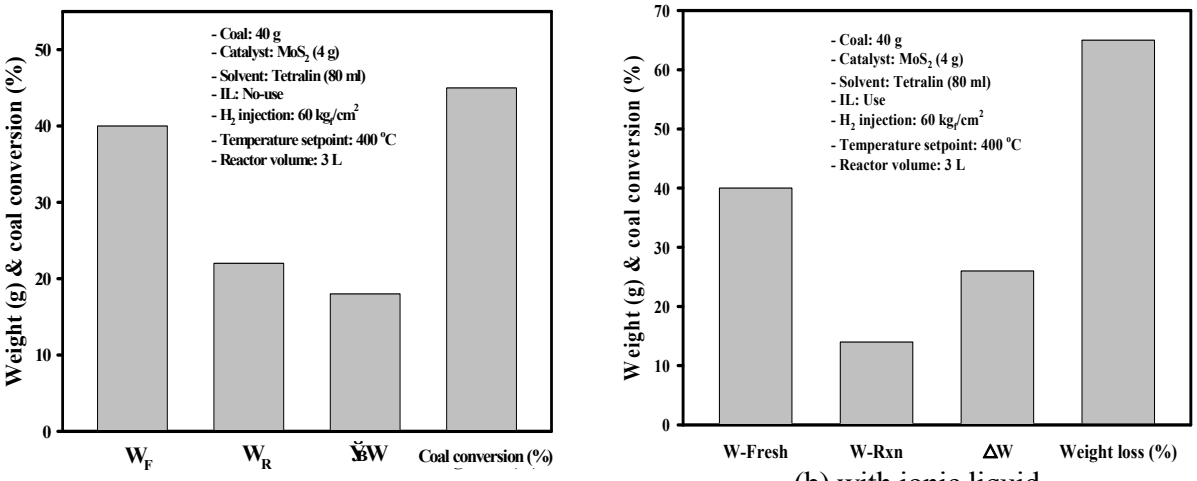
2 Experimental/methodology

A coal was used as a reactant for hydrogenation with H_2 in this study and then the coal was ground, collected by sieving with 200 meshes and dried overnight at 105 ^oC for the removal moisture before using in the reaction. Also, the coal after the water removal was mixed with ionic liquid before the reaction. The commercial tetralin and MoS_2 were respectively used as a solvent and catalyst without the purification.

The hydrogenation of coal was carried out using a batch reactor with a volume of 3 L. Prior to the reaction, the mixture of reagent with 50 g coal, 100 ml tetralin and 10%wt. MoS2 catalyst based on coal weight was produced using ball mill and was put into the batch reactor. The reactor was sealed, purged by gas corresponding to the desired atmosphere. After injecting the gas up to the initial pressure into the reactor, the reactor was heated up to the targeted reaction temperature and then the internal temperature and pressure were simultaneously increased. After the reaction time of 60 min based on reaching up to the targeted reaction temperature, the reactor was cooled down to room temperature and the solid, liquid, and gaseous products were selectively collected, separated and analyzed to investigate the relationship between the reaction characteristics and their physico-chemical composition.

3 Results and discussion

Fig. 1 shows the effect of ionic liquid on the direct coal liquefaction with and without using ionic liquid. As shown in Fig. 1, the conversion of coal increased with using ionic liquid as compared with the case of not using ionic liquid in direct coal liquefaction and the conversion of coal was about 67.8% based on the amount of organic matters.



(a) without ionic liquid

(b) with ionic liquid

Fig. 1. Effect of ionic liquid on the direct coal liquefaction.

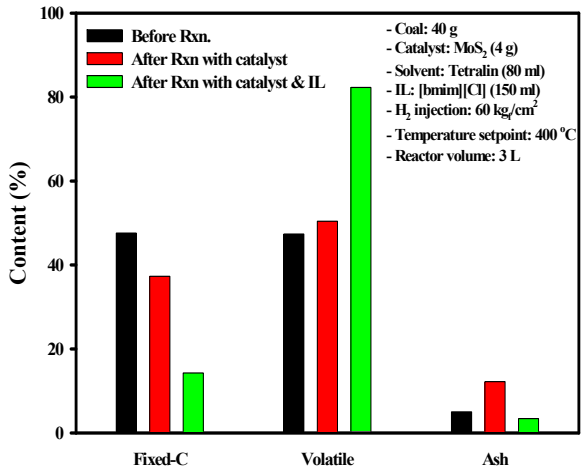


Fig. 2. Conversion of organic matters in direct coal liquefaction over Mo-based catalysts.

Fig. 2 shows the conversion of organic matters in direct coal liquefaction over Mo-based catalysts. In Fig. 2, the content of fixed carbon which was contained in the organic matters of coal decreased with using the ionic liquid as compared with the case of not using ionic liquid and then it was estimated that the conversion of the organic matters increased with using ionic liquid because the dissolution of the fixed carbon of coal was improved by the ionic liquid.

4 Conclusions

In this study, the ionic liquid was used to improve the conversion of organic matters of coal in the direct coal liquefaction and then the effect on the ionic liquid on the direct coal liquefaction was investigated. As a result, it was known that the cracking and dissolution efficiency of organic matters of coal were improved by the ionic liquid in hydrotreating process of direct coal liquefaction over Mo-based catalyst.

Esterification of Levulinic Acid with Butanol over Ion-Exchange Resins: a Screening Study

Tejero M.A., Ramírez E., Fité C., Tejero J., Cunill F.*

Chemical Engineering Department, Faculty of Chemistry, Universitat de Barcelona, Barcelona, Spain

* fcunill@ub.edu

Keywords: butyl, levulinate, levulinic acid, catalysis, ion-exchange, resins

1 Introduction

Alkyl levulinates are biomass derived chemicals with a large spectrum of applications. They have the potential to substitute compounds currently derived from petro-chemical routes as additives to conventional diesel or gasoline because of their physicochemical properties. Alkyl levulinates are synthesized most often from levulinic acid (LA), but also from furfuryl alcohol or directly from cellulose and sugars. LA is a platform chemical formed from hydrolysis of lignocellulose, the most readily available form of biomass, using the Biofine process.

The most widely studied alkyl levulinate is ethyl levulinate (EL), both its synthesis pathways and possible applications have been explored thoroughly. Comparatively, the potential of butyl levulinate (BL) has been left untapped. As an additive for diesel, BL is even more promising than EL: BL remains in diesel solution down to the diesel cloud point, BL blends have very small particulate matter emissions, it has a lower solubility in water than EL, good lubricity and conductivity, and a low but better cetane number.

Esterification of LA with butanol (BuOH) over several types of catalysts such as zeolites, Ru/C and heteropolyacid (HPA) supported on acid-treated clay montmorillonite (K10) has been described in literature, but the catalysis with acidic ion-exchange resins has never been attempted to the best of our knowledge. The present work studies the behaviour of different sulphonated polystyrene-divinylbenzene resins in the synthesis of BL from LA.

2 Methodology

The acidic resins used were Amberlyst™ 15 (A15), A16, A35, A36, A39, A46, A70 (Room & Haas); Purolite® CT-224 (CT-224) (Purolite), and Dowex 50Wx8, Dowex 50Wx4, Dowex 50Wx2 (Dow). The mass of dry catalyst used was 0.5 g and stirring speed was fixed at 500 rpm. Relevant resin properties are specified in Table 1.

Table 1. Properties of the acidic resin catalysts used in this study.

Catalyst	Type	Sulfonation type	Acid Capacity (meq H^+/g)*	DVB%	d_p (mm)	V_{sp}** (cm^3/g)
A15	macro	Conventionally sulphonated	4.81	20	0.40-0.63	0.622
A16	macro	Conventionally sulphonated	4.80	12	0.40-0.63	1.136
A35	macro	Oversulphonated	5.32	20	0.40-0.63	0.504
A36	macro	Oversulphonated	5.40	12	0.40-0.63	1.261
A39	macro	Conventionally sulphonated	4.82	8	0.40-0.63	1.643
A46	macro	Surface-Sulphonated	0.87	25	0.40-0.63	0.190
A70	macro	Conventionally sulphonated	2.55	8	0.40-0.63	1.149
CT-224	gel	Oversulphonated	5.34	4	0.32	1.859
Dowex 50Wx2	gel	Conventionally sulphonated	4.83	2	0.297-0.149	2.677
Dowex 50Wx4	gel	Conventionally sulphonated	4.95	4	0.297-0.149	1.920
Dowex 50Wx8	gel	Conventionally sulphonated	4.83	8	0.297-0.149	1.404

*Titration against standard base. **specific volume of swollen polymer in water, measured by ISEC technique.

The experiments were carried out in a 100ml batch reactor. System composition is as determined by means of in-line sampling to a gas chromatograph equipped with a TCD detector. Experiments last 8h at 353-393 K and 2.5 MPa in order to guarantee a system in liquid phase. Catalyst screening was done working with an excess of BuOH (molar ratio BuOH/LA = 3) in order to both minimize the possible formation of humins by polymerization of LA and avoid the formation of two liquid phases due to the formation of water during the course of the reaction.

3 Results and discussion

The conducted experiments confirm that acidic polymer catalysts can be used in order to obtain very high conversion (Fig 1) and selectivity in the esterification of LA with BuOH to BL. Selectivity toward BL remains always over 98% for all catalysts. The most relevant by-product is dibutyl ether (DBE), even though it is never more than 2% even at 393K. At operating temperature of 353K, selectivity remains over 99%.

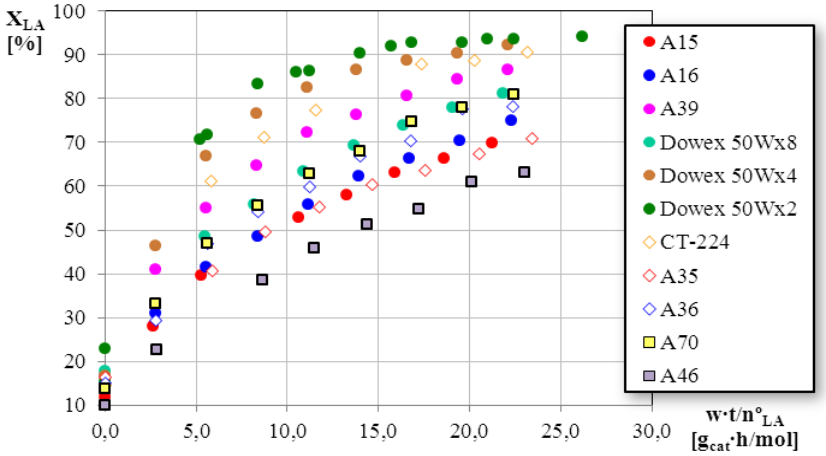

Fig. 1. Comparison of the evolution of the conversion of LA over contact time.

The catalyst with highest activity was Dowex 50Wx2. Overall gel-type resins presented better yields than macroporous ones. Because of the high polarity of LA and the formation of water, catalysts with greater capacity for swelling would favour LA esterification. Thus resins with a lesser degree of cross-linking (DVB%) present higher reaction rates. Incidentally, CT-224 was less active than Dowex 50Wx4 (both 4% DVB) despite having a higher number of active sites. This might be because oversulphonation confers greater stiffness to the polymeric structures, which impedes swelling. The lowest activity is that of A-46, which is surface-sulphonated and therefore has a very low number of active sites. BL yield was not much lower than those obtained with A15, A16 and A35. This suggests that for resins with a high degree of cross-linking (DVB>12%), swelling might be so poor that the reaction takes place mainly on active sites close to the surface. Although A70 also has a lower number of active sites, activity rates are on par with Dowex 50Wx8, yet lower than A39 (all 8% DVB). Presumably the inner structure of the active sites of A70, due to the electron donating chloride groups present in the matrix of thermostable resins confers a higher acid force to said sites, which might have a compensatory effect. Globally, higher reaction rates roughly correspond with large V_{sp}.

4 Conclusions

Esterification of LA catalysed by acidic ion exchange resins always has over 98% selectivity. Reaction rates improve as the degree of polymer cross-linking diminishes. Gel-type resins with higher swelling show better results as a whole. The reaction rates increase significantly when the swollen polymer phase is highest. Ion-exchange catalysts have been found to be more efficient than zeolites, because they have been proven to have better yields at lower temperatures and higher concentrations of LA. Compared with heteropolyacid supported on acid-treated clay montmorillonite, which have similar activity rates and selectivity, ion-exchange resins are cheap and readily commercially available.

Etherification of Isobutene with C_1 to C_4 Linear Primary Alcohols in Liquid-Phase: Experimental Equilibrium and Thermodynamic Analysis

Badia J.H., Fité C., Bringué R., Ramírez E., Cunill F.*

Chemical Engineering Department, Faculty of Chemistry, Universitat de Barcelona, Barcelona, Spain

* fcunill@ub.edu

Keywords: etherification, isobutene, primary alcohols, ion-exchange resins

1 Introduction

Experimental studies on equilibrium conditions and thermodynamic properties concerning innovative processes are mandatory to determine their feasibility. Recent examples in different disciplines are graphene synthesis, pharmaceutical drugs design, or novel biofuels production.

Regarding biofuels, oxygenate additives, as methyl *tert*-butyl ether (MTBE) and ethyl *tert*-butyl ether (ETBE), have been produced worldwide for decades. Increasing the ethers length, by using alcohols larger than methanol or ethanol, leads to a decrease of their vapor pressure and solubility in water, and to an increase of these ethers boiling point. As fuels, these properties are desirable because they allow a reduction of evaporative emissions and of water contamination risk, and because they provide a dilution effect of some harmful fuel components.

Larger linear alcohols, such as *n*-propanol or *n*-butanol to obtain propyl *tert*-butyl ether (PTBE) or butyl *tert*-butyl ether (BTBE), respectively, can be industrially produced through the oxo process. Alternatively, biomass-based production routes are also being studied, namely condensation of bioethanol and/or biomethanol (Guerbet Catalysis) and ABE fermentation (which produces Acetone, n-Butanol and Ethanol using microorganisms of the genus *Clostridium*). Consequently, PTBE and BTBE from *n*-propanol and *n*-butanol can be computed for the biofuel target.

Prior to scale-up studies on the feasibility of industrializing these processes, equilibrium information based on experimental data must be collected and thermodynamic properties analyses must be carried out. Actually, equilibrium and thermodynamic information of reacting systems involving alkenes and several alcohols is scarce. The present study, based on experimental work, helps to reduce this lack of information.

2 Experimental

Reactants were methanol, ethanol, 1-propanol, 1-butanol, and either 2-methylpropene (isobutene) (>99.9% G.C.) or a synthetic C4 mixture (25% wt isobutene, 40% wt isobutane and 35% wt *trans*-2-butene) as the isobutene source. All resins used as catalysts were macroreticular, strongly acidic, sulfonated polymers of styrene divinylbenzene. Most of the experiments were performed with Amberlyst™ 35 (A-35), and resins Amberlyst™ 15 (A-15), Purolite® CT275 (CT-275) and Lewatit® K 2620 (K2620) were also tested for comparative purposes.

Experiments were carried out at 313-383 K and 1.5-2.0 MPa. Assayed alcohol/isobutene molar ratios ($R^o_{OH/IB}$) were in the range 0.6-2.4. Experimental devices used were a series of catalytic fixed bed tubular microreactors (length: 15 cm, i.d.: 7 mm) disposed in line and submerged in a thermostatic bath, and a 200 cm^3 stainless-steel jacketed batch reactor equipped with a catalyst injector. Each experimental device was attached in line to an Agilent gas chromatograph equipped with a capillary column (PONA Cross-linked Methyl Silicone Gum of 50 m × 0.2 mm × 0.5 μm) to quantify the medium composition. In the fixed bed reactor, equilibrium was considered to be reached when the outlet stream composition at steady-state and at the assayed temperature did not vary with decreasing flow rate (Liquid Hourly Space Velocities ranged 1.8-20 h^{-1}). In the batch

reactor, equilibrium was reached when the composition showed no significant evolution in time (experiments lasted 5-8 h).

3 Results and discussion

MTBE experiments were conducted with A-35 and A-15 at only two temperatures, mainly to compare the results obtained in the fixed bed reactor setup with those quoted in literature, usually obtained in batch reactors. Given some lack of agreement between sources concerning ETBE equilibrium and thermodynamic data, a more extensive study was proposed: ETBE experiments were performed in both reactors systems, in a wider temperature range (313.15-383.15 K) than published to date and using A-35, CT-275 and K2620 as catalysts. MTBE and ETBE equilibrium constants, determined in separated devices with different catalysts, were in good agreement with literature data. Concerning PTBE and BTBE syntheses, available thermodynamic data are very scarce on both ethers. Thus, an extensive work has been done to estimate thermochemical data; different group-contribution methods (Joback and Modified Benson methods) were used and compared with literature data, when available. PTBE and BTBE equilibrium constants were experimentally obtained in the batch reactor device, with A-35 and using different initial compositions in the temperature range of 323 to 353 K.

Figure 1 depicts *ln* K_i, experimental equilibrium constant, versus *1/T* for the four etherification equilibria. As it can be seen, the van't Hoff equation fit well to experimental results. PTBE and BTBE equilibrium constants are between those of MTBE and ETBE, which accounts for high conversion in industrial processes.

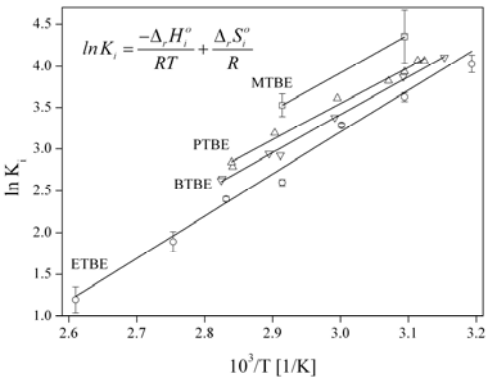

Fig. 1. Van't Hoff plot considering constant reaction enthalpy change within the temperature range

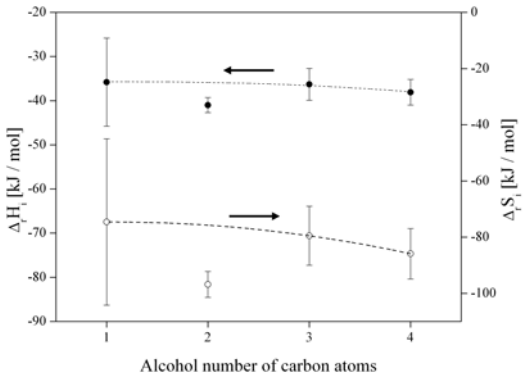

Fig. 2. Standard enthalpy and entropy changes variation with the alcohol number of carbon atoms

Estimated values for reaction enthalpy show a decreasing trend with the alcohol length with the exception of ETBE formation, which presents a lower value than expected in that trend, as shown in Figure 2. Analogous results have been obtained for the entropy variation. Estimated values agree with published data, when available.

From reaction enthalpy and entropy variations, formation enthalpies have been estimated for MTBE, ETBE, PTBE and BTBE, respectively. Values for MTBE and ETBE agree with those reported in literature, which supports the reliability of the obtained values for PTBE and BTBE, which were not published to date to the best of our knowledge.

4 Conclusions

Etherification reactions of isobutene with C_1 to C_4 linear primary alcohols have been found to be reversible and exothermic, irrespectively of the catalyst and reactor operation mode, as expected. Enthalpy and entropy variations have been estimated for each etherification reaction, and these values have been used to estimate formation enthalpies of MTBE, ETBE, PTBE, and BTBE. MTBE and ETBE results agree with published results, which support the reliability of PTBE and BTBE estimated values.

From Data to Knowledge: Analysis of Published Articles in Literature for Photo-Catalytic Water Splitting

Can E., Yildirim R.*

Bogazici University, Department of Chemical Engineering, Istanbul, Turkey

* yildirra@boun.edu.tr

Keywords: photo-catalytic water splitting, hydrogen production, knowledge extraction, data mining

1 Introduction

Solar energy is predicted to be a compelling solution to our increasing global energy demands in the future because it is free, renewable, and sustainable. Hydrogen has been also considered as a promising energy carrier due to its high energy density (140 MJ Kg^{-1}) which is greater than those of gasoline and coal. Besides, the energy production from hydrogen combustion does not cause carbon emission; it results in a harmless by-product of water [1]. Hence, splitting water into hydrogen and oxygen by photocatalysis has attracted considerable attention recent years

Photo-catalytic water splitting (PWS) can be investigated in 3 steps; (i) absorption of photons with energies exceeding the semiconductor band gap and leading to the generation of electron and hole pairs in the semiconductor; (ii) migration of these photo-generated particles (e^- and h^+) which resulted in charge separation; (iii) surface chemical reactions between these carriers and present compound (e.g., water, water-alcohol solution) [2].

TiO_2 is the most commonly studied and one of the most efficient alternatives among about 140 materials tested in the literature for PWS, but the energy conversion is still low. There are also some extensive works in the literature involving perovskites because of their promising activity under the visible light. Also dye sensitization of a semiconductor like TiO_2 is another method that is widely used to utilize visible light for PWS[3].

To develop an efficient photocatalyst, several parameters are needed to be optimized. Great time, labor and money are required to adjust these parameters so that the best activity is achieved. At that point, data mining, which is a method to extract knowledge from the published articles and performed experiments, can help to decide the preparation and operational variables of a new process. There are various types of data mining tools; the common ones are linear regression, logistic regression, k-nearest neighbor algorithm, decision trees, support vector machine, and artificial neural networks.

In this work, the aim is to extract knowledge from published articles about photo-catalytic water splitting in literature, then to examine whether the result of an unperformed experiment can be estimated, or not.

2 Computational Work

A great number of articles, which were published for last 10 years (between 2005 and 2014) about PWS in the literature, were studied and a comprehensive database which consists over 5000 data points from 86 different papers were constructed. The database consists of 32 variables such as semiconductor type, catalyst preparation method, promoter type and weight percent, reaction solution, light intensity and light type, and band gap, crystal structure, and particle size of catalyst material that affect quantum yield. Then models were developed using that database to predict an unperformed experiment and understand the process better. The learning algorithms that were used in this work are artificial neural network, decision tree and support vector machine. Some other supplementary tools like principal component analysis were also used to complete task.

3 Results and Discussion

TiO_2, (especially nano-sized) is the most commonly studied material due to its low cost high abundance and relatively high activity towards PWS; the 68% of TiO_2 used was in pure anatase phase, while 13% is P25 (anatase:rutile, 4:1). However, the perovskites type photo-catalysts seem to be more efficient because of their higher charge carrier mobility and charge carrier lifetime, and they result higher hydrogen production rate (μmol/g-cat/h). In all these works reported in the literature, the semiconductor materials with band gap value from 3 to 3.4 eV and particle size between 50-100 nm were examined most commonly.

Some descriptive statistics were obtained from the database first to understand the trends (number of publication, type of semiconductor, promoter, etc.) in last 10 years. As an example, Figure 1.a shows the number of scientific publications on PWS has been studied from 2005 to 2014 using a number of literature databases, including Elsevier, Wiley Online Library, and ACS Publications. The annual number of publications on PWS has increased 346% in 2014 in respect to 2005. Then more detailed analysis performed using k-nearest neighbor regression (KNNR), artificial neural networks and support vector machine. Figure 1.b shows the prediction for the results of a publication[4] by KNNR model developed from the other publications on perovskite catalysts; the model predictions are in good agreement with the experimental results reported.

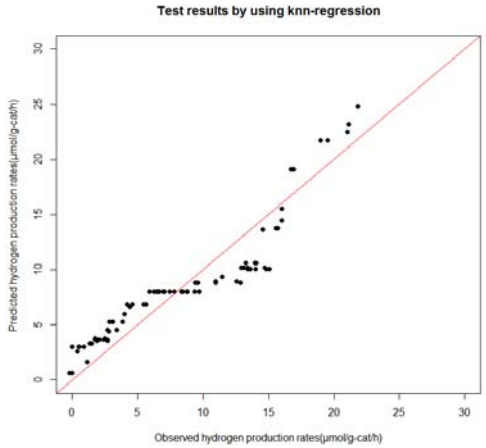

Fig 1. (a) The number of annual published articles on PWS last decade, (b) Test results of an article [4] by using k-nearest neighbor regression

3 Conclusions

The results shows that the models developed from the database indeed can generate useful knowledge to understand the process, to see trends, to make predictions for the conditions at which the experimental data are not available.

Further Insights into the Effect of Sulphur on the Activity and Selectivity of Cobalt–based Fischer–Tropsch Catalysts

Barrientos J.*, Boutonnet M., Järås S.

KTH - Royal Institute of Technology, Stockholm, Sweden

* javbar@kth.se

Keywords: Fischer-Tropsch, cobalt, sulphur, selectivity, deactivation

1 Introduction

The catalytic conversion of synthesis gas into hydrocarbons (Fischer-Tropsch synthesis, FTS) is receiving great attention due to its potential for converting different carbon sources (coal, natural gas and/or biomass) into liquid transportation fuels. It is generally known that sulphur compounds are severe poisons for cobalt-based Fischer-Tropsch (FT) catalysts [1]. The effect of S on the FT performance has been analysed in various literature studies [1-5]. Nevertheless, there is still no full agreement regarding its effect on the FT product distribution [4, 5].

Among different S poisoning studies it is noteworthy to mention the work from Visconti et al. [4] in which they prepared catalyst samples with different S loadings and tested these under relevant FT conditions. In this study, they observed that the selectivity to long-chain hydrocarbons decreased with increasing S content. Unfortunately, these poisoned catalysts were tested at different CO conversions and thus exposed to different water partial pressures, fact that affects both product selectivity and catalyst stability [6]. More recently, Borg et al. [5] studied the performance of cobalt-based FT catalysts with *in situ* H_2S addition. Contrariwise, they found that S has no significant effect on the primary product distribution. Pansare and Allison [7] also studied the effect of *in situ* H_2S on selectivity. Conversely, they claimed that sulphur decreased the selectivity to long-chain hydrocarbons.

In the present study, sulphur was added *ex-situ* to a cobalt-based catalyst. The resulting poisoned catalyst samples were tested under realistic FT conditions at the same operating CO conversion. The objective of this work was to elucidate this controversial effect of S and offer a better understanding of the influence of this poison on catalyst performance.

2 Experimental/methodology

A γ-Al_2O_3-supported catalyst consisting of 12 wt% Co and 0.5 wt% Pt was impregnated with different aqueous solutions of ammonium sulphide. This S impregnation was performed on previously reduced catalyst samples in order to better simulate the S-Co^0 interaction. By using this method, catalyst samples loaded with 10, 100, 250 and 1000 ppm of S were prepared. The catalyst samples were reduced in situ in a fixed-bed reactor at 350 °C for 16 h in H_2. The catalytic tests were performed at 20 bar, 210 °C and an inlet molar H2/CO ratio=2.1. The gas hourly space velocity was adjusted in order to operate at a CO conversion of 30% for all the experiments.

A fresh catalyst sample was reduced at the aforementioned conditions in a quartz tubular reactor. After reduction, the catalyst was exposed to a H_2S/H_2 flow ($H_2S/H_2=10^{-5}$) at 623 K for 2 days. The S content of the resulting catalyst was analysed in order to estimate the sulphur capacity of the catalyst, and thus, the sulphur coverage for the different poisoned samples.

3 Results and discussion

A catalyst deactivation model relating the catalyst activity to the sulphur coverage was

developed. The effect of sulphur on selectivity was successfully evaluated at the same CO conversion. The results showed that the presence of sulphur on the catalyst surface enhances the selectivity towards methane and reduces the selectivity to long chain hydrocarbons. This effect is more pronounced at high sulphur coverages. Figure 1 illustrates both the effect of sulphur on catalyst activity and on the FT product distribution.

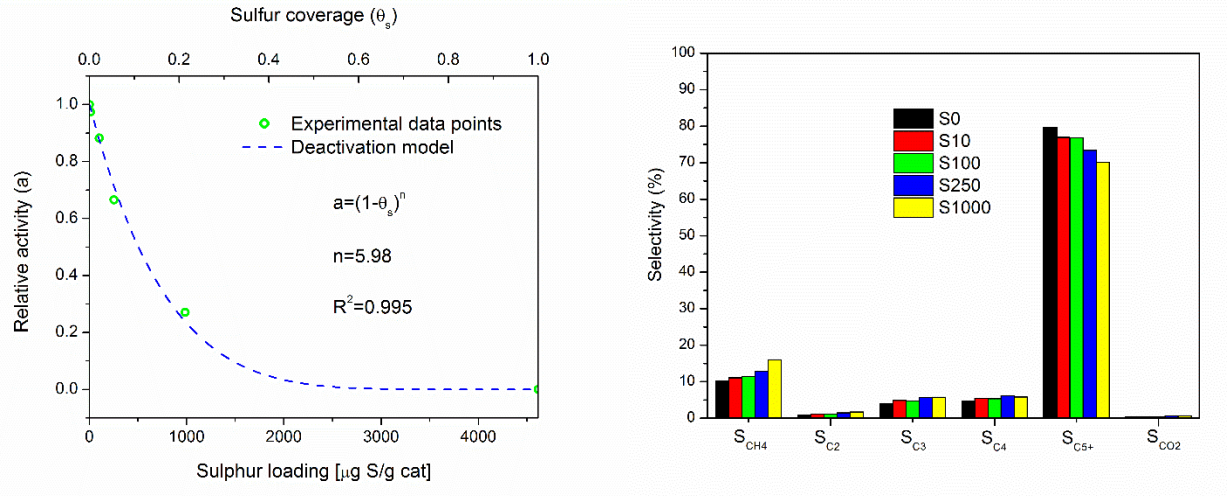

Fig. 1. Deactivation model relating the catalyst activity to the sulphur loading and the sulphur coverage (left). Carbon-based selectivities obtained for the different poisoned catalysts at 20 bar, 483 K, inlet H_2/CO=2.1 and CO Conversion=30%.

4 Conclusions

This study revealed that sulphur does have an effect on product selectivity. Further results of this work will be discussed and compared with these obtained in previous studies.

Keywords: hydrocracking, wax, noble metal, silica-alumina, kinetic modelling

1 Introduction

Synthetic fuel production using the Fischer-Tropsch (FT) technology will play an important role in the future energy system. FT wax can be upgraded to middle distillates through a hydroprocessing step that combines cracking and isomerization. Hydroprocessing of FT wax is usually carried out on bifunctional catalysts, containing a metal and an acid function. Noble metals (Pt, Pd) supported on mesoporous silica-alumina have been previously studied and have shown high diesel selectivities [1]. However, most of the published information concerns the use of Pt-based catalysts, while Pd performance has been mainly studied on batch systems [2] or using short-chain paraffins as model compounds [3].

The aim of this work is to study and compare the catalytic behavior of Pt and Pd in paraffinic wax hydrocracking. The experimental data obtained in a lab-scale trickle-bed reactor has also been used to develop a kinetic model, based on the LHHW formalism [4].

2 Experimental / methodology

Catalysts were prepared by incipient wetness impregnation of a commercial silica-alumina support (*Siral 40*) with aqueous solutions of metal nitrates. Catalysts were characterized by means of nitrogen adsorption, H_2 chemisorption and TPD of ammonia.

Hydrocracking tests were performed in a fixed-bed tubular reactor at the following conditions: T=300 - 330 °C, P=35 bar, H_2/wax= 0.1 (wt/wt); WHSV=1-4 h^{-1}. Prior to the reaction, catalysts were reduced in situ in H_2 flow at 400°C. The wax was fed to the reactor with a high-pressure syringe pump and thermal mass flow controllers were used to feed the gases. The gaseous phase was analyzed on-line with a Perkin Elmer Clarus 500 GC. Unconverted wax and liquid products were collected in two consecutive traps and analyzed off-line with an Agilent 6890 GC.

A LHHW kinetic model has been successfully developed to predict experimental outcomes. In the model, vapor-liquid equilibrium is taken into account; liquid and gas phase reaction rates have been considered trough the evaluation of fugacities; finally, ideal probability of C-C bond breakage has been accounted when modeling the cracking reactions. The set of kinetic constants used in the model has been iteratively calculated by means of non-linear optimization.

3 Results and discussion

The physicochemical properties of two of the studied catalysts are shown in Table 1.

Table 1. Physicochemical properties.

Catalyst	Metal loading (wt%)	BET surface area (m^2/g)	avg. pore diameter (nm)	pore volume (cm^3/g)	metal dispersion (%)	avg. crystallite size (nm)
Pt06S40	0.60	447	7.9	0.94	103 [1]	1.1
Pd033S40	0.33	452	7.8	0.95	21	5.3

[1] *A dispersion higher than 100% is probably due to an adsorption stoichiometry exceeding 1*

The product distribution obtained over Pt- and Pd-based catalysts with the same metal molar loading is shown in Fig.1, for similar conversion levels (around 35%). Platinum is slightly more active than palladium, but results in higher selectivities to methane and ethane, which is attributable to a monofunctional hydrogenolysis mechanism. The selectivity to the middle distillate fraction is higher in the case of platinum. Both catalysts lead to a significant increase in the degree of isomerization of the feed.

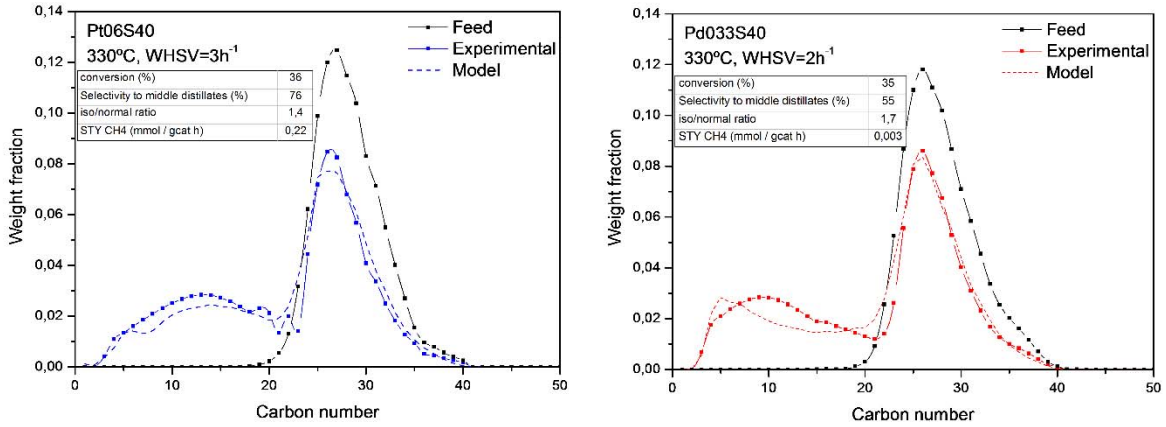

Fig. 1. Product distribution over Pt- and Pd-based catalysts at similar conversion levels.

The influence of process parameters on conversion and selectivities can be predicted with the developed kinetic model, which shows a good agreement with experimental data (Fig.1). Pt- and Pd-based catalysts will be compared considering the differences in kinetic constants (mainly activation energies, frequency factors and Langmuir adsorption constants).

4 Conclusions

Hydrocracking of paraffinic wax has been carried out over Pt/ and Pd/Siral 40 and the experimental results were used to obtain a kinetic model. Further work is ongoing to improve the model and evaluate the performance of bimetallic PtPd catalysts.

Keywords: hydrodeoxygenation, nickel phosphide catalysts, aliphatic esters

1 Introduction

The limited reserves of fossil fuel, increasing oil consumption, climate changes and some other reasons have recently caused an intensified search for alternative sources of energy [1,2]. Fatty acid based feedstocks such as vegetable oil, tall oil, waste-cooking oil ("yellow grease") or animal fat attract much attention. There is a commercial-available technology to convert these crudes into efficient fuel – hydrodeoxygenation (HDO). HDO leads to the mixture of hydrocarbons in the diesel fuel boiling range. This products are frequently called "green diesel", "second generation biodiesel" or "renewable diesel".

Conventional hydrotreating sulfide catalysts and precious metal catalysts are active in HDO. But sulfide catalysts suffer from deactivation in absence of sulfiding agent and precious metals are highly-priced. Transition metal phosphides are considered as promising materials for HDO of renewable feedstocks [3,4]. Supported phosphide catalysts such as Ni_2P/SiO_2, Co_2P/SiO_2, MoP/SiO_2, WP/SiO_2, Ni_2P/MCM-41 etc. are widely investigated in hydroprocessing of model compounds and real feedstocks [5].

The aims of the present work are the study of the silica-supported nickel phosphide catalysts in HDO of vegetable oil model compounds – aliphatic methyl esters (methyl heptanoate $C_6H_{13}COOCH_3$ – MH, methyl laurate $C_{11}H_{23}COOCH_3$ – ML, methyl palmitate $C_{15}H_{31}COOCH_3$ – MP), investigation of reaction conditions and carbon chain length influence on catalytic properties.

2 Experimental/methodology

The catalysts were prepared by impregnation of silica with aqueous solutions of $Ni(OAc)_2$ and $(NH_4)_2HPO_4$. At the impregnation step Ni:P molar ratio was maintained 1:2, nickel loading was about 2.5 w.%. Impregnation followed by drying at 110°C, calcination at 500°C, reduction *in situ* in hydrogen flow at 0.1 MPa, 600°C. The catalytic tests were carried out using fixed-bed continuous-flow stainless steel reactor. The HDO of the methyl esters diluted in *n*-dodecane (0.270 mol/l) were conducted at 290-310°C, 3.0 MPa, 600-1050 H_2/feed volume ratio. Catalytic activity was evaluated as the rate of the reaction at about 20% conversion of ester. Reaction mixtures were analyzed by GC-MS and GC-FID. The catalysts were characterized by elemental analysis, N_2 physisorption, H_2-TPR, XRD, HR-TEM, XPS.

3 Results and discussion

Corresponding to H_2-TPR experiments of calcinated precursors reduction of phosphates on silica surface starts at the temperatures of 600°C. XRD analysis of reduced catalysts confirmed for all catalysts the presence of Ni_2P phase on the surface of the SiO_2. Coherent-scattering region according to XRD data was 5.5 nm before reactions and almost the same after reactions.

Corresponding to HR-TEM data the mean particles sizes of nickel phosphide on the silica surface were 2.9 nm before reactions and about 3.2 nm after reactions.

XPS revealed that even passivated phosphide particles are oxidized in air. Surface atomic ratio of $Ni^{\delta+}$ to the total Ni content and $P^{\delta-}$ to the total P content are reduced during the storage in air. Therefore, *in situ* reduction is essential to carry out correct catalytic experiments.

The main HDO products of MH were *n*-hexane and *n*-heptane, of ML – *n*-undecane and *n*-dodecane, of MP – *n*-pentadecane and *n*-hexadecane. The content of acids and alcohols did not exceed 0.005 mol/l. For all of the feedstocks selectivity toward C_nH_{2n+2} hydrocarbons (where n is 7, 12 and 16 for MH, ML and MP correspondingly, Fig. 1) did not depend on ester conversion and was about 30-40%. The main gas phase products were CO and CH_4. But absence of CO_2 do not prove absence of decarboxylation route ($DeCO_2$), because methanation and water-gas shift reactions can take place during HDO. HDO activity also depends on hydrocarbon chain length and H_2/feed ratio.

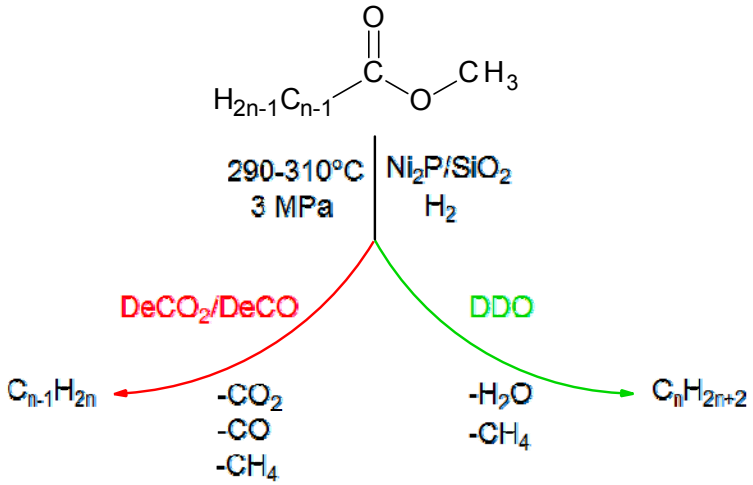

Fig. 1. HDO routes of aliphatic methyl esters: $DeCO_2$/DeCO – decarboxylation/decarbonylation, DDO – direct hydrodeoxygenation

4 Conclusions

Ni_2P/SiO_2 catalysts were synthesized by incipient wetness impregnation of SiO_2 followed by reduction *in situ* in reactor. It was found that two parallel reaction pathways occur on the Ni phosphide catalysts surface during HDO of aliphatic methyl esters: decarboxylation/decarbonylation through CO_2, CO and $C_{n-1}H_{2n}$ hydrocarbons formation and direct hydrodeoxygenation through H_2O and C_nH_{2n+2} hydrocarbons formation. Hydrocarbon chain length influence on activity but almost does not effect on selectivity.

Keywords: hydrogen production, ammonia decomposition, mixed oxide support, cobalt catalyst

1 Introduction

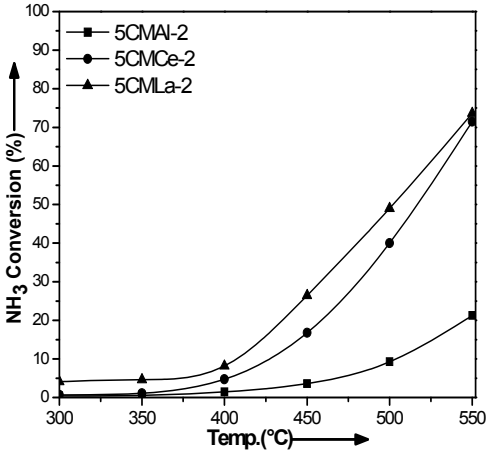
Ammonia is a potential hydrogen carrier for hydrogen delivery. Because of its several desirable characteristics made it practical to store energy at much higher density against to hydrogen storage system [1]. However ammonia decomposition process for the production of CO_x free hydrogen is more attractive from an economic standpoint in comparison with other process.Much research has been devoted mainly to Group VIII metals (Ru, Ni, Ir, Fe, Co and Rh) or metal carbide/nitrides (MoNx, VCx, MoCx, VNx, etc.)[2-4]. It has been found that Ru is the most active catalyst for ammonia decomposition [4]. But high price and limited availability of Ru system is an obstacle for large scale applications. Hence developing an affordable and active catalyst for ammonia decomposition is highly desirable. Although the application of MWCNTs was found to be most active as support, there are disadvantages in the use of CNTs in this reaction, e.g. high cost, methanation, and low metal support interaction. Many literatures reported that support basicity is a necessity for efficient catalyst in ammonia decomposition reaction hence basic mixed oxides as support may enable the tailoring of a catalyst with proper strength of basicity [5]. In this respect present work, aiming the role of support composition of mixed oxide systems obtained from Mg-X (X = Al,Ce,La) hydrotalcite precursor on the activity of Co based catalyst in ammonia decomposition. To get a closer insight into the role of the support and aiming better understanding of the supported Co system on Mg-La supports with different Mg/La ratios for ammonia decomposition will also been investigated.

2 Experimental

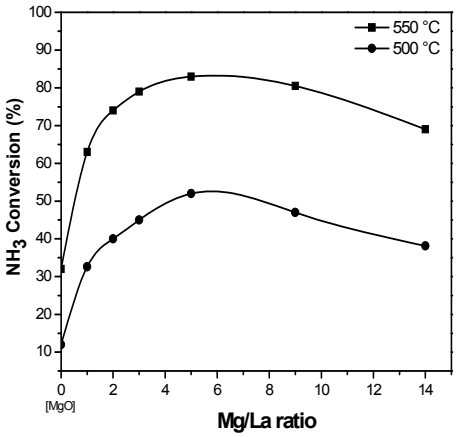
All mixed oxide support materials were prepared by co-precipitation of Mg and X(Al,Ce,La) nitrates under super saturation conditions using a mixture of bases KOH and K_2CO_3 and calcined at 450 °C for 18 h in air. These supports were impregnated with 5wt% of Co using aqueous cobalt nitrate solution in rotary evaporator. After impregnation the catalysts were dried in oven for overnight at 100 °C and calcined the catalysts at 500 °C for 5h in nitrogen flow. These Co catalysts on MgX support (X=Al,Ce,La with Mg/X ratio 2) were denoted as 5CMAl-2, 5CMCe-2, and 5CMLa-2. Similarly Mg-La mixed oxide system with different Mg/La ratios (Mg/La = 1, 2, 3, 5, 9, 14) were prepared and impregnated with 5wt% Co which were designated as 5CMLa-1, 5CMLa-2, 5CMLa-3, 5CMLa-5, 5CMLa-9, and 5CMLa-14 respectively. Catalysts were characterized by BET, XRD, TPR, TG-DTG, CO2 TPD and CO chemisorption techniques. Catalytic activity tests were performed in a fixed bed quartz reactor under atmospheric pressure (PID system, Eng &Tech, Spain) conditions and the analysis performed by an online gas chromatograph (GC-450 Varian, USA) equipped with a thermal conductivity detector and a Poropak Q column.

3 Results and discussion

The 5wt%Co catalysts supported on MgLa, MgCe and MgAl mixed oxides(5CMLa-2, 5CMCe-2 and 5CMAl-2) were evaluated for ammonia decomposition activity at the temperature range from 300 to 550°C under atmospheric pressure. It was found that 5CMAl-2 catalyst is showing least activity compared to other catalysts though it having high surface area than others, which is due to formation of stable $COAl_2O_4$ species. Though having high surface area and high metal dispersion 5CMCe-2 catalyst is showing equal and less activity at 550°C and lower temperatures in comparison with 5CMLa-2 catalyst. These results reveal that surface area and metal dispersion are not the only parameters for ammonia decomposition activity. The high activity for 5CMLa-2 catalyst is due to high basic nature of MgLa mixed oxide which contains moderate basic sites due to Mg and strong basic sites due to La. It already reported that due to the size difference between Mg^{2+} and La^{3+} MgLa mixed oxide appears as stronger base with a smaller number of sites. To increase basic site we optimize Mg,La ratio in MgLa mixed and we found Mg/La=5:1 ratio is having more basic sites compared with other ratios. Similarly surface area, metal dispersion and metal reducibility also increased at this ratio. The XPS results also confirmed the presence of more surface cobalt species at this ratio. Consequently the 5CMLa-5 catalyst is showing highest activity among all catalysts.



Activity study of Cobalt catalysts on MgX-2 support (Al, Ce, La) at temperature range 300-550 °C and GHSV- 6000h^{-1}



Activity study of Cobalt catalyst on Mg-La support with different Mg/La ratios at 550 & 500°C and GHSV-6000h^{-1}

4 Conclusions

Calcined Mg-La hydrotalcite precursor is the promising support for the ammonia decomposition reaction. It is highly basic, thermally stable and unveiling higher conversion values with paramount number of Co surface atoms. Co catalyst over Mg-La support is showing better activity in comparison with other supports which is due to high basic in nature. In addition cobalt catalyst on MgLa support with Mg/La=5 ratio (5CMLa-5) is found very efficient for the ammonia decomposition reaction at atmospheric pressure compared with other catalyst having different Mg,La ratios. Hence MgLa ratio 5 is seems to optimal ratio for ammonia decomposition reaction

Keywords: ethanol steam reforming, nickelates, structured catalysts

1 Introduction

Oxygenates such as light alcohols derived from biomass are very perspective convenient fuel for intermediate temperature solid oxide fuel cells (IT-SOFC). Being economically sustainable, bioethanol is one of the most promising renewable fuels, its storage and transportation are easier than that of hydrogen, and internal steam reforming can be carried out directly inside the IT-SOFCs [1]. Realization of bio-ethanol steam reforming (ESR) over structured catalysts at short contact times promotes the increase of hydrogen and syngas yield. Structured supports of high thermal conductivity provide an efficient heat transfer within the reactor preventing generation of hot spots and degradation of catalysts. The main problem in ESR of all oxygenates is carbon formation and sintering of cheap Ni-containing catalysts which are the most suitable for the practical application [2]. In the previous work, catalysts based on Ln ferrites-nickelates were shown to provide a high activity, stability and selectivity in ESR. However, they have a low specific surface area (SSA) and cannot provide required performance being supported on structured substrates. The perspective approach to get over these difficulties is loading perovskites on the supports of a high SSA such as γ-Al_2O_3 with additives of alkali-earth elements to prevent formation of coke. In this study, the catalysts *m*$LnNi_{0.9}Ru_{0.1}O_3$/*n*Mg-γ-Al_2O_3 (Ln = La, Pr, *m*=10-20%wt, *n*=6-15%wt) were synthesized and tested in the ESR as granulated and structured ones.

2 Experimental

*n*Mg/Al_2O_3 supports were prepared via impregnation of aluminum hydroxide (DISPERAL) or γ-Al_2O_3 by water or organic (citric acid+ ethylene glycol) solution of $Mg(NO_3)_2$. The amount of Mg was varied from 6%wt to 15%wt. 10-20%wt of $LnNi_{0.9}Ru_{0.1}O_3$ were supported on *n*Mg/Al_2O_3 from water solution of corresponding salts followed by calcination at 500-700°C. Powdered catalysts were supported on structured substrates (platelets of corundum/Al-Si-O or metal Ni-Al foams or metallic microchannel plates) from suspension in iso-butyl alcohol, then dried and calcined at 700°C in air.

The catalysts were characterized by XRD, BET, TEM with EDX, UV-vis, XPS and TPR-H_2, FTIRS of CO test molecule. ESR was carried out in the temperature range of 500-800°C using feed 10% C_2H_5OH+40% H_2O, N_2 balance over 0.25-0.5 mm catalyst fraction or platelets with a supported active component (pre-treatment in H_2 at 500°C for 1 hour) in a plug-flow reactor at contact time 0.07s (fraction) and 0.15 s (platelets). Stability tests of structured catalysts were carried out in a pilot reactor under a realistic reaction mixture containing 30%C_2H_5OH+60%H_2O + 0÷2.5%O_2 + 7.5÷10%N_2.

3 Results and discussion

The SSA of catalysts was 50-110 m^2/g decreasing with nickelate loading. According to XRD data, the main phase in nMg/Al_2O_3 is spinel with appearance of MgO at Mg concentration of 10-15%. The increase of γ-Al_2O_3 lattice parameter evidences Mg incorporation into its structure. XPS analysis shows the enrichment of the support surface with Mg depending on the method of Mg addition. Loading of $LnNi_{0.9}Ru_{0.1}O_3$ results in further increase of the spinel lattice parameter evidencing incorporation of Ni into support with formation of $NiAl_2O_4$ being dependent on Mg concentration. This is confirmed by UV-vis data showing stabilization of Ni^{2+} mainly in tetrahedral positions of $NiAl_2O_4$ at 6%Mg while increasing Mg concentration leads to preferential stabilization of Ni^{2+}_{Oh} in NiO-MgO solid solution. The absence of perovskite reflections in XRD patterns of catalysts suggests its high dispersion that is also shown by TEM data revealing the presence of $Ln_2Ni_{1-x}Ru_xO_4$ on the catalyst surface. Thus, nickel could be distributed among different compounds as a result of its interaction with γ-Al_2O_3 and/or MgO that provides a high dispersion of Ni in the catalysts. The data of H_2-TPR and Ni2p XPS confirm the presence of different nickel states in the initial catalysts depending on Mg content. According to TEM data, reduction of initial catalysts in hydrogen or reaction media leads to formation of Ni-Ru alloy particles strongly interacting with LnO_x/MgO-Al_2O_3.

Study of the catalysts activity in ESR shows that the presence of Mg provides considerably higher values of ethanol conversion, hydrogen yield and coking stability as well. The optimal composition of the catalyst with high activity and stability has been defined. For Mg-promoted catalysts, FTIRS of adsorbed CO revealed decreased concentration of acid Lewis centers responsible for the coke formation. A low concentration of Lewis centers leads to decrease of ethylene selectivity and favours formation of intermediate hydrogen-enriched carbonaceous species which are easier oxidized that leads to effective catalyst performance.

Testing of the catalysts supported on structured foam platelets has shown that, at temperatures below 750°C, ethanol conversion and hydrogen yield are higher for the optimized active component loaded on the metallic Ni-Al foam as compared with ceramic foam. Evidently, performance of Ni-Al foam supported catalyst is better due to its high thermal conductivity that provides effective heat transfer along the catalytic bed. A long-term testing of this catalyst in ESR and oxidative ethanol steam reforming using realistic reaction mixture shows its high activity and stability in both reactions during 50 hours.

4 Conclusions

The catalysts $LnNi_{0.9}Ru_{0.1}O_3$/6-15%Mg/Al_2O_3 (Ln=La, Pr) have been characterized and studied in ethanol steam reforming as fractions and layers on structured ceramic and Ni-Al alloy substrates. The influence of Ln nature and Mg concentration on the structural and redox properties of the catalysts has been elucidated. High activity and coking stability of catalysts are provided by a high dispersion of metallic Ni and Ni-Ru alloy due to strong interaction with LnO_x/MgO-γ-Al_2O_3 support and suppressing support acidity by Mg/Ln cations. The optimal catalyst supported on Ni-Al foam substrate shows high and stable performance in a realistic reaction mixture during 50 hours.

Impact of SO_2 as Air Pollutant on Spatial PEMFC Performance

Reshetenko T.V.*, Davies K.

Hawaii Natural Energy Institute, University of Hawaii, Honolulu, USA

* tatyanar@hawaii.edu

Keywords: PEMFC, Pt cathode, airborne contaminant, sulphur dioxide, segmented cell, spatial EIS

1 Introduction

Durability, reliability and high performance of proton exchange membrane fuel cells (PEMFCs) under different environmental conditions are very important issues which must be addressed to enable the widespread adoption of these devices. Most PEMFCs use air as an oxidant which may contain pollutants such as SO_2, NO_x, CO, NH_3 and some organic compounds resulting from conventional gas and diesel powered engines and natural sources. The air contaminants are known to cause damage, significant performance loss and even cell failure in fuel cell systems where air filters cannot be employed due to weight or volume limitations. Impacts of SO_2, NO_x, CO, NH_3 on the oxygen reduction reaction and PEMFC performance were previously studied using the well-known rotating ring disk electrode technique and the convenient single cell approach [1-4]. The evaluation of fuel cell performance with a single, lumped cell does not reveal spatial behaviour. In contrast, a segmented cell system provides locally resolved voltage, current and impedance. It is a powerful tool for understanding the poisoning mechanisms and for improving the PEMFC environmental adaptability and durability. In this work, the spatial performance of a fuel cell exposed to 2 ppm SO_2 and different operating conditions was studied with a segmented cell system.

2 Experimental/methodology

A segmented cell tests were performed with commercially available 100 cm^2 membrane/electrode assemblies (MEAs) [5]. Each electrode contained a Pt/C catalyst with a loading of 0.4 $mg_{Pt}\,cm^{-2}$. A segmented 25BC gas diffusion layer (GDL, 10 segments of 7.6 cm^2) and a Teflon gasket were employed at the cathode, whereas a single GDL piece was applied at the anode. The MEA was operated under galvanostatic control of the whole cell current (0.2 and 1.0 $A\,cm^{-2}$). Other operating conditions were: 80°C, 48.3 kPa_g back pressure, 100/50% relative humidity and 2/2 stoichiometry for the anode and cathode respectively. The dry contaminant was injected into the humidified cathode air stream. The poisoning proceeded until the cell voltage reached a steady value. Subsequently, the SO_2 injection was stopped to evaluate the cell self-recovery with air. Cyclic voltammetry was applied to determine electrochemical area (ECA) and assess catalyst recovery after SO_2 impact.

3 Results and discussion

Figure 1 shows the voltage response and normalized current density for each segment vs. experiment time at an overall cell current density of 1.0 $A\,cm^{-2}$. For the first 16 h, the cell was operated with pure air resulting in a cell voltage of 0.665 V. The injection of 2 ppm SO_2 significantly decreased the voltage during a transition period that lasted ~6-7 h eventually reaching a steady state of 0.370 V. The voltage decrease was accompanied by a significant change in the current density distribution which undergoes several steps. Recovery was only partial and took ~4 h, the cell voltage reached 0.475 V instead of initial performance of 0.665 V. Chemisorption of SO_2 at intermediate potentials (0.4-0.8 V) most likely results in formation of zero-valent sulphur and leads to a decrease of the ECA, a shift of the oxygen reduction from a 4-electron to a 2-electron mechanism and an increase of H_2O_2 production, which negatively impact the PEMFC performance [3]. Moreover this sulphur species can be oxidized only at high potential (> 1.0 V) which explains the observed partial

recovery of the cell.

Figure 2 shows spatial electrochemical impedance spectroscopy (EIS) data for segments 1, 4, 7, and 10, recorded during various experiment phases. The impedance of all segments increased significantly after 1 h of SO_2 exposure. A low frequency pseudo-inductive behaviour was observed for all segments which might be associated with electrochemical transformations of adsorbed sulphur-containing species on Pt. However, further SO_2 exposure decreased the impedance of all segments. Operation with pure air after the poisoning resulted in local recovery of the cell: the inlet segments 1-6 almost restored their activity, while the outlet part did not recover. A detailed analysis of the spatial PEMFC behaviour under SO_2 exposure at low current density operation (0.2 A cm^{-2}) and recovery, possible SO_2 poisoning mechanisms and modelling results will be presented and discussed.

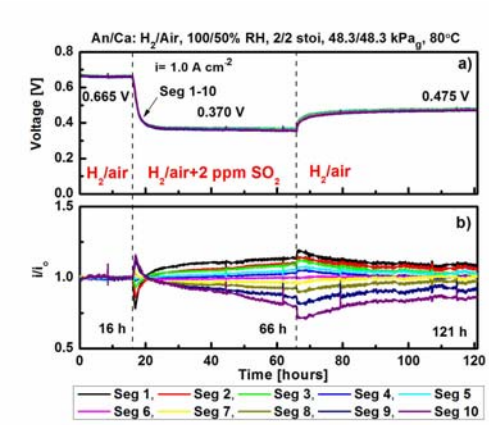

Fig. 1. Voltage (a) and normalized current density for each segment (b) vs. time.

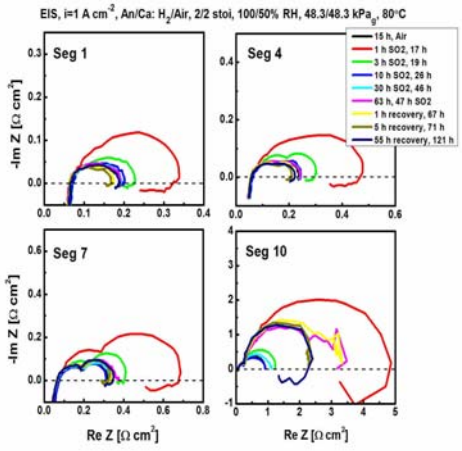

Fig. 2. EIS data for segments 1, 4, 7, 10 during the different phases of exposure to 2 ppm SO_2.

4 Conclusions

The segmented cell approach was successfully applied to study spatial PEMFC performance under SO_2 exposure as well as localized MEA properties (ECA, H_2 crossover). Moreover, the results provide the basis for a cathode poisoning model. Sulphur dioxide as an airborne pollutant was found to cause severe irreversible performance loss which is accompanied by significant current density redistribution downstream. The observed redistribution is connected with a mechanism of electrochemical SO_2 transformation and strongly depends on operating conditions. The performance can be partially recovered by reintroducing neat air and increasing potential (> 1.0 V) at which zero-valent sulphur species can be oxidized.

Keywords: ultra-low sulfur diesel, alumina, nanorods, hydrodesulfurization, NiWS

1 Introduction

Nowadays, the use of diesel and gasoline fuels has increased drastically as well the quantity of pollutants emitted into the atmosphere. Thus, the production of clean fuels meeting the new environmental regulations is one of the main challenges in catalysis [1]. The conventional materials used in hydrotreating reactions consist of molybdenum sulfided promoted by cobalt or nickel, and supported over phosphated-γ-Al_2O_3 [2]. However, typical catalysts are not always able to reduce the sulfur concentrations until the required levels needed for transportation fuels, especially, in the complex petroleum fractions as Mayan-Mexican oil. In this work [3], we get insight on the use of 1D γAl_2O_3 nanorods as support for NiW ultra-deep HDS catalyst, their structure, electronic properties and morphology. Therefore, sulfided samples were tested on the 4,6´dimethyl-dibenzothiophene (4,6´DM-DBT) reaction, which is known to be more refractory to desulfurize than DBT molecule The samples also have been extensively characterized by a variety of techniques (N_2 physisorption, XRD, TPR-H_2, TPD-NH_3, FT-IR of adsorbed pyridine and HRTEM). Also, theoretical calculations have been performed by using the tight-binding method within the extended Hückel framework through the YAeHMOP computer package including f-orbitals [4].

2 Experimental/methodology

The 1D γ-Al_2O_3 nanorods linked network (Al-nR) support was prepared by soft template sol-gel method adding the triblock copolymer surfactant *pluronic* as structure directing agent. The entire synthesis procedure was reported elsewhere [2]. The obtained solids were calcined at 500°C for 4 h with a heating rate of 1°C min-1. The NiW catalyst was prepared by successive impregnation, using the pore filling method, with an aqueous solution of ammonium metatungstate (AMT) and nickel nitrate. The concentration of AMT solution was selected in order to get 20 wt. % of W (pH = 3.7) while that of nickel was adjusted to define a nominal atomic ratio r =Ni/(Ni + W) equal to 0.31 (pH = 4.4). The green final solid was calcined at 450°C for 4 h under a flow of air with a heating rate of 1°C min−1.

3 Results and discussion

Evidence of high dispersion for Ni and W species was exhibited by XRD and TPR in the oxide state for the NiW/Al-nR catalyst. This was well confirmed by HRTEM in the sulfided state; NiWS/Al-nR catalyst shown between 1-2 layers stacking and **L** values as 1.9±0.36 nm (Fig. 1A), which represents 1.7 nm lesser value than that obtained for the conventional catalyst. HRTEM and EDP rings pattern confirmed the presence of 1D γ-Al_2O_3 nanorods and a preferential plane (110), which was repeated periodically over its surface (Fig.1B). By one hand this plane is more favorable for anchoring WS_2 slabs with a tilted orientation because of the

flexibility of the hydroxyl groups, and by the other hand, the curvature of the nanorods and the excess of aluminum could allow the formation of WSAl bonds. Therefore, the NiWS type II nano-slabs in a tilted orientation was suggested as it is shown at Fig.1C. NiWS/Al-nR sample exhibited higher 4,6′DM-DBT HDS activity, same hydrogenation ability and better hydrogenolysis properties than a commercial NiWP/γ-Al_2O_3 sulfided catalyst, which probably does not lie on its weak acidity, but on the enhanced dispersed active sites. Theoretical calculations modeling the inclusion of Ni atoms on 2H-WS_2 and 1T-S-W-S (Fig.1D) cluster considering Ni in different positions were performed (Fig.1E). The computational calculations showed that Ni in the edge of the cluster exhibit a clear less metallic character than when Ni is in the corner of a 2H-WS_2 crystallite. The observed increase on the direct desulfurization pathway for 4,6′DM-DBT reaction was in agreement with these theoretical results and with a possible increase on the WS_2 nano-slabs decoration degree by Ni atoms.

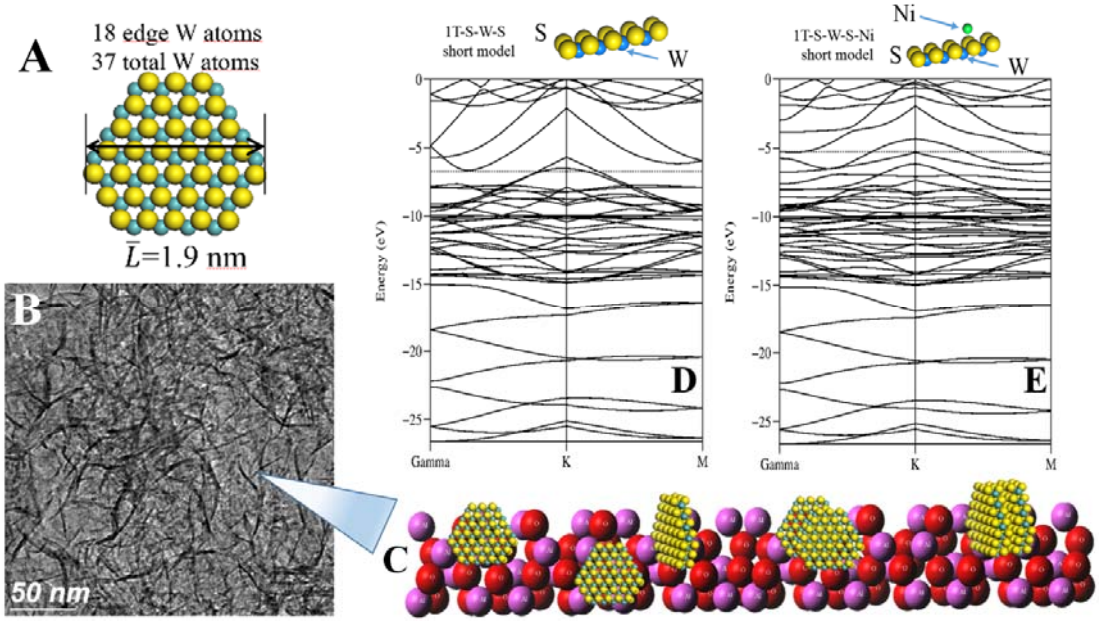

Fig. 1. Schematic representation for the WS_2 nanoslabs and its average slab length (A). Typical HRTEM micrograph of the Al-nR (B). NiWS type II nano-slabs in a tilted orientation over the Al-nR (C). The atoms are not to scale and the sizes only are illustrative. Also, Energy bands vs k points in the reciprocal space for cluster energy bands a) 1TS-W-S and b) 1T-S-W-S-Ni

4 Conclusions

The properties of the 1D γ-Al_2O_3 nanorods support play a key role on the formation, dispersion, activation and the catalytic properties of the sulfide active phase. The calculated model of slabs particles as 1T-S-W-S cluster with Ni on the top of an edge site resulted with less metallic character that when the model was a 2H-WS_2 3D crystal with Ni in a corner site, indicating that an electronic effect is occurring between the nanorods and the active sites.

Keywords: membrane reactors, hydrogen production, hydrocarbon, fuels, metal, catalysts

1 Introduction

Driven by the concern over greenhouse gas emissions, air quality and security of energy supply, hydrogen has become a contender to replace gasoline and diesel as future transportation fuel. There is an enhanced interest of discovering new ways to convert current transportation liquid fuels, such as gasoline or diesel to high content hydrogen products. Traditionally hydrogen is mostly consumed by the refining industry, 95% of which is supplied by steam reforming of natural gas[1]. Large-scale hydrogen production from natural gas by steam reforming is a well known process that uses purification methods such as pressure swing adsorption or cryogenics. However, hydrogen production at a smaller scale from fossil fuels requires further development to meet the requirements of purity, economics and versatility to fuel cell specifications. The utilization of membrane reactors for this purpose is one of the most promising options, given its advantages in energy efficiency and the ability to integrate two different processes (reaction and separation) in a single step. This paper focuses on the work currently performed for novel proof-of-concept oil to hydrogen catalytic membrane technology at the Nanomaterials Centre (NANOMAC) in partnership with Saudi Arabian Oil Company. A combination of experimental runs on autothermal reforming, water gas shift combined with hydrogen separation are conducted using functionalized silica membrane systems to purify hydrogen from a reformate stream sourced from oil based fuels. The small-scale membrane reactor will be evaluated in relation to its future economic and thermodynamic potential that could include a promising prospect of inexpensive CO_2 separation

2 Experimental/methodology

The experiments were performed using 1gram pre-reduced commercial autothermal reforming catalyst in a continuous tubular system with an interchangeable membrane tube/reactor. Two thermocouples controlled the operation temperature, one placed on the oven and the other at the centre of the catalyst bed. Air was used as source of oxygen. Two HPLC pumps fed water and hydrocarbon which were mixed and pre evaporated-evaporation before the reaction region. The total reaction pressure was maintained by using a backpressure regulator connected to a gauge. Effluent from the reactor was cooled in a double pipe condenser to liquefy the condensable vapours. The gas and liquid samples were analyzed by means of chromatography techniques. The autothermal reforming reaction was investigated at different reaction conditions as follows: T = 500 ºC, P = 3bars, WHSV = 5000 h^{-1}, O/C (molar) = 0.5, S/C (molar) = 3.

3 Results and discussion

Experimental runs were conducted on a catalytic membrane reactor (CMR) schematically shown in Figure 1. A commercial autothermal reforming catalyst in combination with a mesoporous silica membrane was operated at 500 ºC (limiting temperature of silica membrane

550 ºC) using gasoline as liquid feed.

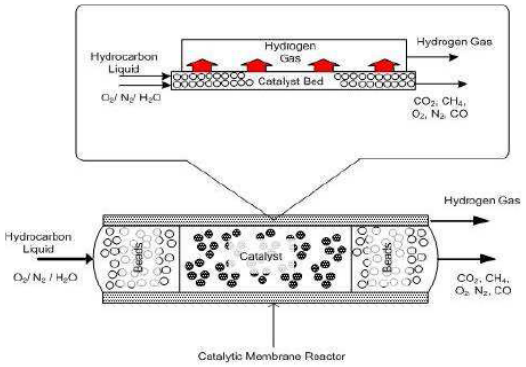

Figure 1: Schematic of the catalytic membrane reactor

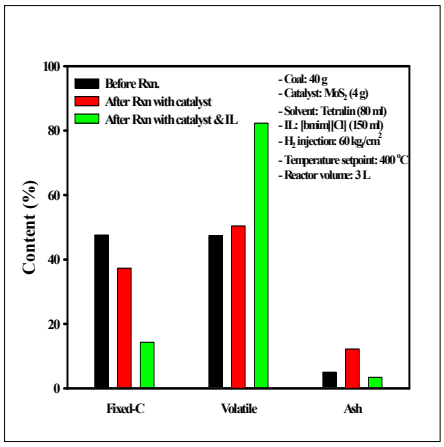
As we can see in Figure 2 at the reaction temperature of 500 ºC and as the result of continuing removing hydrogen through the membrane, the hydrogen concentration not only increases with respect to fixed bed operation but also it maintain constant with time. Figure 3 compares the distribution of products gases for the CMR operation. It can be seen from Figure 3 that hydrogen is the main product of reaction (~ 75 %) with low concentration of CO, CO_2 and CH_4.



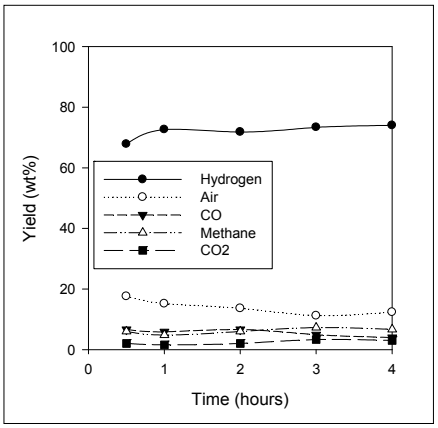


Figure 2: CMR and Fixed Bed Reactor Operation **Figure 3:** Gas Product Distribution on CMR Operation

It was found that carbon deposition is one of the problem to overcome, as if the hydrogen flux through the membrane is increased, the catalyst active sites quickly deactivate as a result of the hydrocarbon exposure. Coke formed not only deactivate the metal active sites but also block the silica membrane pores causing a sharp increase in catalyst bed pressure. If the reaction could be done at low temperature as is the case of CMR and optimum operating conditions, carbon formation could be significantly minimized.

Keywords: pyrolysis, gasification, biomass, catalysts, kinetics

1 Introduction

Pyrolysis is an intermediate stage of wood gasification with carbon dioxide or water vapor. The positive influence of catalysts in this process appears in decomposition of heavy pyrolysis products which represent a significant problem for the pyrolysis equipment. Therefore, in our study we have investigated the kinetics of pyrolysis and gasification of softwood in the presence of heterogeneous catalysts (Cu_2O, CuO, ZnO, NiO, MnO, Mn_2O_3, MnO_2, Fe_2O_3, Cr_2O_3, V_2O_5, La_2O_3, MoO_2, TiO_2).

2 Experimental procedure

Spruce wood was used as a substrate for the pyrolysis. The studies were carried out on TG-DSC analyzer STA 409 PC (NETZSCH, Germany), 25-1200 °C, aluminum oxide crucibles, 10 °C·min^{-1}. Finely ground spruce wood (particle size 0.1 mm) was milled with catalyst (10% by weight) and pressed into a 20 mg tablet. Pyrolysis was carried out in argon, gasification – in CO_2 and water vapor. The energy of activation was defined for assessment of catalysts influence on pyrolysis. We chose the Coats-Redfern method because there are many experimental data on wood pyrolysis, obtained by this method [1-3]. The standard deviation of the activation energy was ±1.5 kJ·mol^{-1}.

3 Results and discussion

All studied catalysts, except Cr_2O_3, increased the temperature of pyrolysis beginning (T_b), determined by TG (see the Table). The order of reaction of catalytic thermodestruction in some cases appeared above the first: second – in presence of CuO, ZnO, MnO, Mn_2O_3 and Fe_2O_3, and third with La_2O_3 and NiO. Additives of CuO, TiO_2, V_2O_5, MoO_2 and MnO_2 led to decrease E_a of pyrolysis on ~2 ÷ 5 kJ·mol^{-1}. Probably, at the initial stage of pyrolysis catalyst adsorbs products of depolymerization of lignocellulosic components on the surface. It is shown on the TG curves as a delay in beginning of mass loss and increase of the apparent reaction order. The mechanism of cleavage of liquid and gaseous products on the catalyst [4] consists in the chemisorption of a carbon atom by the catalyst (1 on Fig), which initiates cleavage of hydrocarbon molecules with release of H_2. Catalytic cleavage leads to the accumulation of carbon phase on the catalyst surface (2, 3 on Fig).

The processes of gasification are described by equations: $C + H_2O \rightarrow CO\uparrow + H_2\uparrow$ (925.9 °C) и $C + CO_2 \rightarrow 2CO\uparrow$ (849.7 °C). In the presence of the catalysts there was observed a decrease of T_b and the activation energy. The strongest changes in the kinetic parameters were observed in the course of gasification with NiO. So at the gasification of this sample with water vapor E_a value increased to 90 kJ·mol^{-1}, thus the reaction order was third. In CO_2 E_a = 145 kJ·mol^{-1}, the reaction order was second, and T_b decreased dramatically.

Table. Kinetic parameters of pyrolysis and charcoal gasification with water vapor and CO_2

Cat.	pyrolysis		water vapor gasif.		CO_2 gasif.	
	T_b, °C	E_a, kJ·mol^{-1}	T_b,°C	E_a, kJ·mol^{-1}	T_b,°C	E_a, kJ·mol^{-1}
without cat.	299.9	82.3	925.9	86.8	849.7	115.9
Cu_2O	306.7	76.9	892.7	46.4	818.7	90.7
CuO	305.3	85.0	897.1	47.3	810.3	84.6
ZnO	308.4	86.1	885.4	63.6	820.9	99.0
La_2O_3	306.2	93.5	871.4	42.1	807.4	84.9
TiO_2	308.1	78.6	910.8	53.6	822.7	95.1
V_2O_5	306.5	80.6	895.7	49.0	811.2	86.3
Cr_2O_3	296.9	82.7	915.8	55.8	831.6	118.6
MoO_2	305.3	79.1	916.3	53.2	804.2	91.6
MnO	309.4	87.3	914.8	46.7	805.9	80.6
Mn_2O_3	308.3	86.4	905.7	50.3	800.2	84.5
MnO_2	314.7	71.1	920.1	39.6	798.2	70.3
Fe_2O_3	308.4	84.7	785.7	72.6	764.4	104.5
NiO	313.2	94.0	472.5	90.1	553.2	145.3

The mechanism of gasification of carbon is the reverse mechanism of carbon precipitation on the catalyst. Both carbon dioxide and water vapor oxidize the catalyst surface atoms, thus facilitating access carbon to oxygen. Further, due to diffusion of the carbon atoms via the catalyst to its surface there is a reaction: $C + Me_mO_{n+1} \rightarrow CO\uparrow + Me_mO_n$ (4, 5 on Fig).

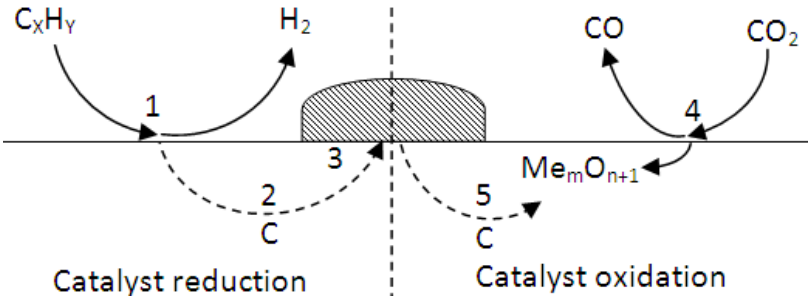

Fig. Proposed mechanism of action of oxide catalysts at pyrolysis and gasification

4 Conclusions

Summarizing experimental data, it was found out that all studied catalysts have impact on a pyrolysis stage. In this way they promote decomposition of heavy products of pyrolysis. It was defined that the catalysts reduce the temperature of beginning of gasification, both in the atmosphere of carbon dioxide, and in water vapors. On the basis of thermogravimetry data measurements and calculation of kinetic parameters it is defined that NiO has the greatest impact on the mechanism of gasification.

Kinetics of the Dehydration of 1-Butanol to Di-n-Butyl Ether: a Next Generation Biofuel

Pérez-Maciá M.A., Bringué R., Iborra M., Tejero J., Cunill F.*

Chemical Engineering Department, Faculty of Chemistry, Universitat de Barcelona, Barcelona, Spain

* fcunill@ub.edu

Keywords: biofuel, di-n-butyl ether, 1-butanol, dehydration, kinetics, ion-exchange, resin

1 Introduction

In the search of more efficient and cleaner next generation biofuels the di-n-butyl ether (DNBE) can be considered a very promising candidate [1]. DNBE has a desirable high cetane number (100); its moderate boiling temperature (142.4 ºC) reduces the volatile organic compounds emissions while permits a facile vaporization of the fuel after injection; its volumetric energy content is comparable to that of petroleum fuels (36 MJ/L) and, more important, it can be obtained from lignocellulosic biomass: 1-butanol can be produced through the ABE fermentation process [2] and subsequently DNBE could be obtained by the dehydration of 1-butanol.

In a previous work [3] we showed that di-n-butyl ether can be successfully synthesized through the bimolecular dehydration of 1-butanol over acidic ion-exchange resins. Among the tested resins, Amberlyst-70 proved to be the most suitable catalyst for industrial use due to its high selectivity to DNBE and its thermal stability, up to 473 K. In this work, a kinetic study of the dehydration of 1-butanol to DNBE over the ion exchange resin Amberlyst-70 is presented.

2 Experimental/methodology

Experiments were carried out in a 100-mL-cylindrical high pressure autoclave equipped with a stirrer and with an electrical furnace. In each experiment 70 mL of 1-butanol were charged into the reactor and, after checking for leaks, the stirring speed was set at 500 rpm and the mixture was heated up to the working temperature (413 – 463 K). When the temperature set point was reached, 1 g of sieved (particle size: 0.4-0.63mm) and dry catalyst (dried at 383 K, firstly at 0.1 MPa during 2 h and then at 1 kPa overnight) was injected into the reactor and the pressure was adjusted up to 4 MPa by means of N_2 in order to ensure liquid phase medium. The composition of the liquid mixture was analyzed in-line using a GL chromatograph equipped with a TCD detector. Samples were taken hourly during 7 hours.

3 Results and discussion

Preliminary experiment varying the mass of loaded catalyst, the stirring speed and the particle size showed that, under the selected working conditions (1g of catalyst, 500 rpm and 0.4-0.63 mm particle size), the reaction rate is not influenced by mass transfer limitations.

Three mechanistic models, with various assumptions on rate determining steps and quasi-steady state for surface species have been considered: (1) a Langmuir - Hinselwood - Hougen - Watson (LHHW) formulation; (2) an Eley-Rideal (ER) formulation in which the formed DNBE molecule remains adsorbed; (3) an ER formulation in which the formed water remains adsorbed. The elementary steps for all three mechanisms are shown in Table 1. In the three mechanisms it has been taken into account the possibility that 1 or 2 additional active sites (*) could participate in the surface reaction. Furthermore, simplified kinetic models were derived from the basic kinetic models by assuming that the amount of free active sites and/or the

adsorption of alcohol, ether and/or water are negligible. Activity coefficients calculated by the UNIFAC - DORTMUND predictive method were used to account for the non-ideal behaviour.

Table 1. Mechanistic models.

LHHW	ER-DNBE	ER-H_2O
$BuOH + * \overset{K_{BuOH}}{\longleftrightarrow} BuOH^*$	$BuOH + * \overset{K_{BuOH}}{\longleftrightarrow} BuOH^*$	$BuOH + * \overset{K_{BuOH}}{\longleftrightarrow} BuOH^*$
$2\,BuOH^* \overset{K_{sur}}{\longleftrightarrow} DNBE^* + H_2O^*$	$BuOH + BuOH^* \overset{K_{sur}}{\longleftrightarrow} DNBE^* + H_2O$	$BuOH + BuOH^* \overset{K_{sur}}{\longleftrightarrow} DNBE + H_2O^*$
$DNBE^* \overset{1/K_{DNBE}}{\longleftrightarrow} DNBE + *$	$DNBE^* \overset{1/K_{DNBE}}{\longleftrightarrow} DNBE + *$	$H_2O^* \overset{1/K_{H_2O}}{\longleftrightarrow} H_2O + *$
$H_2O^* \overset{1/K_{H_2O}}{\longleftrightarrow} H_2O + *$		

The rate expression based on water desorption as the rate limiting step in the LHHW elementary mechanism (Equation 1) has been found to be statistically the most reliable representation with physicochemical meaning of the experimental data. This equation assumes that the number of unoccupied active sites is negligible:

$$r = \frac{k\cdot\left(K_{eq}\frac{a_{BuOH}^2}{a_{DNBE}} - a_{H_2O}\right)}{\frac{K_{BuOH}}{K_{H_2O}}\cdot a_{BuOH} + \frac{K_{DNBE}}{K_{H_2O}}\cdot a_{DNBE} + \left(K_{eq}\frac{a_{BuOH}^2}{a_{DNBE}}\right)} \quad (1)$$

being Keq = exp(26.8/R+307.5/RT), in the range of 413 - 453 K.

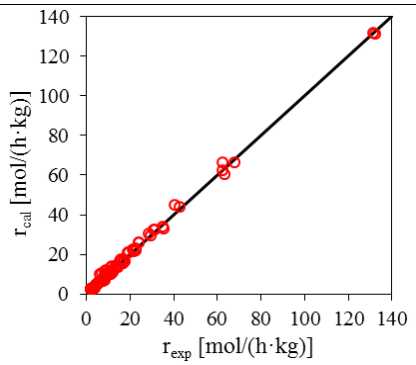

Fig. 1. Calculated with equation (1) vs. experimental reaction rates.

This model sustains the important water inhibiting effect observed. Future studies adding water in the reaction medium will be essential towards improving the kinetic model and provide more detailed information regarding the reaction mechanism.

Kinetic and adsorption equilibrium constants were grouped for mathematical fitting purposes. The optimal values of the fitted parameters are gathered in Table 2:

Table 2. Optimal values of the fitted parameters.

k [mol/(h·kg)]	K_{BuOH}/K_{H_2O}	K_{DNBE}/K_{H_2O}
$22.5 \pm 1.0\cdot\exp\left(\frac{-121421 \pm 3428}{RT}\right)$	$\exp\left(\frac{35.7 \pm 2.1}{R} - \frac{-46905 \pm 21015}{RT}\right)$	$\exp\left(\frac{49.0 \pm 2.6}{R} - \frac{6724 \pm 21414}{RT}\right)$

The dependence of the kinetic constant and the adsorption constants with the temperature follows the Arrhenius law and the Van't Hoff law, respectively. However, the high uncertainty of the adsorption enthalpy differences suggests little sensitivity to these parameters in the fit.

4 Conclusions

A classical LHHW model based on a mechanism in which de desorption of water is the rate determining step is proposed to explain the dehydration of 1-butanol to DNBE. Furthermore, both 1-butanol and DNBE participate in the adsorption term of the kinetic model. The activation energy was found to be 121±3 kJ/mol, in good line with literature data for such reaction.

Knowledge Extraction for Fischer-Tropsch Synthesis from Published Data in the Literature

Burnak B., Yildirim R.*

Bogazici University, Department of Chemical Engineering, Istanbul, Turkey

* yildirra@boun.edu.tr

Keywords: Fischer-Tropsch, CO hydrogenation, data mining, support vector machine, GTL, BTL

1 Introduction

Fischer-Tropsch Synthesis (FTS) is a clean and efficient method to produce sulfur and nitrogen-free liquid fuels and various oxygenates from syngas derived from coal, natural gas, shale gas, coal-bed gas, biogas, and biomass. FTS has been receiving renewed attraction in the literature due to depleting crude oil reserves, propagating demand in clean alternative fuels, and increasingly stringent environmental regulations [1-2].

In conventional industrial processes, the reaction temperature is maintained within 330 – 350° for high temperature Fischer-Tropsch (HTFT) conditions to increase gasoline and light olefin yield, whereas low temperature Fischer-Tropsch (LTFT) is performed within 220 – 250° range to increase wax and diesel fuel production. A typical FTS reactor operates under 25 – 45 bars [3].

Iron, nickel, cobalt, and ruthenium have been shown to enhance FTS reaction rates significantly. However, high prices and scarcity of ruthenium and high methane selectivity of nickel make them unfeasible candidates for industrial practices. Hence, most of the recent researches focus on supported iron or cobalt catalysts. Cobalt based catalysts tend to form longer hydrocarbon chains, endure longer in the reaction conditions, and show high catalytic activity, whereas iron based catalysts are preferred with low H_2:CO ratio (1:1) since it enhances WGS activity [1].

Studies demonstrate that, in addition to the type of active metal, the design of an effective catalyst requires the consideration of the support, promoter type, and applied preparation methods. Apart from the catalyst design variables, reaction conditions and feed stream composition also affects the resultant syngas conversion and product distribution [2].

Considering that FTS is invented in 1920s [3], there is a vast amount of improvement and research accumulated in the literature over decades. Abundance of the attributes related to the reaction makes the system complex and recondite. Hence, data driven models can be constructed to capture general trends and patterns by analyzing retrospective studies.

In this work, experimental data published in the literature for FTS were analyzed using support vector machine (SVM) to extract knowledge from information accumulated over years. A thorough database was constructed by using the experimental data published in the last decade. SVM was used to determine the effects and relative significances of various catalyst preparation and operating condition variables on the performance of FTS catalyst.

2 Computational Work

An extensive database containing 2404 instances for FTS catalyst performance was constructed from 223 research papers published between 2005 and 2014. The database involves 22 attributes regarding catalyst design variables such as active metal loading, support metal loading, support type, catalyst preparation method, calcination and reduction conditions (temperature, duration), as well as operating conditions such as reaction temperature, total pressure, feed composition, time on stream, gas hourly space velocity, and reactor type. All instances have three main outputs, namely CO

conversion, H_2 conversion, and selectivity to each product. The database was analyzed by constructing an SVM model in R 3.1.2 environment.

4 Results and discussion

Prior to constructing the model, the dimension of the input set was reduced by classical multidimensional scaling (MDS) to avoid the curse of dimensionality. Root mean square error (RMSE) was employed to measure the success of the models and the parameters yielding the least RMSE were chosen as the optimal set. Figure 1 shows the predictions of the model for the entire dataset. It can be observed that most of the predictions lie on the identity line with minor residuals. More detailed analyses were also performed to test the prediction power of the models for unstudied conditions, to determine the effects of individual variables, to determine the most promising experimental conditions and so on.

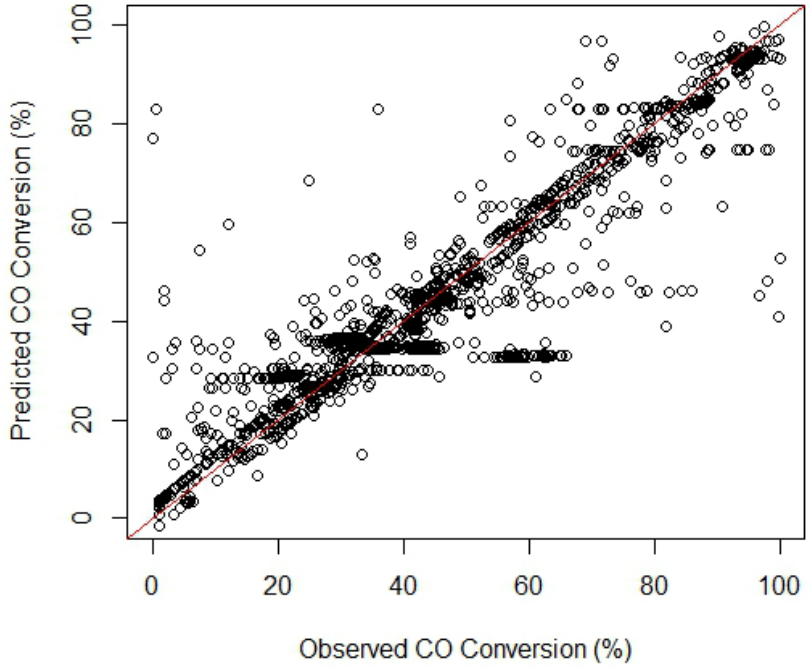

Fig.1 Predicted CO conversion vs. actual CO conversion.

4 Conclusions

A support vector machine model can be successfully implemented to model the Fischer-Tropsch synthesis data reported in the literature; the models developed can guide future experimental studies to find the optimal preparation and operation conditions.

Low Temperature Decomposition of Hydrogen Sulfide the Metal Catalysts under Layer of Solvent to Produce Hydrogen and Diatomic Sulfur

Startsev A.N.*, Kruglyakova O.V., Chesalov Yu.A., Paukshtis E.A., Avdeev V.I., Ruzankin S.Ph., Zhdanov A.A.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russian Federation

* startsev@catalysis.ru

Keywords: hydrogen production, H_2S decomposition, ambient conditions, diatomic sulfur

1 Introduction

Hydrogen sulfide, H_2S, attracts attention of many researchers as an inexhaustible source of hydrogen, but numerous attempts in the development of a suitable technology for hydrogen recovery from H_2S were not crowned with success because of high cost of hydrogen produced. However, recently it was shown that the catalytic decomposition of hydrogen sulfide into hydrogen and diatomic sulfur

$$2\ H_2S \leftrightarrow 2\ H_2 + S_2^{(gas)} \qquad (1)$$

occurs on metal catalysts at ambient conditions with H_2S conversion about 15 % [1-3]. Along with hydrogen, diatomic gaseous sulfur appeared to be the reaction product. The paper demonstrates that H_2S conversion can be considerably (up to 100 %) upgraded on passing H_2S at room temperature through the metal catalyst being immersed into the solvent capable of dissolving sulfur produced [4].

2 Experimental

Experiments were carried out at room temperature in a glass absorber equipped with a magnetic stirrer. Metal catalyst, mainly a chip of stainless steel, was placed into solvent and a mixture of argon with H_2S was bubbled through the solution. At the absorber outlet, non-reacted H_2S was trapped in the aqueous zinc acetate solution for quantitative analysis. The reaction products, hydrogen and gaseous sulfur, were detected with a gas chromatograph. As a sulfur solvent, aqueous solutions of monoethanolamine (MEA), $HOC_2H_4NH_2$, and sodium carbonate, Na_2CO_3, which are widespread in industry to extract hydrogen sulfide from the exhaust gas emissions, were used. Besides, water, ethanol and aqueous hydrazine were tested as well.

3 Results and discussion

On passing H_2S through the metal catalyst at room temperature, two gaseous products are formed, hydrogen and diatomic sulfur [1-3], though H_2S conversion is relative low. When the catalyst is placed into solvent, H_2S conversion increases even in the case of water (Table). In ethanol and, especially, in aqueous hydrazine, H_2S conversion increases significantly, however gaseous sulfur formed leaves solvents on blowing-off with argon.

With MEA or soda, only hydrogen is detected in the gas phase, while sulfur is accumulated in the solvent. In 12 hours of experiment, at the steady-state level of hydrogen production (Figure) 3.6 g of sulfur was discovered in the mother solution (Table). In Infrared and Raman spectra of the solution no new bands (in comparison with the initial solvent) were found what unambiguously indicates on the dissolved diatomic gas formed in the reaction (1). An important point is that no other bands like S – S, S – H or S – O were detected with IR and Raman spectroscopy, what means high selectivity in the reaction (1) producing only hydrogen

and gaseous diatomic sulfur.

Table. H_2S decomposition on the chip of stainless steel placed into solvent. Catalyst mass is 5 g, reaction temperature is ambient. Ar flow is ~ 10 ml/min, H_2S flow is ~ 3 ml/min.

Solvent	Solvent volume, ml	Hydrogen sulfide, mmol		H_2S conversion, %	Sulfur mass in solution*, g
		fed	non-reacted		
Gas phase	-	9.23	8.81	4.6	-
Water	180	11.8	9.7	17.2	0
Ethanol	100	12.7	6.09	52.2	0.10
5% hydrazine	77	19.5	0.29	98.5	0.46
5% MEA	200	110.6	2.3	97.9	3.64
Na_2CO_3 [Na] = 0.84 %	100	53.4	10.9	79.6	1.30

* - X-ray fluorescent analysis data after non-reacted H_2S being removed with argon flow

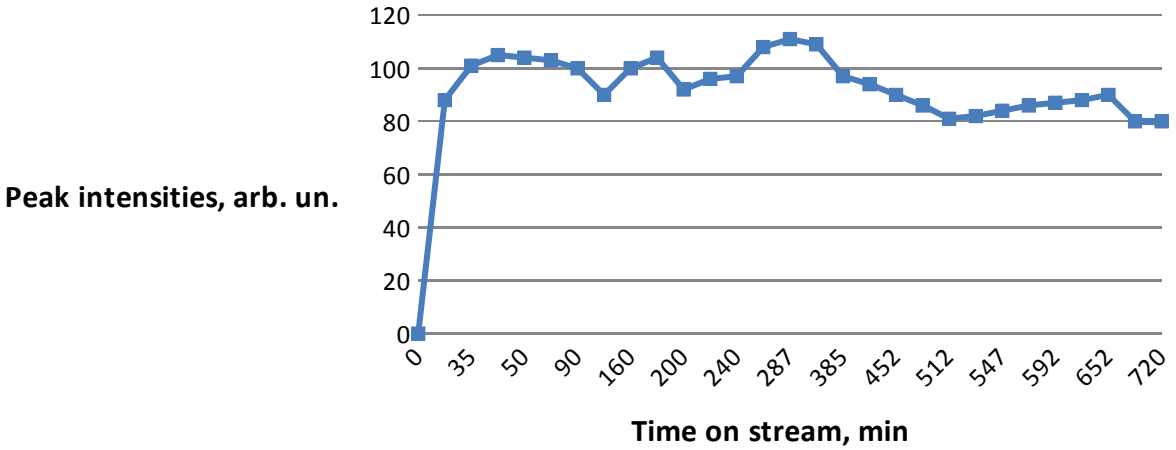

Fig. 1. Hydrogen evolution on passing H_2S through the stainless steel chip placed into 5 % MEA aqueous solution.

Main regularities of hydrogen production and sulfur recovery from the solutions are been discussed. The S_2 electronic state and the reaction (1) thermodynamics are considered. According to DFT calculations, S_2 molecule forms loosely bounded adducts with the solvent molecules. As was suggested, dissolved diatomic sulfur can be used for synthesis of new chemical substances.

4 Conclusions

Hydrogen sulfide decomposition at ambient conditions on metal catalysts under layer of solvents seems to offer new challenges and very promising opportunities to produce hydrogen from renewable inexhaustible resources, at the same time very toxic H_2S is utilized.

Material Performance of CoO_x, CeO_2 and Co-Ce Mixed Oxide on Oxygen Storage for Solar Thermal Hydrogen Production

Calisan A., Kaya D., Uner D.*

Chemical Engineering Department, Middle East Technical University, Ankara, Turkey

* uner@metu.edu.tr

Keywords: TPR, TPO, thermal, decomposition, cobalt oxide, ceria, oxygen transport, mechanism

1 Introduction

Solar thermal hydrogen production can be briefly described as high temperature decomposition of an oxide to obtain a lower oxygen-to-metal stoichiometry. The metal can be reoxidized by steam injection, producing hydrogen. Chueh *et al.* reported that nonstoichiometric ceria can be effectively used over 500 cycles between 800 °C for water splitting and 1500 °C for thermal decomposition [1]. The main challenge is to decrease the decomposition temperatures, since it was estimated that upto 80% of the final selling price of hydrogen is coming from the contribution tracking heliostats [2]. Liu *et al.* reported that redox ability of cobalt oxide is better than ceria and this ability increases when cobalt is doped on nanometric ceria [3]. In this study, our aim is to investigate oxygen storage capacities of cobalt, cerium and their mixed oxides by testing their oxygen storage capacities over repeated cycles.

2 Experimental/methodology

Material Synthesis

CoO_x (Ege Ferro, 99%) and CeO_2 (99.9% Alfa Chem.) were used directly on pure sample experiments. The Co-Ce mixed oxide materials was prepared by the citrate based sol-gel modified pechini method. $Ce(C_2H_3O_2)\cdot 1.5H_2O$ and $CoCl_2\cdot 6H_2O$ reagents were bought from Alfa Chem (99.9%) and Matheson Coleman & Bell (99.6%). Reagents were dissolved in deionized water in separate beakers and then mixed. In a separate beaker appropriate amount of citric acid was dissolved in deionized water. Previously mixed reagents were added to citric acid solution. Solution was concentrated by evaporation at approximately 50 °C with stirring until gelation. (Ce,Co)/CA complex was put in oven at 120°C overnight. Final compound, then, calcined at 250°C (10°C/min) for 2 hours and at 600°C (10°C/min) for 4 hours. Material characterization was done by using Rigaku X-ray diffractometer (30kV, 15mA) with Cu Kα radiation (λ=1.54Å). Temperature programmed reduction (TPR), oxidation (TPO), and thermal decomposition (TPtD) experiments were done by using Micromeritics Chemisorb 2720 under the fixed flow 25ccpm. Samples were heated up to 800°C at 10 °C/min. 10% H_2-Ar, 2% O_2-He, He was used during TPR, TPO and TPtD respectively. Thermodynamic analysis were conducted by constructing Ellingham and Predominance diagrams.

3 Results and discussion

Thermodynamic analysis was performed by generating Ellingham and Predominance diagrams of the pure and mixed oxides of cobalt and ceria. The results of the analysis revealed the stability limits of the compounds and limiting temperatures. The combination of properties of cobalt and ceria is intended here: by activating the ceria sites for water splitting and the cobalt sites for decreasing the thermal decomposition temperatures.

The TPR, TPO and TPtD analysis was performed for determining the oxygen storage capacities and oxygen transfer mechanisms of cobalt, cerium and cobalt-cerium mixed oxide

structures. It was observed that oxygen capacity of the metal oxide is directly related to cobalt content in the mixed oxides. The reduction and oxidation temperatures were shifted depending on the Co/Ce ratio. As the cerium content increases the capacity of oxygen per gram material decreases as shown in Figure 1. The TPR and TPO experiments were followed by TPtD analysis. Thermal decomposition was started after 700°C for all samples except for CeO_2. The temperature range was too low to observe the thermal decomposition of this material. For $Ce_{0.75}Co_{0.25}O_x$ compound, similar oxidation peaks with reduced ceria sample were observed between 50-100 ℃. Repeated TPO, TPtD and TPO analyses revealed consistent oxygen release and storage capacities at similar temperatures each time. Data analysis by Kissinger method and redhead analysis are in progress to reveal the process orders and activation energies. The results of the thermal decomposition and regeneration is being modelled in terms of an appropriate gas solid reaction mechanism to be used for design and scale up purposes.

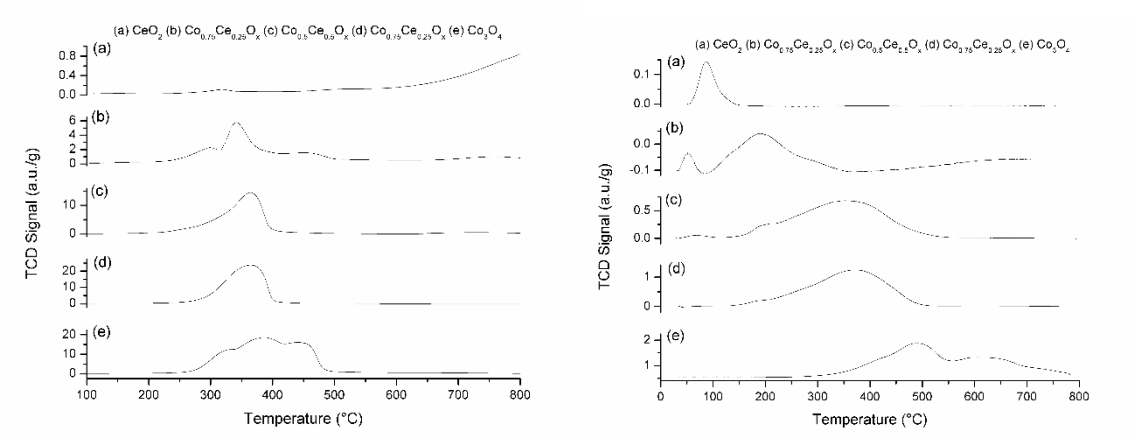

Figure 1. TPR (left) and TPO (right) profiles of the candidate materials on per gram fresh sample basis

4 Conclusions

In this study, the synergy between the unique properties of two metals with different oxide stability was investigated. Cobalt and cerium materials were selected according to thermodynamic analysis. Different molar ratio compounds were synthesized. Reduction, oxidation, and thermal decomposition experiments revealed that while ceria could not be activated by thermal decomposition up to 800 °C, cobalt content increased the oxygen storage and release capacity of the material. For $Ce_{0.75}Co_{0.25}O_x$ stoichiometry, low temperature activation by thermal decomposition was possible. The reduced from of this compound could be oxidized at temperatures between 50-100 ℃.

Keywords: carbon support, carbon corrosion

1 Introduction

Recent decades have marked by increased interest in alternative energy, in particular, in the proton exchange membrane fuel cells (PEMCF). PEMFC have several advantages, such as low temperature operation, high environmental friendliness, etc. However, these fuel cells have a significant drawback - the gradual oxidation of the carbon support during the cathodic oxygen electroreduction reaction [1], which reduces greatly the service life. Therefore, the study of corrosion resistance of carbon supports is an important task for the fuel cells commercialization. The special accelerated testing protocols - so-called "Start-stop" tests have been developed before [1] to study the carbon support corrosion in the three-electrode electrochemical cell.

2 Experimental/methodology

Commercial KetjenBlack DJ-600 sample was modified with pyrocarbon in a vertical furnace by passing ethylene in argon mixture at variable ethylene concentration (5-15 vol. %) and temperatures (650-780°C).

Modification with nitrogen was performed in the same furnace at different temperature (780-890°C) using saturated vapor of acetonitrile in argon.

Electrochemical measurements were performed in a standard three electrode cell with a hydrogen electrode as a reference electrode and a platinum foil as the counter electrode. During oxidation test the carbon support was subjected by the 1.0 - 1.5 V triangular potential with a scan rate of 0.50 V/s. The rate of potential quinone-hydroquinone (Q-HQ) peak (at ~ 0.6 V RHE [2]) change in the cyclic voltammogram (CVA) was chosen as stability criterion.

3 Conclusions

Figure 1 shows the dependence of the peak potentials in the Q-HQ region upon the cycle number for the KetjenBlack DJ-600 samples, modified with nitrogen (right) and pyrocarbon (left) and compared to the unmodified support.

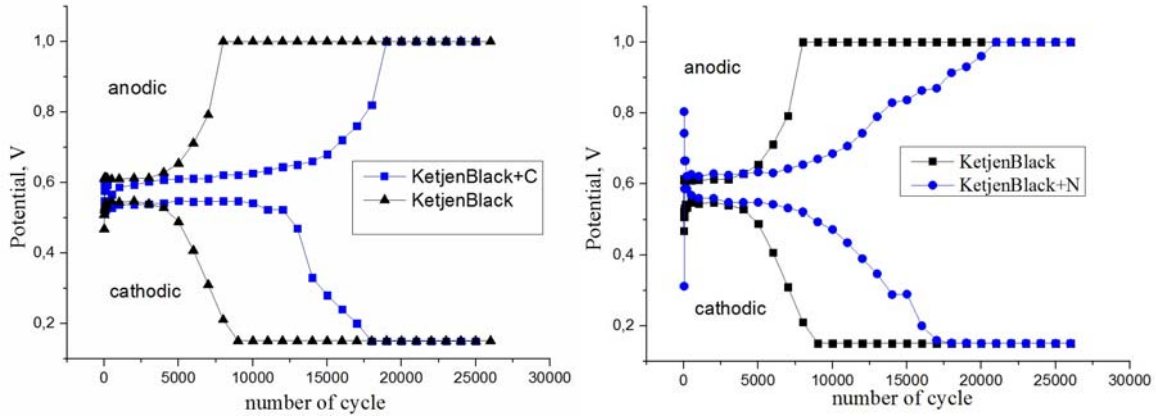

Fig. 1. The potentials of the Q-HQ peak for samples doped with nitrogen (890°C, right) and pyrocarbon (780°C, left).

Upon the cycling the shifts of the anodic and cathodic peak potentials of such groups to the higher and lower voltage values, respectively, are observed. Such a shifts can characterized the corrosion resistance of the samples: the higher the number of cycles when the shift is observed the higher is the stability of the samples. The results show that the modification of carbon black surface by both pyrocarbon and nitrogen increases the corrosion resistance of the support as it is seen from the higher number of cycles needed for the change of the Q-HQ peak potential. This behavior was explained by a partial curing of defects on the carbon black surface during the modification, leading to increasing the resistance of the support [3].

Keywords: tar abatement, naphthalene, phenol, nickel on alumina

1 Introduction

Biomass conversion, i.e. gasification, is a highly desirable route to produce bio-hydrogen. However, at present several concerns regarding syngas quality and tars content are still to be solved. Tars are mixtures of heavy molecules that condense in cold plant points thus causing clogging and fouling of heat exchangers and pipelines. In principle, steam reforming of tars allows to purify syngas and to increase the overall efficiency since it works at temperatures compatible to those of the gasifier. The aim of our study was to characterize activity of Ni-based catalysts and to study the effect modifiers on structure and catalytic performances. Taking into account that real biomass-derived syngases contain together with heavy molecules, also lighter ones that can react each other, we used for catalytic experiments model mixtures containing phenol and/or naphthalene and alcohols such as ethanol or methanol, developing one liquid phase mixture that would be easily fed through a HPLC pump, thus reducing the line complexity.

2 Experimental/methodology

Different families of catalysts have been prepared by conventional wet impregnation and incipient wetness impregnation of Puralox 200 Sba (pure γ-Al_2O_3, 200 m^2/g) and Siralox 5/170 supports (γ-Al_2O_3 with 5% SiO_2, 170 m^2/g), both from Sasol, with Ni hexahydrate nitrate water solution, in order to obtain different nickel loadings (5%, 16%, 39% $w_{Ni}/w_{support}$). The addition of Mg, B and La was also investigated.

A complete characterization of catalysts before and after reaction with XRD, IR, UV-vis, H_2-TPR, FE-SEM was carried out to understand better the effect of modifier addition to catalyst formulation.

Catalytic activity experiments were carried out using model mixtures fed to tubular fixed bed reactor. Ethanol/phenol steam reforming experiments was carried out with the conditions described in [1]. The same catalysts were tested for steam reforming of methanol/phenol and methanol/naphthalene. In this case 88 mg catalyst were diluted in 440 mg of silica glass. For methanol/phenol mixture was used the following gas phase composition (%v/v) 0.5% phenol, 9.6% methanol, 16.5% water, 73.4% He (as carrier gas). In the case of methanol naphthalene mixture the gas composition used was 79.2% He, 10.9% H_2O, 9.9% CH_3OH and 145 ppm of $C_{10}H_8$. The reaction temperature was varied from 773 K to 1073 K waiting for each point the steady state. Products analysis in all cases was performed in the same way as described in [1].

3 Results and discussion

The addition of silica to alumina (Siralox vs Puralox) gives rise to morphologically more stable materials, retaining higher surfaces area after calcination (e.g. 142 m^2/g vs. 107 m^2/g after calcination at 1073K). The addition of Nickel to Siralox with consequent calcination at 973 K

gives rise to at least three main surface species, i.e. highly dispersed Ni^{2+} species, and, at higher coverages, two different types of NiO particles, surface and bulk-like [2]. If calcination is performed at higher temperature (1073 K) a structure similar to $NiAl_2O_4$ will be also observed. By the use of Puralox as bare support, $NiAl_2O_4$ is observed at lower coverages and lower calcination temperatures than for Siralox, showing that, in some way, the addition of silica hinders the penetration of Ni into the alumina bulk.

The addition of Lanthanum [3] (20% La_2O_3 $w/w_{alumina}$) to the formulation of 20%NiO/Al_2O_3 (Al_2O_3 Puralox calc. at 1023 K) does not prevent a huge interaction between Ni and alumina with $NiAl_2O_4$ formation, even if Lanthanum disperses on alumina in a disordered state.

Experiments of steam reforming of phenol/ethanol mixtures show that the silica-free alumina support does not produce a better catalyst than the silica-containing support, while the addition of lantana promotes the catalyst activity, although not strongly. All catalysts we studied here were deactivated by sulfur, we must invoke the poisoning of the metallic nickel sites as the main reason.

In order to have a better understanding of investigated catalysts activity in tar abatement, new mixture involving polyaromatic compounds were developed and studied. Preliminary data on methanol/naphthalene conversion shows that the highest Nickel loading (Ni39/Puralox calcined at 1073 K) catalyst is able to convert totally naphthalene at 873 K, while Ni16 achieve a maximum naphthalene conversion of 73 % only at the highest temperature (1073 K) where also methanol is completely converted. In the case of phenol/methanol Ni16 (Ni16/Puralox calcined at 1073 K) catalyst achieves the complete conversion of both reactant only at 1073 K while Ni39 converts completely the reactant at 1023 K giving a hydrogen yield of 79%.

4 Conclusions

Effect of modifiers was successfully investigated on a series of Ni/Al_2O_3 catalysts. Lanthanum addition to alumina in catalyst formulation increases catalytic activity and at the same time reduces coke deposition even if was not preventing the strong interaction of Ni on alumina. The presence of silica in catalyst formulation allows to retain a higher surface area also at high calcination temperature even if less reducible Ni species, i.e. $NiAl_2O_4$ are produced.

The two proposed model mixtures are effective to model syngas coming from biomass gasification, simplifying testing operation. Ni39/Puralox (calc. 1073 K) is effective to convert naphthalene and phenol in the tested conditions.

Nickel Carbonyl Formation under Low Temperature Methanation Conditions. The Importance of Intraparticle Heat and Mass Transfer Effects

Gonzalez N., Boutonnet M., Järås S., Barrientos J.*

KTH - Royal Institute of Technology, Stockholm, Sweden

* javbar@kth.se

Keywords: nickel, carbonyl, methanation, deactivation, mass transfer

1 Introduction

Substitute natural gas (SNG) can be produced from coal, biomass or other carbonaceous sources via gasification of these materials and subsequent catalytic conversion of synthesis gas into methane (methanation) [1]. Nickel-based catalysts perform satisfactorily in regards to activity and selectivity to methane. Nevertheless, these are threatened to severe deactivation phenomena. For instance, at high CO partial pressures and low temperatures there is a high potential for nickel carbonyl formation [2].

In a previous work from Shen and Dumesic [2], a criteria based on the equilibrium partial pressure of $Ni(CO)_4$ was stablished for stable Ni particle size. For instance, nickel catalyst particles were found to sinter at temperatures slightly above 300° C and CO partial pressures as low as 85 kPa. Contrariwise, Rostrup-Nielsen et al. [3] claimed that carbonyl formation is, in practice, not a problem at temperatures above 300 °C. According to Zielinski [4], the formation of nickel aluminates can reduce the potential of carbonyl formation. Nevertheless, nickel particle sintering at similar low temperature conditions is still observed when using alumina-supported catalysts [5, 6].

More recently, Nguyen et al. [1] suggested that the use of big catalyst pellets leads to both a CO and a temperature gradient in both the gas-solid interphase and inside the catalyst pellet. Therefore, the catalyst surface may be exposed to a sufficiently high temperature and low CO partial pressure that nickel carbonyl formation is suppressed.

The objective of the present work is to elucidate the effect of catalyst pellet size on nickel carbonyl formation.

2 Experimental/methodology

The catalyst carrier used in this work was a γ-Al_2O_3 cylindrical pellet (3mm diameter and 3mm length) from Saint Gobain NorPro. A catalyst batch consisting of 30 wt% Ni was prepared by wetness impregnation of the aforementioned support. After impregnation the catalyst was calcined at 450 °C (ramp: 2.5 °C/min) for 3 h, crushed and divided into different size fractions.

The catalyst samples were reduced *in situ* in H_2 flow for 4 h at 500 °C. The different catalysts were then tested at 310 °C, 20 bar and an inlet H_2/CO ratio of 3. The spent samples were analysed by X-ray diffraction in order to estimate the average nickel particle size and therefore, evaluate nickel particle sintering.

Internal shell heat and mass transfer balances were performed for the different tested samples in order to calculate intraparticle CO concentration and temperature profiles. These calculations were performed by using COMSOL Multiphysics 5.0.

3 Results and discussion

Preliminary results point to a clear decrease in nickel carbonyl-induced particle sintering

with increasing catalyst pellet size. The observed results were supported by the models developed with COMSOL Multiphysics. Figure 1 presents a modelled spherical particle of 75 µm diameter and another cylindrical particle with the previously mentioned dimensions. As can be observed most of the large cylindrical catalyst particle is exposed to a higher temperature and lower CO partial pressure than that of the bulk gas phase, fact that reduces the potential for nickel carbonyl formation.

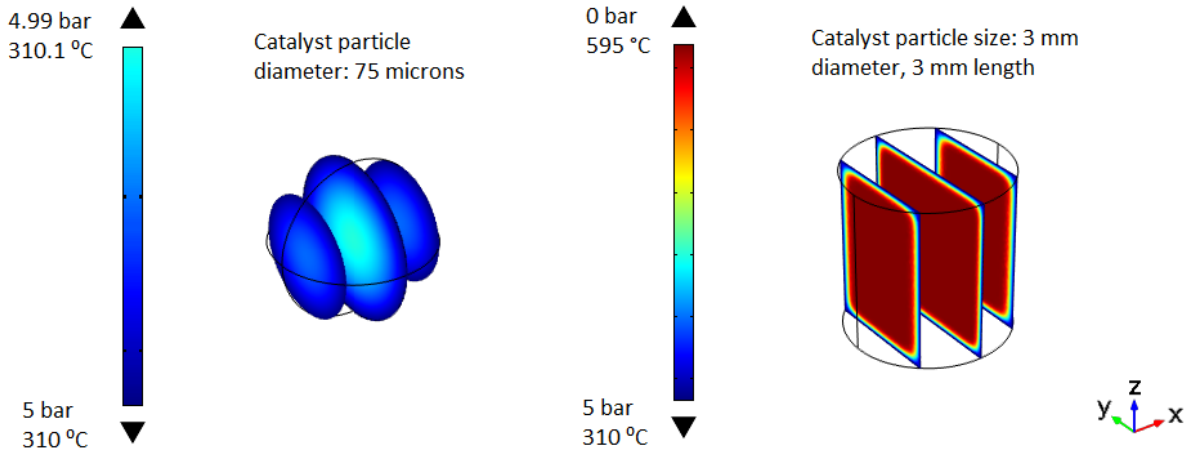

Fig. 1. Slice profiles of the internal CO partial pressure and temperature for a spherical catalyst particle of 75 µm (left) and a cylindrical particle of 3x3 mm (right). Boundary conditions: H_2/CO=3, 20 bar, 310 °C. The profiles were computed with COMSOL Multiphysics 5.0 software.

5 Conclusions

Further results of this work will be presented and the importance of the catalyst pellet size in different applications will be discussed.

Keywords: perovskites, composites, oxygen, mobility, isotope, exchange

1 Introduction

State-of-the-art SOFC cathode materials based upon Sr-doped perovskites (LSFN, LSFC, LSM etc.) deteriorate in intermediate (IT) temperature range due to segregation of alkaline-earth oxides in surface, carbonization blocking surface sites and interaction at the cathode – electrolyte interface resulting in La and Sr zirconates formation blocking oxygen transport. Developing Sr-free materials with Pr completely substituting La aids in eliminating such negative effects. Perovskites like $PrNi_{1-x}Co_xO_{3-\delta}$ and their composites with doped ceria provided high overall electric conductivity, improved and stable performance as SOFC cathodes in IT range [1]. However, the oxygen mobility and reactivity in these materials controlling their performance are still not properly characterized, which is the aim of this research.

2 Experimental/methodology

Nanocrystalline oxides $PrNi_{1-x}Co_xO_{3-\delta}$ (PNC; $x = 0 \div 0.6$), $Ce_{0.9}Y_{0.1}O_{2-\delta}$ (YDC), $Pr_{0.8}Ni_{0.5}Co_{0.5}O_{3-\delta}$ and $Ce_{0.65}Pr_{0.25}Y_{0.1}O_{2-\delta}$ were synthesized by modified polymerized complex precursor (Pechini) technique. Nanocomposites PNC – YDC were prepared by using ultrasonic dispersion in isopropanol with addition of surfactants. All samples were characterized by XRD and TEM with EDX analysis. Temperature programmed desorption of oxygen (TPD O_2) was carried out at heating rate 5 °C/min and He flow rate 2.5 $l \cdot h^{-1}$. The oxygen mobility and surface reactivity were studied by the oxygen isotope exchange with $^{18}O_2$ and $C^{18}O_2$ in isothermal (IIE) and temperature programmed (TPIE) modes in static and flow (SSITKA) reactors.

3 Results and discussion

For the $PrNi_{1-x}Co_xO_{3-\delta}$ samples calcined under air at temperatures up to 1100 °C the crystal structure corresponds to orthorhombic perovskite phase with some admixture of Pr_6O_{11} phase. For $PrNi_{1-x}Co_xO_{3-\delta}$ – YDC (1:1) composites sintered under air at temperatures up to 1100 °C the structure of perovskite phase is preserved, though pronounced redistribution of cations between domains (up to $Pr_{0.8}Ni_{0.5}Co_{0.5}O_{3-\delta}$ and $Ce_{0.65}Pr_{0.25}Y_{0.1}O_{2-\delta}$ compositions) takes place.

Perovskites calcined at 1000 °C demonstrate intense oxygen desorption situated in the intermediate temperature range. Total amount of oxygen desorbed in TPD run is ~ 20 monolayers, thus demonstrating fast oxygen migration from the bulk to the surface. In $PrNi_{0.5}Co_{0.5}O_{3-\delta}$ – YDC composites much more intense desorption in the intermediate-temperature range is observed greatly exceeding that in LSFN(C) - GDC and LSM - GDC nanocomposites [2]. This suggests fast diffusion of large fraction of bulk oxygen along the PNC-YDC domains interface. In SSITKA $C^{18}O_2$ experiments all oxygen in samples was

completely exchanged for ^{18}O at the end of the run. Two types of bulk oxygen with tracer diffusion coefficients D_O differing by ~2 orders of magnitude were revealed by detailed modeling of SSITKA data. For perovskites sintered at 1000 °C $D_{fast} \sim 10^{-7}$ cm^2·s^{-1} (~ 10-15 % of all oxygen) and $D_{slow} \sim 10^{-9}$ cm^2·s^{-1} (~ 85-90 % of oxygen) at 700 °C. D_{fast} is comparable with that for LSFC and LSFN and by 4-5 orders of magnitude higher than that for LSM [2]. For composites sintered at 1000 °C $D_{fast} \sim 10^{-6}$ cm^2·s^{-1} (~ 70 % of oxygen) and $D_{slow} \sim 10^{-8}$ cm^2·s^{-1} (~ 30 % of oxygen) at 700 °C. These values of D_{fast} in composites are by 2-3 orders of magnitude higher than that for well-known LSCF-GDC composite [2]. Apparently $Ce_{0.65}Pr_{0.25}Y_{0.1}O_{2-\delta}$ domains in composite (Figure 1) are mainly responsible for their high oxygen mobility in agreement with earlier data for $Ce_{0.45}Pr_{0.55}O_{2-\delta}$ [3].

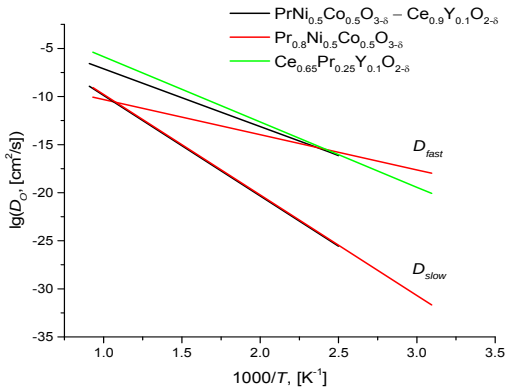

Fig. 1. Temperature dependence of oxygen tracer diffusion coefficients for to $PrNi_{0.5}Co_{0.5}O_{3-\delta}$ – $Ce_{0.9}Y_{0.1}O_{2-\delta}$, $Pr_{0.8}Ni_{0.5}Co_{0.5}O_{3-\delta}$ and $Ce_{0.65}Pr_{0.25}Y_{0.1}O_{2-\delta}$ sintered at 1100 °C

Such a high oxygen mobility in PNC-YDC composite cathodes allowed to obtain power density for anode-supported thin form solid oxide fuel cells up to 420 mW/cm^{2}at 700 ^{o}C [4] which exceeds that for traditional cathode materials.

4 Conclusions

Composites based on $PrNi_{1-x}Co_xO_{3-\delta}$ and doped ceria demonstrate very high lattice oxygen mobility and surface reactivity due to disordering caused by cations redistribution between phases. This allows them to provide promising performance as cathode materials for intermediate temperature SOFC along with a high stability to carbonization due to absence of alkaline-earth dopants.

Production of Hydrogen Enriched Gas by Biogas Reforming over the Multicomponent Co-containing Catalysts

Itkulova S.S.*, Nurmakanov Y.Y., Abdullin A.M., Ospanova A.Z., Imankulova S.A.

D.V. Sokolsky Institute of Organic Catalysis and Electrochemistry, Almaty, Kazakhstan

Keywords: biogas, multicomponent catalysts, hydrogen, dry and steam reforming

1 Introduction

Nowadays, enormous attention is focused on the development of technologies involving renewable sources due to inevitable depletion of fossil fuels. Moreover, fossil fuels are the major producers of greenhouse gases, mostly carbon dioxide. Biogas is considered as a clean and environmental friendly fuel that is produced from anaerobic digestion of biomass, manure etc. Biogas contains mainly of CH_4 and CO_2 and may be associated with traces of other gases such as hydrogen sulphide, ammonia, hydrogen, carbon oxide, nitrogen, oxygen, and water vapor. Content of admixtures depends on a source from which biogas is originated. The technologies for biogas reforming reaction are the same that are used for the natural gas reforming: Steam Reforming (SRM), Dry Reforming (DRM) (eq. 1), Partial Oxidation (POX), Autothermal Reforming of methane or their combination. Reforming of biogas is an attractive way of utilization both greenhouse gases by using DRM or DRM-SRM combination. Also, its exploitation would be advantageous from financial point of view [1, 2]. By DRM syngas with a H_2/CO ratio close to unity is produced, which is useful for Fisher-Tropsch synthesis of long-chain hydrocarbons and oxygenates [3-4]. Adding steam to biogas will provide the production of the additional hydrogen.

$$CH_4 + CO_2 \leftrightarrow 2H_2 + 2CO \qquad \text{(eq. 1)}$$

However, there is still no large-scale application of CO_2 reforming of CH_4 because of absence of efficient and stable to coke deposition catalysts. Carbon dioxide reforming of biogas is endothermic reaction and it requires a high reaction temperature. The major drawback of this process, which occurs at temperatures above 640°C, is the catalyst deactivation [4]. This paper deals with the development of the new Co-containing catalysts modified with rare earth metal and performing the higher selectivity on hydrogen production and resistance to carbon deposition in dry and steam biogas conversion.

2 Experimental/methodology

The polymetallic catalysts containing Co, a noble metal (M_1), and a rare earth element and supported on alumina were prepared. The total content of Co and noble metal in the catalysts was constant and equal to 5 wt.%. The amount of rare earth metal (M_5) was varied from 0.5 to 10 wt. %.

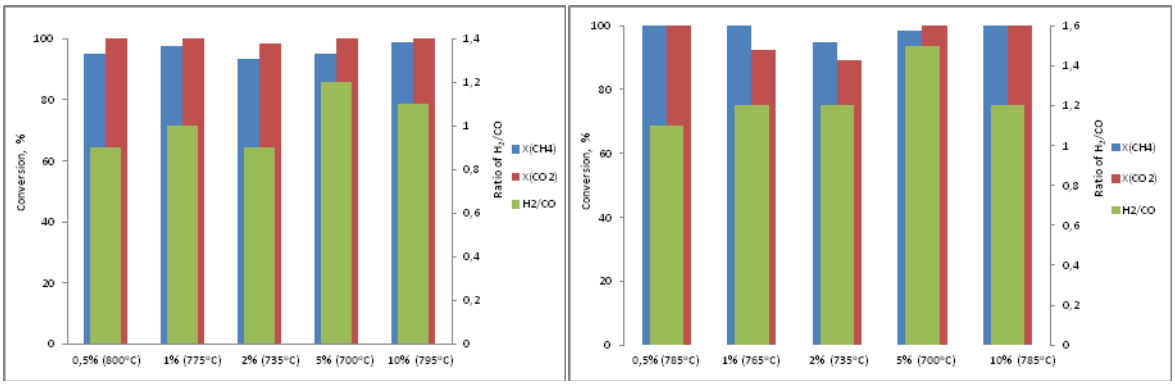
The physicochemical properties of the catalysts were studied using TEM, BET, X-ray and TPR methods.

A model biogas with a ratio of CH_4/CO_2=1 was used. Amount of steam for providing the steam reforming of biogas was varied from 10 to 40 vol.%. The processes were carried out in a laboratory flow quarts reactor supplied with programmed heating and a controlled feeding velocity. The processes were operated under the atmospheric pressure and temperature varied within 300-800°C. The gas hourly space velocity (GHSV) was 1000 hr^{-1}. The initial and final

reaction products were analyzed on-line using the GC's.

3 Results and discussion

The catalysts activity was tested in the dry and steam reforming of biogas. Growing temperature from 300 to 700-800°C is accompanied with increase in biogas conversion from 5 to 95-100% in both processes. The effect of the amount of the rare earth metal on biogas conversion and yield of hydrogen was examined. The comparative data corresponding are presented in Fig.1 for the dry (a) and steam reforming (b) of biogas.



a b

Fig. 1. Comparative characteristics of the 5%(Co-M_1)M_5/Al_2O_3 catalysts in the dry (a) and steam reforming (b)

Syngas with the various ratio of H_2/CO is the only product in both processes. At steam reforming, the biogas is converted with the highest degree in comparison with dry reforming under the same conditions. Also, adding steam to biogas leads to prevailing hydrogen content in syngas formed up to 65% depending on the amount of rare earth metal and conditions.

The catalysts have shown the high stable activity in both dry and steam reforming of biogas. No loss of the 5%(Co-M_1)-5%M_5/Al_2O_3 activity was occurred during 150 hours of its continuous exploitation. No coke formation was observed by TEM.

4 Conclusions

The new multicomponent catalysts based on Co/Al_2O_3 modified with additives of noble and rare earth metals perform the high activity, stability and resistance to coke formation in production of hydrogen enriched gas by steam biogas conversion.

Reuse of Low Value By-Products of a Biodiesel Industry. Esterification/Transesterification over Acid Catalysts

Domingues C.[1], Soares Dias A.P.[1*], Neiva Correia M.J.[1], Carvalho R.[2]

1 - LAETA, IDMEC, CERENA, IST, Universidade de Lisboa, Lisboa, Portugal

Keywords: renewable energy, biodiesel, esterification, acid oils, acid catalysts, VPO

1 Introduction

Today most of the energy is based on fossil fuels, which have a negative impact on the environment and creates a world dependence on crude producers. This dependence on fossil fuels generates worldwide socio-economics instability. The use of biomass is viewed as the most interesting alternative to produce energy with low environmental impacts. Biodiesel produced by alcoholysis of vegetable oils is pointed out as a feasible renewable fuel for diesel engines. In fact the transportation sector is major contributor to the greenhouse gases emissions and it is imperative to find a low carbon fuel for this sector.

The use of low value by-products as raw-materials for biofuels production can contribute with higher reduction of GHG, being one of the major advantages for sustainability of biofuels. However, a common drawback of this type of products for biodiesel is its high acidity that prevents the use of the commonly used alkaline catalysts. Nevertheless, acid heterogeneous catalysts allow the use of these low grade and cheaper oils and also continuous reactors, thus contributing to reduce the operating costs low grade and cheaper oils as raw-materials and continuous reactors thus contributing to reduce the operating costs [1].

2 Experimental/methodology

The esterification/transesterification of oily by-products, from a local biodiesel industry and a semi-refined rapeseed oil was carried out over acid catalysts prepared by a sol-gel like technique. Vanadyl phosphate catalysts (V/P=1 atomic ratio) were prepared using aqueous solutions of ammonium precursors and citric acid as complexation agent. After total evaporation of water at 80 ºC and vigorous stirring the xerogels were dried overnight at 120 ºC. The dried materials were crushed in a pyrex mortar and the powders were calcined for 5h in a muffle at temperatures from 500 ^{o}C to 700 ^{o}C. Details are given elsewhere [2].

The fresh and post reaction catalysts were characterized by XRD and HATR-FTIR in order to evaluates the active phases and species, and the deactivation processes.

The catalytic activity of the prepared materials was evaluated for the methanolysis reaction of semi-refined rapeseed oil and oily by-products from Iberol containing water, fatty acids and FAME. A high pressure stainless steel reactor equipped a mechanical stirrer was used for the reaction batches. For each reaction batch 100g of oil or by-product were mixed with 5g of powdered catalyst and 33 g of methanol. The reaction temperature was kept at 125ºC (6 atm) for 6h. After reaction the catalyst was separated by filtration and the FAME content of the oily liquid fraction was assessed by NIR [3].

The acidity of the raw fats and the esters phases (FAME) was assessed by KOH titration as described elsewhere [4].

3 Results and discussion

The fresh catalysts displayed orange to green shades depending on the calcination temperatures, whereas the post reaction powders showed dark orange/brown shades. These observances seem to indicate different vanadium oxidation states for fresh and post reaction catalysts.

The diffractograms, showing different crystalline phases and crystallinities, and the data on the catalytic behaviour in the Fig.1 underline the important role of calcination on the activity of the prepared catalysts. Additionally data showed that the prepared catalysts are quite active for the transesterification reaction of rapeseed oil even in mild reaction conditions (125ºC and 6 atm). In analogous reaction condition the prepared catalysts were also active for the esterification/transesterification of the acid by-products from the local biodiesel industry (Table 1). Using the same conditions oleic acid was 79% converted into methyl esters. The calcination temperature of the catalysts had a different effect on the transesterification and esterification capabilities (Fig. 2). The recalcination of the deactivated catalysts allows their reuse without significant decay of the activity.

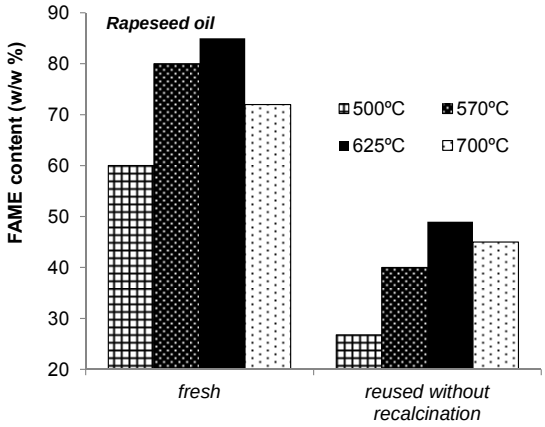

Fig. 1 Effect of the calcination temperature on the catalytic performances (rapeseed oil, 6h, 125ºC).

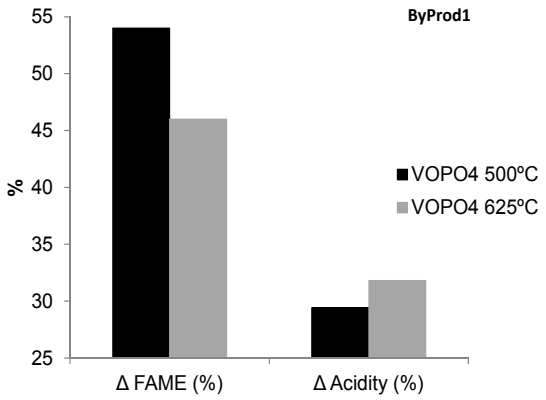

Fig. 2 Transesterification versus esterification activity of catalysts with different calcination temperatures (Byprod1; 6h, 125ºC).

Table 1. Acidity and FAME content of raw fat by-products and after reaction (calc. Temp. 625ºC).

	Raw fat (% w/w)		Esters phases (% w/w)	
	Acidity	**FAME (%)**	**Acidity**	**FAME (%)**
Byprod1	39.3	44.5	9.6	87.0
Byprod2	37.9	46.9	3.2	94.1
Byprod3	25.7	65.9	2.8	95.2

4 Conclusions

High acidity and low value by-products from a biodiesel industry were converted into biodiesel using heterogeneous acid vanadyl phosphate catalysts The non-traditional sol-gel like used technique revealed to be a simply route to synthetize such materials. The calcination temperature displays an important role on the catalytic performances of the prepared VPO materials.

Keywords: carbon oxides methanation, nickel-ceria, cobalt-ceria, iron-ceria

1 Introduction

The selective CO methanation in hydrogen-rich gas mixtures in the presence of CO_2 is a promising way for deep CO removal designed for low-temperature proton-exchanged membrane fuel cell feeding applications, as well as a challenging fundamental problem of substrate-selective hydrogenation. Besides the target CO methanation reaction (1), undesirable CO_2 methanation (2) and reverse water-gas shift (3) reactions may occur, causing considerable hydrogen losses and increasing CO outlet concentration:

$CO+3H_2 = CH_4 + H_2O$; $\Delta H^o = -206$ kJ/mol (1)

$CO_2+4H_2 = CH_4 + 2H_2O$; $\Delta H^o = -165$ kJ/mol (2)

$CO_2 + H_2 = CO + H_2O$; $\Delta H^o = 41$ kJ/mol (3)

In spite of extensive research efforts Ru- and Ni-based systems remain the most active catalysts for CO and CO_2 methanation [1]. At the same time, metals such as Co and Fe are known to be active in carbon oxides hydrogenation reactions, including Fischer-Tropsch synthesis and RWGS, but the properties of Fe and Co-based systems in the selective CO methanation are not studied.

This work reports the results of comparative study of Ni-, Co- and Fe/CeO_2 catalysts, prepared from nitrate and chloride precursors, in the selective CO methanation.

2 Experimental/methodology

Catalysts with metal loading of 10 wt.% were prepared by incipient wetness impregnation of CeO_2 by the water solutions of metal's nitrate (Ni/CeO_2, Co/CeO_2, Fe/CeO_2) and chloride (Ni(Cl)/CeO_2, Co(Cl)/CeO_2, Fe(Cl)/CeO_2) salts. They were characterized by BET, XRD, TEM, EDX, XPS, FTIR and CO chemisorption techniques. Selective CO methanation was studied in a flow reactor at atmospheric pressure in the temperature interval 180 − 360 °C, at WHSV = 29 000 $cm^3g^{-1}h^{-1}$ and feed gas composition (vol.%): 1.0 CO, 20 CO_2, 10 H_2O, 65 H_2 and He-balance.

3 Results and discussion

Fig. 1 represents the temperature dependencies of the CO and CH_4 outlet concentrations in selective CO methanation for all studied catalysts. It is seen, that Fe-based and Co(Cl)/CeO_2 catalysts were inactive in CO and CO_2 methanation reactions. Ni/CeO_2 and Co/CeO_2 catalysts were active in both CO and CO_2 methanation, but showed low selectivity. Ni(Cl)/CeO_2 catalyst showed the best performance in selective CO methanation, being less active than Ni/CeO_2 and Co/CeO_2, but considerably more selective.

XRD, TEM and EDX analysis showed the presence of chlorine on the surface of Ni(Cl)/CeO_2, even the CeOCl particles (Table 1). Thus the observed differences in catalytic behavior of Ni-based catalysts could be associated with chlorine influence.

The TOFs calculated for Ni/CeO_2 and Ni(Cl)/CeO_2 catalysts at 210 °C (at this temperature

CO conversion was < 15 % and CO methatation selectivity was 100 %) were similar (Table 1). These data mean, that Ni/CeO_2 and $Ni(Cl)/CeO_2$ catalysts exhibited similar activity in CO methanation. In other words, the presence of chlorine does not significantly influence on the CO methanation activity, but it dramatically inhibits the CO_2 hydrogenation activity, thereby promoting catalyst selectivity.

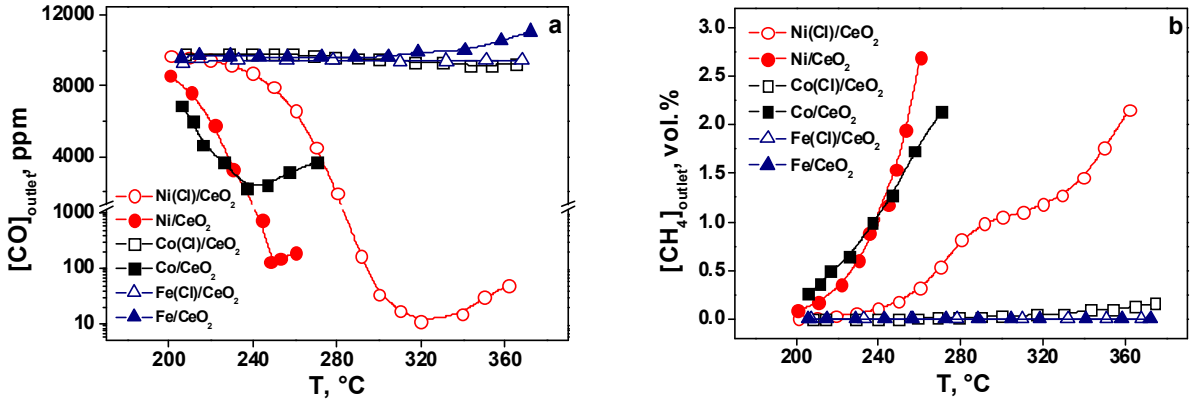

Fig. 1. The temperature dependencies of the CO (a) and CH_4 (b) outlet concentrations for the selective CO methanation over the studied catalysts. Feed gas composition (vol. %): 1.0 CO, 65 H_2, 10 H_2O, 20 CO_2 with He as balance. WHSV: 29 000 $cm^3g^{-1}h^{-1}$.

Table 1. Ni-based catalyst's characterization.

Catalyst	Phases	X[a], wt.%	D_{XRD}[b], nm	D_M[c], nm	TOF×10^3, s^{-1}
CeO_2	CeO_2	100	9	–	–
Ni/CeO_2	Ni	4	10	13	5.0
	CeO_2	96	9		
$Ni(Cl)/CeO_2$	Ni	10	>100	120	4.0
	CeOCl	48	9.5		
	CeO_2	42	19		

[a]Phase mass fraction according to the XRD analysis; [b]Average particle size determined by the XRD analysis; [c]Average size of metal particles according to the pulse CO chemisorption data.

Based on the data obtained, the nature of the active centers, origin of the observed activity order and probable mechanisms of CO and CO_2 methanation over Ni/CeO_2 and $Ni(Cl)/CeO_2$ catalysts are discussed.

4 Conclusions

Catalytic properties of Ni-, Co- and Fe/CeO_2 catalysts, prepared from nitrate and chloride precursors, in the selective CO methanation were studied. The $Ni(Cl)/CeO_2$ catalyst, prepared from $NiCl_2$ precursor, was the most efficient. This phenomenon could be explained by ceria surface blocking by chlorine species and appropriate inhibition of CO_2 hydrogenation activity.

Steady State and Dynamic Performance Analysis of OSR and Serial OSR-PROX Reactors

Başar M.S., Aksoylu A.E.*

Boğaziçi University, Department of Chemical Engineering, Istanbul, Turkey

* aksoylu@boun.edu.tr

Keywords: fuel processor, hydrogen production, oxidative steam reforming, preferential oxidation

1 Introduction

The release of large amounts of greenhouse gases through the combustion of fossil fuels has forced the researchers to develop efficient and easy-to-use decentralized power production systems in the range of 2-5 kW. By combining fuel processor (FP) and fuel cell (PEMFC) systems in small stationary units, like houses and small scale businesses, CO-free H_2 necessary for PEMFCs is produced from hydrocarbons, like CH_4, C_3H_8, LPG, etc., by FP. In the current study, a lab scale FP prototype was designed, constructed, and used in analyzing steady state and dynamic performances of individual C_3H_8 oxidative steam reforming (OSR) reactor, and serial OSR and preferential oxidation (PROX) reactors utilizing novel Pt-Ni/δ-Al_2O_3 [1] and Pt-Sn/AC [2] catalysts, respectively. The experiments have been conducted for different OSR feed compositions and reactor temperature combinations, which were determined by experimental design, and for the presence and absence of additional O_2 stream fed to the PROX reactor.

2 Experimental

The system consists of a feed section having mass flow controllers for inlet gases, an HPLC pump for water feed, a mixing zone; a reaction section having up to three vertical cylindrical ovens, which are placed inside a main oven. Temperature of each oven is controlled individually by a programmable temperature controller. The analysis section includes a Hiden Analytical HPR-20 QIC Mass Spectrometer equipped with a Faraday/SEM detector and 8-way manifold/diverter system. The bimetallic 0.2wt.%Pt-10wt.%Ni/δ-Al_2O_3 OSR and 1wt.%Pt-0.25wt.%Sn/AC PROX catalysts were prepared by sequential impregnation. 150 mg and 250 mg of fresh catalysts were placed into the OSR and PROX reactors, respectively, and were freshly reduced *in situ* prior to the tests. The experiments were conducted in the temperature range of 623-743 K in OSR unit and 380-423 K in PROX unit. After the steady state was reached for the initial OSR feed composition, step changes were applied to either C_3H_8, O_2 or H_2O flow rate, or to the O_2 flow rate at the inlet of the PROX reactor. C_3H_8, O_2 and H_2O flow rates were kept in the ranges of 5.1-7.3 ml/min, 7.3-10.3 ml/min and 44.7-59.6 ml/min, respectively. Helium was used as a balance for keeping the total feed flow fixed at 100 ml/min.

3 Results and discussion

In OSR performance tests, first, the composition of the OSR outlet was determined at steady state for the original feed; then, a positive or negative step change was given to one of the concentrations of the OSR reactants, and the transient concentration profiles for each product were determined on-line-real-time; finally, the steady state product concentrations were determined for each step change. Increasing O_2 concentration by applying a positive step (C/O_2: 2.7 → 1.9) in the feed stream resulted in increased steady state H_2, CO_2 and CO concentrations and decreased CH_4 concentration, which is an indicator of increased total oxidation and suppressed CO_2- and/or CO-methanation reactions, as given in Figure 1. Opposite trends were observed for the negative step (C/O_2: 1.9 → 2.4) applied to O_2 concentration in the feed stream.

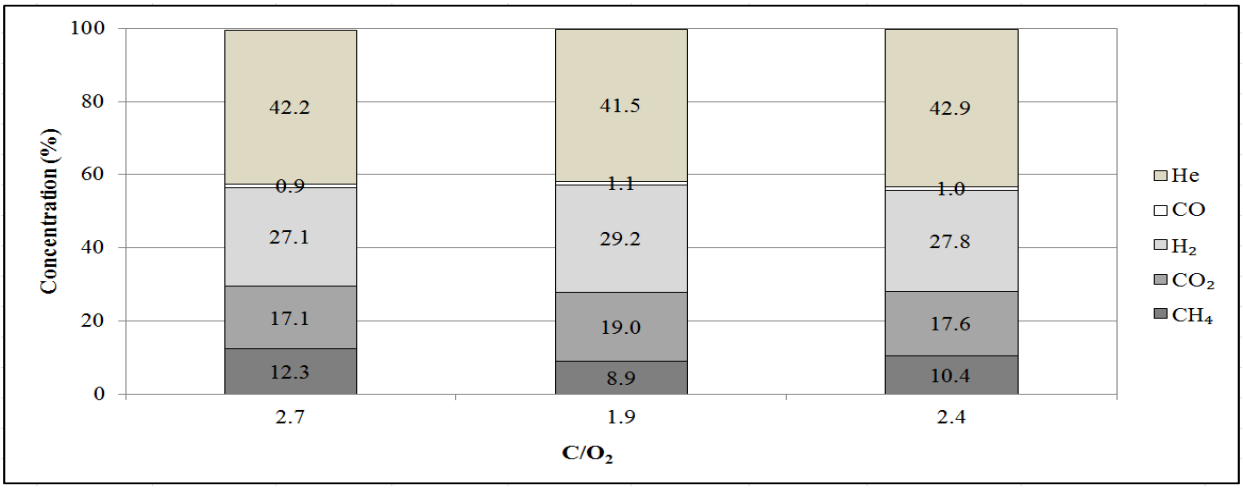

Fig. 1. Steady state concentrations of H_2, CO_2, CH_4 and CO gases at the OSR outlet at 723 K for (+) and (-) steps applied to O_2 concentration in the feed stream of OSR.

In serial OSR-PROX tests, feeding an additional O_2 stream clearly increased H_2/CO product ratio, since rate of CO oxidation reaction was greater than the rate of H_2 oxidation side reaction in the PROX reactor, as given in Figure 2. H_2/CO product ratio reached ca. 50 under the presence of 4 ml/min additional O_2 to the PROX reactor.

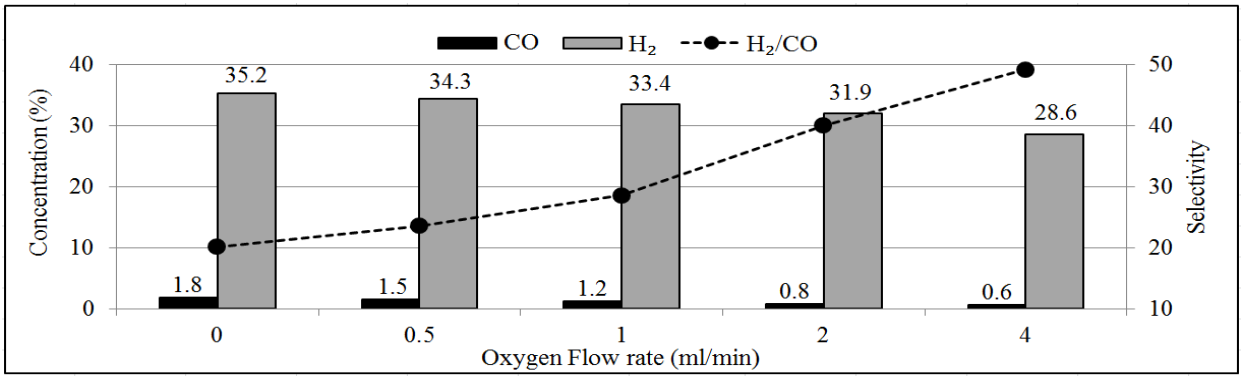

Fig. 2. Steady state concentrations of H_2 and CO, and H_2/CO ratio at the PROX outlet as a function of additional O_2 flow rates to the PROX reactor for 723 K-383 K OSR-PROX temperature combination.

4 Conclusions

Owing to the HT-WGS activity of the OSR catalyst, CO concentrations as low as 1% at the exit of OSR and 0.1% at the exit of the serial OSR-PROX system were achieved when C_3H_8 conversion in the OSR reactor was a 100%. Results confirmed the beneficial effect of O_2 addition to the PROX reactor on selectivity.

Keywords: hydrogen, reforming structured catalysts process, intensification

1 Introduction

The depletion of fossil fuels and the growing energy demand of the recent years shifted research attention toward alternative energy sources. Between them, hydrogen–fuel cells combination attracts the greatest interest in scientific research and technology innovation for hydrogen production intensification. Despite the amazing target to exploit renewable sources for energy, hydrogen production by fossil fuels reforming still remain the most viable solution in a transition phase toward an hydrogen based economy. Actually, the main technique to produce hydrogen is methane steam reforming (SR), a catalytic endothermic process in which the hydrocarbon reacts with steam to produce hydrogen and carbon monoxide. Due to its endothermicity, very high reaction temperature and heat flux towards the reaction system are required to achieve high methane conversion [1]. In the process intensification direction; the combination of these requirements up to now results the main limiting step of the process. Previous studies demonstrated that high thermal conductivity supports (foams, honeycomb monoliths) allow a flatter thermal profile along the catalytic bed, so resulting in a higher average temperature at the outlet section of the catalytic bed, and consequently in higher hydrocarbon conversion [2]. Furthermore, the highly conductive supports helps to flat the radial temperature profile, so reducing hot-spot phenomena, and mainly minimizing the heat transfer resistance from the heating medium to the catalytic volume. Moreover, the use of structured catalysis allows to reduce pressure drops and to minimize mass transfer limitation in the catalytic volume. In this aim, the thermal advantages achieved by using highly thermal conductive honeycomb monoliths as catalytic support may be further enhanced by forcing the flux to cross the monolithic walls. In this aim the use of Wall-Flow monoliths appear a viable solution towards the methane steam reforming intensification [3].

2 Experimental

Structured catalysts were prepared by starting from Silicon Carbide (SiC) porous walls monoliths (Pirelli Eco-technology, 150 cpsi), activated by nickel. Several aspects were investigated in this work: the nickel loading, the effect of a preliminary CeO2 based slurry deposition on the support, and the flux geometry. The Ni loaded SiC monolith was prepared by repeated impregnation phases in 1M nickel acetate solution ($C_4H_6O4Ni\text{-}4H_2O$), drying (120°C, 30min) and calcination (600°C, 2hr), in order to obtain a Ni loading of 30%wt. This procedure allows realizing a uniform and homogeneous distribution of the nickel oxide on the monolith walls and inside the porosity. For the washcoated samples, the support was preliminarily dipped in a CeO2 based slurry (2:1wt ceria : pseudo-bohemite) several times (dipping-drying-calcination cycles) up to reach a washcoat loading of 20%wt; then Ni was deposed by the impregnation steps reported above up to reach a Ni loading of 20%wt. Finally, some samples were converted in Wall-Flow configuration, by alternately plugging channels in the inlet and outlet sections, so forcing the process gas to cross the porous walls. The prepared samples were characterized by X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDAX), Surface area evaluation (BET)

and Hg penetration porosimetry.

The experimental tests were carried out in a tubular lab scale catalytic reactor in isothermal conditions. The activity tests were performed on the catalytic monoliths in the Flow-Through (FT) and Wall Flow (WF) configurations, by varying reaction temperature and GHSV (Q/V_{cat}) values.

3 Results and discussion

XRD analysis showed that the increase in the Ni load results in the increase of the characteristic NiO signals. SEM and EDAX images proved a uniform distribution of the active species and the washcoat (if present) over the SiC surface, thus confirming the effectiveness of the preparation procedure. Moreover, the porosimetric analyses confirmed that slurry was deposed inside the pores, as the mean pores diameter was reduced. The activity tests results, summarized in Figure 1, highlighted the better performances of the WF configuration than the FT, in terms of hydrogen yields and methane conversion. The WF configuration enhancement was more evident in the more extreme conditions, at the lowest operating temperatures and at highest reactants flow rate. The same behaviour was observed in the washcoated samples, since a marked improvement in catalytic performances was observed by using the WF configuration. Moreover, the comparison between hydrogen production on non-washcoated and washcoated samples confirmed the strong role of ceria on the steam reforming reaction trend: the oxygen-storage capacity, proper to the cerium oxide, accelerates the migration of oxygen from steam to the carbon [4], so resulting in a clear increasing in catalytic system performances.

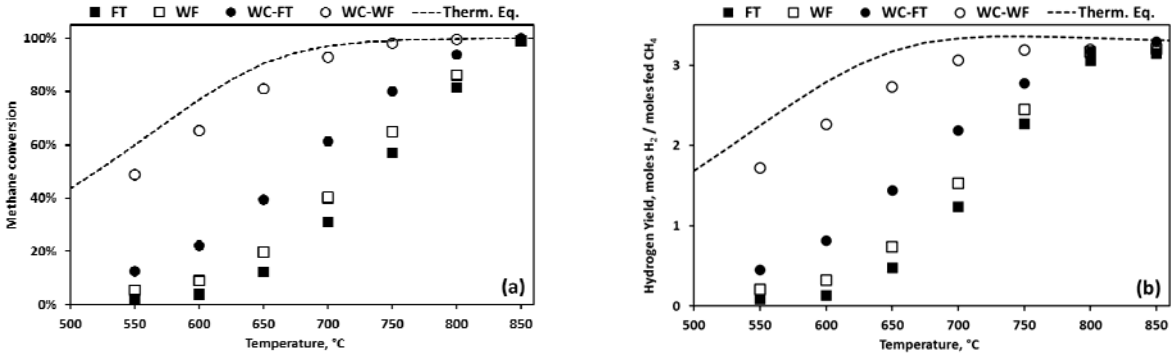

Fig. 1. Methane conversion (a) and Hydrogen yield for prepared samples tests

4 Conclusions

Specific experimental tests were carried out in order to evaluate the influence of flux geometry of Nickel based monolithic catalyst on methane SR reaction. The activity tests highlighted the improvements due to the WF configuration with respect to the FT, in terms of hydrogen yields. By forcing as to cross the monolith catalytic porous walls, heat and mass transfer mechanisms between gas and solid phases were enhanced, so resulting in faster reaction kinetics. The role of ceria as catalytic support was also investigated, highlighting that the Ni-CeO_2 interactions and the OSC properties linked to the ceria clearly improves catalyst performances.

Structured Pt(2%)/CeO_2/Al_2O_3 WGS Catalyst Design: Introduction of Buffer Layer

Gonzalez Castaño M., Ivanova S., Centeno M.A., Odriozola J.A.*

Instituto de Ciencia de Materiales de Sevilla (IMCSE), Centro Mixto US/CSIC, Sevilla, España

* odrio@us.es

Keywords: water gas shift, Pt(2%)/CeO_2/Al_2O_3, micromonolith, buffer layer

1 Introduction

The WGS reaction ($CO + H_2O \rightleftharpoons CO_2 + H_2$) is moderately exothermic, equilibrium limited and characterized by high contact times needed to achieve good CO conversions [1]. The implementation of WGS units, in real and portable devices for hydrogen production and purification, involves a significant volume reactor diminution, onlybe achieved by the use of structured microreactors. In this context, the metallic micromonoliths are interesting candidates by allowing operation at higher space velocities, allowing the process intensification by a decrement of the reactor volumes, as well as, more efficient control of the reaction temperature due to improved heat and mass transport [2].

Noble metals, in particular Pt based catalysts, supported on reducible oxides have been described as very active WGS systems [3]. For these catalysts, two WGS mechanisms have been proposed: redox and associative mechanism. No matter the mechanism, water molecules should be activated prior the reaction, being a water dissociation a key step in WGS reaction [4]. The water activation is normally related the oxygen defect concentration on the surface of the catalyst, e.g. vacancies.

The aim of this study is to develop more efficient structured catalysts for the Water Gas Shift (WGS) reaction by improving the number of water activation sites. For this, a buffer layer is introduced to increase the active sites able to dissociate the water molecules. Different amounts of Pt(2%)/CeO_2/were deposited on metallic micromonoliths, characterized and tested in diverse reaction conditions. The prepared bilayer micromonoliths were constituted by: i) a CeO_2/Al_2O_3 layer as a buffer layer and ii) (Pt(2%)/CeO_2/Al_2O_3) as catalyst layer. The total amount of deposited catalyst was maintained constant meanwhile the amount of buffer was varied.

2 Experimental

The platinum was deposited on commercial CeO_2/Al_2O_3 (Sasol) by wetness impregnation using tetrammineplatinum (II) Nitrate Solution (Johnson Matthey) as precursor. The solid was calcined at 350°C during 8h with 5°C/min heating ramp. The buffer layer was composed by the same CeO_2/Al_2O_3 employed for the catalyst preparation.

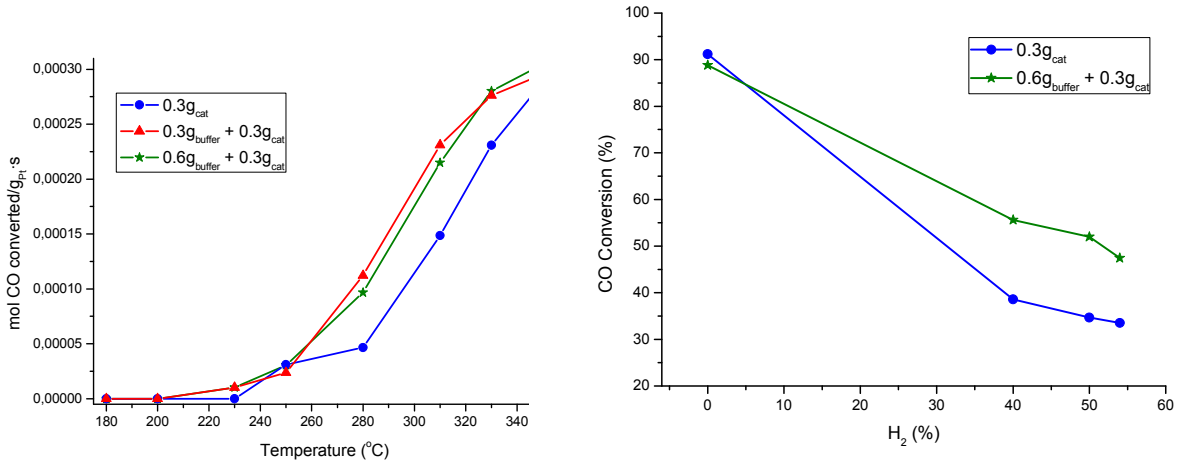
The catalysts were deposited on ferritic stainless steel micromonoliths by washcoating. Two different suspensions were prepared: the buffer and the catalysts one. In order to achieve homogeneous and well-fixed catalyst layer, the rheological properties of the suspensions were adequate. The micromonoliths were calcined after each layer deposition at 450 °C and 350 °C for buffer and catalyst layer respectively. The catalytic activity was tested at 4000h^{-1} in hydrogen production conditions (4.5%CO+30%H_2O) and in clean-up conditions (7%CO+9%CO_2+30%H_2O+50%H_2) labeled respectively, model and real mixture.

3 Results and discussion

The buffer presence in the structured catalysts influences in different ways the catalyst

behavior depending on the reaction conditions probably due to the higher oxygen vacancies introduced in the buffer layer. While in model conditions the CO conversion declines, in real conditions an improved catalytic performance was observed (Fig. 1a). Moreover, the buffer layer thickness does not significant influences the catalytic performances in any reaction conditions tested. Considering the main compositional differences between the "model" and the "real" mixture, H_2 and CO_2 presence, the variation of those components was evaluated. While no significant changes are observed with the $\%CO_2$ variation, the benefit offered by the buffer incorporation in H_2 presence becomes more evident (Fig. 2a). The CO conversion decrement exhibited when H_2 is incorporated to the feed stream, expected because of the WGS equilibrium, is lowered with buffer layer presences. It should be noted that ceria based catalyst deactivation effects are related to ceria over-reduction and/or to stable carbonaceous species formation, blocking active sites. Hence, the benefit offered by the buffer layer could be related with an extra resistance achieved versus the deactivation effects happened in real mixture due to the H_2 presence.

Fig. 1. a) Catalytic activity in real mixture; b) Effect of $\%H_2$ variations on the feed stream at 310°C.



4 Conclusions

In H2 presence, the buffer layer incorporation enhances the catalytic performance probably due to the higher oxygen vacancies concentration for the water activation. The bilayer configuration is able to keep higher oxygen vacancies concentration available to activate water molecules leading to improved catalytic behaviours. It could be suggested that the buffer layer provides to the micromonolith an attenuation of the overreduction rate and hence, to carbonaceous species deactivation. In this way, the water molecules keep finding sites to be dissociated and this result on the observed increment of the catalytic performance in real conditions. Therefore, a bilayer structured catalytic system able to increase the activity and stability of the micromonolithic structures was achieved.

Synthesis and Characterization of CuO-ZnO-Al_2O_3 with Protonated Beta or Y-Typed Zeolite Supporter for Dimethyl Ester Production

Lin K.-S.*, Chiang C.L., Adhikari A.K., Chuang H.-W.

Department of Chemical Engineering and Materials Science/Environmental Technology Research Center, Yuan Ze University, Chung-Li City, Taiwan

Keywords: dimethyl ester, carbon dioxide, CuO-ZnO-Al_2O_3, nanocatalyst, Beta/Y-type zeolites, ultrasonic treatment, XANES/EXAFS

1 Introduction

Carbon dioxide is one of the green house gases (GHGs) that have caused climate change significantly [1]. To reduce the affect of GHGs on the climate, several solutions have been proposed: improve the energy utilization efficiencies, introduce the alternative energies, capture/storage the CO_2, and convert the CO_2 to valuable chemicals [2,3]. Among the solutions, conversion of CO_2 is the most favorite method, because it can create profit by using CO_2 as a feedback to produce various valuable hydrocarbon fuels (e.g. dimethyl ester, DME). Due to the thermodynamic barriers of CO_2, it needs catalysts to decrease the activation energy and then accelerate the reaction rate during the conversion of CO_2 to other chemicals. The copper-based catalysts (e.g. CuO-ZnO-Al_2O_3, CZA) are the most popular commercial catalyst for the conversion of CO_2 to DME by reason of its cheap price and unique redox property [4]. The conversion reactions between CO_2 and DME are multistage that include methanol hydration ($CO+2H_2 \rightarrow CH_3OH$), methanol dehydration ($2CH_3OH \rightarrow CH_3OCH_3$ (DME) $+H_2O$), and water-gas shift (WGS, side-reaction, $CO+H_2O \rightarrow H_2+CO_2$). In this study, protonated beta (HBZ) and Y-Type zeolites (HYZ) were adopted as catalytic supporters to offer well-defined structure, and maximize the contact between methanol synthesis/dehydration sites in CZA catalyst.

2 Experimental

The syntheses of CZA/HBZ and CZA/HYZ were a two-stage procedure including co-precipitation and ultrasound treatment. Activated phase of CZA was prepared via co-precipitation method firstly. The aqueous solutions (1 M) of copper, zinc, aluminum nitrite hydrates ($[Cu^{2+}]$: $[Zn^{2+}]$: $[Al^{3+}]$=6:3:1), and sodium carbonate were made in advance for co-precipitation treatment. Sodium carbonate solution added into the metal nitrite solution slowly for co-precipitation of CZA until pH=7±0.2 with T=70°C for 1 h. Solid activated CZA was prepared after filtration, washing, drying (110°C, 12 h), and calcination (350°C, 5 h). Secondly, CZA slurry mixed with beta or Y-type zeolitic supporter (CZA: supporter=1:2 wt/wt) via ultrasound treatment with 90 W for 45 min. After drying and calcination, the nanocatalysts, CZA/HBZ and CZA/HYZ were synthesized successfully.

3 Results and discussion

The combination of activated CZA and zeolitic supporters provided new crystal phases of CZA/HBZ and CZA/HYZ, which were confirmed and observed by their characteristic signals in XRD patterns and FE-SEM micro-images respectively in Figure 1. Redox mechanisms of copper in nanocatalysts were investigated by H_2-TPR profile in Figure 2(a). Three reductive peaks appeared from low to high temperatures that meant the formation of CuH (α), interaction of Cu-Al (β), and reduction of bulk CuO particles (γ). Decreases of γ-reductive temperatures of CZA/HBZ and CZA/HYZ that were contributed from well-dispersion of copper in beta (-40.7°C) and Y-type (-47.0°C) zeolites were displayed in Table 1. XANES and EXAFS spectra of CZA/HBZ and CZA/HYZ nanocatalysts revealed the oxidation states of copper (Cu^{2+}) and bond distances of Cu-O (~1.95 Å) in Figure 2(b) and (c), respectively. The introduce of zeolitic supporters shrunk the bond

distances of Cu-O (R), and diminished the particle sizes of bulk CuO that caused the copper well-dispersed inside CZA/HBZ and CZA/HYZ nanocatalysts.

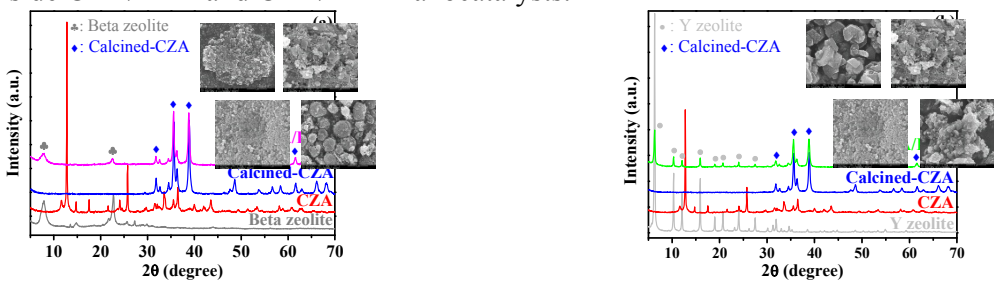

Fig. 1. XRD patterns/FE-SEM micro-images of (a) CZA/HBZ and (b) CZA/HYZ and supporters.

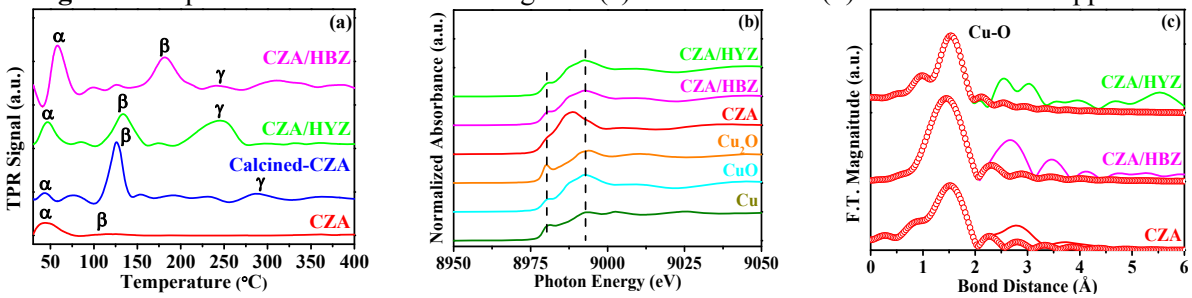

Fig. 2. (a) H_2-TPR profile, (b)XANES, and (c) EXAFS spectra of CZA/HBZ, CZA/HYZ and supporters (The best fitting curves were shown in colourful circle lines).

Table 1. H_2-TPR reductive temperature of CZA, calcined-CZA, CZA/HYZ, and CZA/HBZ.

	Reductive Temperature of Peaks (oC)		
	α	β	γ
CZA	44.2	115.5	Not available
Calcined-CZA	43.6	125.7	288.0
CZA/HYZ	46.7	134.0	247.3
CZA/HBZ	58.2	181.8	241.0

Table 2. Fine structures of CZA, CZA/HBZ and CZA/HYZ nanocatalysts.

Catalyst	Shell	CN (±0.05 Å)[a]	R (±0.02 Å)[b]	$\Delta\sigma^2$ (Å^2)[c]	R-Factor
CZA	Cu-O	2.232	1.96103	0.00175	0.00052
CZA/HBZ	Cu-O	1.470	1.91765	0.00844	0.00132
CZA/HYZ	Cu-O	2.804	1.95745	0.00401	0.00165

Notes: CNa: coordination number; Rb: bonding distance; σc: Debye-Waller factor.

4 Conclusions

Introduction of zeolitic supporters could lead copper well-dispersed in nanocatalysts that were able to overcome the barriers in DME production. Beta/Y-type zeolites as supporters were the great options for the enhancement of commercial copper-based catalysts.

Tar Elimination in Pyrolysis of Sewage Sludge Using HighlyStable Ni/SBA-15 Catalyst

Iro E.*, Hajimirzaee S., Hodgson S., Olea M.

Teesside University, School of Science and Engineering, Middlesbrough, UK

* e.iro@tees.ac.uk

Keywords: tar, Ni/SBA-15 catalyst, catalytic hot gas clean-up unit, dry reforming, catalytic cracking

1 Introduction

Population growth continue to cause a surge in sewage sludge production from waste water treatment plants which is becoming more expensive to dispose and is a major contributor to uncontrolled greenhouse gases emission from landfills and incinerators which sadly, are still the major waste disposal methods in Europe [1]. Interestingly, the high organic matter (about 60 – 70% content) in sewage sludge is fast changing its global perception from an unwanted waste nuisance to a potential sustainable energy and biofuel resource via new thermochemical conversion technologies such as pyrolysis and gasification, which converts the dried sewage sludge to gas with about half the calorific value of natural gas [2], liquid (tar) and solid (char) fractions. By optimising the reactor design and operating conditions, one of the fractions could be adjusted to yield more than the other fractions. In our project, more gas fraction was desired for gas turbine to electricity applications, and so the pyrolysis reactor was operated to produce 55% gas, 16% tar and 29% char. Part of our project task was to develop a catalytic hot gas clean-up unit able to convert all or most of the tar fraction to non-condensable gas fraction to increase the gas produced and eliminate tar which has problematic consequence if present in the gas introduced to any gas turbine. Other impurities in the gas such as solid particles, hydrogen sulphide, hydrogen chloride and nitrogenous compounds removed by other processes are not discussed in this paper [3] .

The aim of this project is to develop a cheap but stable catalyst for tar elimination in the gas upgrading and clean–up process from pyrolysis of sewage sludge to gas turbine applications which could become a more attractive commercial and environmentally friendly option for sewage sludge utilisation.

2 Experimental/methodology

Synthesis of Ni/SBA-15 catalyst

SBA-15 mesoporous silica support was first synthesised by sol-gel method [4]. The complex $[Ni\ (NH_3)]^{2+}$ was then synthesised and by impregnation method at 5°C, dispersed on the prepared SBA-15 mesoporous silica.

Characterisation of Ni/SBA-15 catalyst

The synthesised Ni/SBA-15 catalyst was characterised using Fourier Transformation Infrared spectroscopy (FT-IR), Scanning Electron Microscopy (SEM)/ Energy dispersive X-ray spectroscopy (EDX), X-ray Diffraction spectroscopy (XRD), Transmission Electron Microscopy (TEM) and BET measurements. Catalytic activity, selectivity and catalyst stability was tested using the Hiden CatLab micro reactor operated at atmospheric pressure. Methane at flowrate of 27 ml/min and carbon dioxide at flowrate of 10 ml/min was flown over 35mg of catalyst in a fixed bed reactor and temperature was ramped from room temperature to 850°C. The reaction products were analysed using a quadrupole mass spectrometer. Catalyst life time was tested by passing same flow rate for methane and carbon dioxide over the same amount of catalyst at

500°C for 72 hours.

3 Results and discussion

Figure 1 shows Temperature Programmed Reduction (TPR) of catalyst under hydrogen flow. Figure 2 presents the results of methane decomposition and dry reactions simultaneously taking place. Figure 3 illustrates the results of the catalyst life time test for 72 hours.

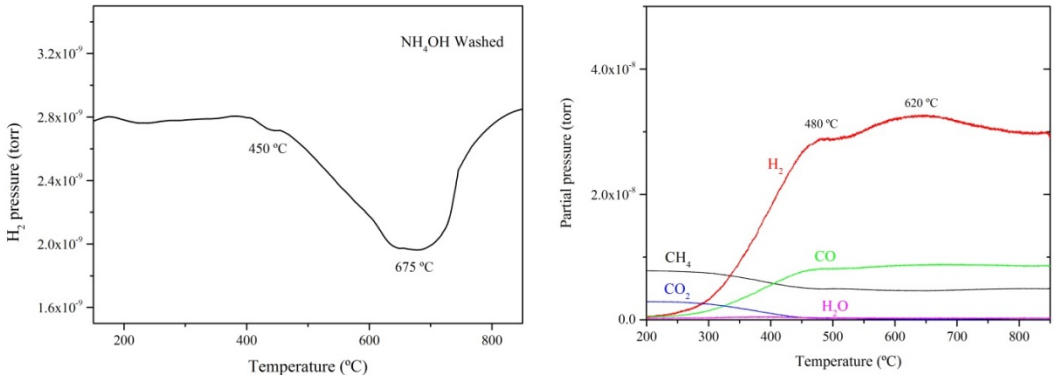

Fig.1. H_2 TPR profile (left) and methane dry reforming over Ni/SBA-15 catalyst (right)

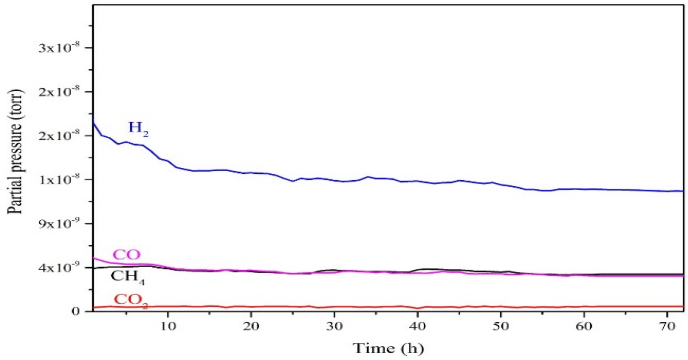

Fig.3. Catalyst life time test

4 Conclusions

Figure 1 shows that the catalyst was well reduced at the higher temperature range, in agreement with XRD and TEM results which confirms well dispersed and strongly attached NiO species on SBA-15 support which has high surface area, large pore size diameter and thick walls for hydrothermal stability which resulted in the high activity, selectivity and stability of the catalyst towards hydrocarbon cracking and reforming reactions. The Ni/SBA-15 catalyst will be scaled-up in pellets to fit into a gas clean-up unit for tar decomposition and methane reforming reactions.

Keywords: hydrogen, water splitting, spinel, oxides, ferrites, TEM and XPS, *in-situ* DRIFTS-MS

1 Introduction

Hydrogen production is presently based on the reforming of natural gas or naphtha. Less energy intensive and more sustainable processes for H_2 production are appealing for both industry and consumer applications. A highly attractive route is steam reforming of bio-alcohols, in principle CO_2 neutral. Costly separation processes can be avoided by splitting the process into two alternated steps (chemical-loop reforming), in the aim of achieving two separate streams of H_2 and CO_x. The principle of the thermochemical-loop cycle is that an oxygen-storage material is first reduced by an ethanol stream, and then reoxidized by water, in order to produce H_2 and restore the original oxidation state of the looping-material. In this work, we report about the reactivity of various spinel ferrites in the production of H_2 from ethanol by chemical-loop reforming.[1,2]

2 Experimental part

The experiments were carried out with mixed ferrites – $CoFe_2O_4$, $MnFe_2O_4$, $Mn_{0.5}Co_{0.5}Fe_2O_4$, $Cu_{0.5}Mn_{0.5}Fe_2O_4$ and $CuFe_2O_4$, prepared by co-precipitation method[1,2]. Characterization techniques used for studying the chemical-physical properties of the materials were: BET, TEM and EDX analysis, XRD, XPS, Raman Spectroscopy and in-situ DRIFTS-MS.

3 Results and Discussion

XRD patterns of all materials showed magnetite-like spinel phases; Mn-based ferrites presented a low crystal size or were in amorphous form. The particle size, morphology and structure of the samples were investigated by TEM. The results indicate that the samples were almost uniform in both morphology and particle size distribution ~2-6 nm (fig.1-A). However, after different duration time of the chemical-loop reforming cycles the materials underwent some morphological changes and were significantly affected by sintered temperature, segregation and coke deposition (fig.1-B,C).

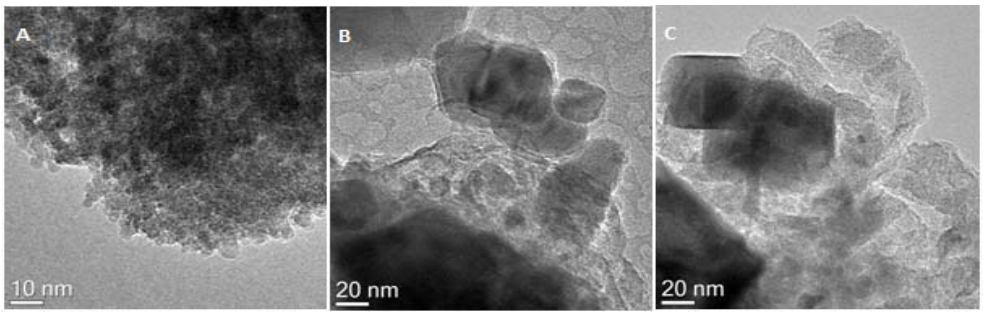

Fig.1. TEM images - $Mn_{0.5}Co_{0.5}Fe_2O_4$: (A) fresh material; (B) 6 min*10 cycles; (C) 20 min*5 cycles

Chosen ferrites were tested in a laboratory-scale plant of chemical-loop ethanol reforming. Average conversion of ethanol during the first reduction step over Mn-ferrites showed the lowest conversion compared to Co- and Cu- ferrites. This might be due to the difference in redox properties of the materials. The study of the second step, the re-oxidation of the reduced spinel with water steam, showed that high yields for hydrogen formation were obtained over chosen mixed ferrites (fig.2). However, the reduction by ethanol led to coke deposition and metal carbides formation. This turned into the generation of CO and CO_2 during the re-oxidation step, because of the gasification of carbonaceous residues. By shortening the time of each step, it was possible to reduce the coke formation during the reduction step and decrease the amount of CO_x formed during the 2nd step of the cycle. A study is in progress on the nature of coke and its mechanism of formation, related with the solid state modifications of the looping materials.

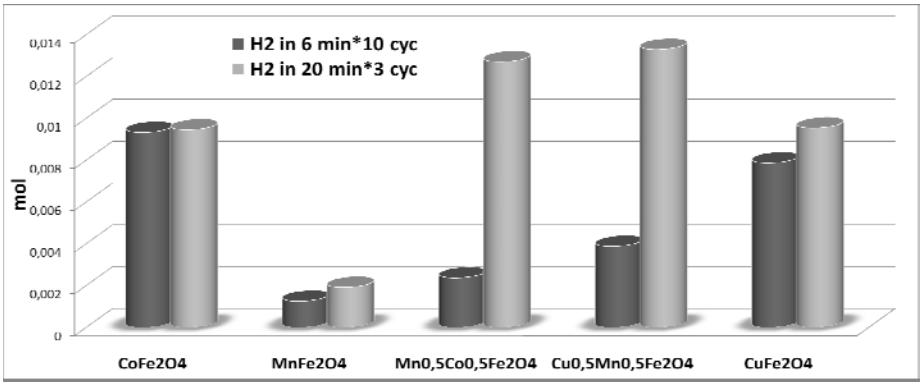

Fig.2. Moles of H_2 obtained by feeding water at 450°C during – 6 min*10 cycles; 20 min*3 cycles

4 Conclusions

The redox properties of mixed ferrites have shown promising features for hydrogen production, which make them suitable to generate hydrogen by oxidation with steam.

The Effect of Zeolite Addition into Cobalt-Based Fischer–Tropsch Catalysts

Sineva L.V.[1,2], Asalieva E.Yu.[1,3], Kulchakovskaya E.V.[1], Mordkovich V.Z.[1,2*]

1 - Department of New Chemical Technologies and Nanomaterials, Technological Institute for Superhard and Novel Carbon Materials, Moscow, Russia

Keywords: Fischer–Tropsch synthesis, composite catalyst, cobalt, zeolite

1 Introduction

Fischer–Tropsch synthesis (FTS) is the main stage of the technology of synthetic oil and high-quality fuel production from carbon containing feedstock (XTL), for example from natural gas or biomass. The interest to the XTL technology is increasing owing to the need to address environmental problems associated with stricter requirements for the quality of motor fuels and the practices of extraction of raw materials for the production of the fuels [1–2].

The products produced by FTS are synthetic fuel, naphtha (flammable, light oil containing various hydrocarbons that are used as feedstock for petrochemicals.), lubricants and more specialized commodities. They are clean burning, almost odorless and biodegradable – qualities that make them environmentally attractive.

Cobalt catalysts for FTS are considered as the most promising ones, because they prevent formation of undesirable aromatics and oxygenates [1–2]. At the present time the supported cobalt systems are the most common in industry and laboratory practice. However, “skeleton” cobalt catalysts represent a possible alternative for the FTS [3].

Since recently zeolite-containing catalysts are considered as promising prototypes for commercial Fischer–Tropsch catalysts due to their sorption selectivity, acidity, porosity and transport properties [4, 5]. Moreover, variations of Si/Al ratio and structural type of zeolite may allow controlling molecular mass distribution of the product, i.e. allow producing light synthetic oil or fuel fractions in the FTS, which is exactly the requirement of the “short-track” XTL. Synthetic crude oil as product of “short-track” XTL represents a mixture of hydrocarbons boiling below 400°C that does not contain sulfur, nitrogen and aromatics.

A number of experimental works are devoted to the synthesis of light synthetic oil or fuel fractions on zeolite-containing Fischer–Tropsch catalysts, using mostly ZSM-5 and Y-type zeolites [4, 6–8]. It is important to note that Beta-type zeolites combine main advantages of both Y-type and ZSM-5 in many respects, especially due to high acidity and large pore size [9]. This is the reason for choosing Beta zeolite as one of the components of the catalysts investigated in this work.

The purpose of this work was to study the effect of Beta zeolite addition into composite skeleton cobalt-based Fischer–Tropsch catalysts.

2 Experimental

The catalysts were produced by the extrusion of paste. Pastes were prepared by the techniques protected by patent [10]. All the paste samples contained 50 wt.% of highly dispersed aluminum metal powder, 30 wt.% of binder (30, 25 or 20 wt.% boehmite and correspondently 0, 5 or 10 wt.% of zeolite Beta in H-form (HB) with SiO_2/Al_2O_3 = 38). Also the paste contained 20 wt. % of highly dispersed skeleton cobalt.

The catalyst was activated in pure hydrogen (3000 h^{-1}) at 400˚C and 0.1 MPa for 1 hr. After

activation the catalyst was heated in a synthesis gas stream at 2 MPa, raising the temperature from 170 to 230˚C. Synthesis gas (molar ratio of $H_2/CO=2$ with 5 vol.% of N_2 as balance and internal reference) was supplied at gas-hour space velocity (GHSV) of 1000 h^{-1} while the temperature was raised and optimized and then GHSV was increased stepwise up to 3000 h^{-1}. Temperature was optimized for every GHSV so that the productivity was maximum possible.

3 Results and discussion

CO conversion, productivity and C_{5+} selectivity increased with zeolite introduction (Fig. 1a). Its content increase led to small but obviously reduction in these indexes.

With the introduction of 5 wt.% HB and growth of its content up to 10 wt.% methane selectivity and yield of CO_2 dropped, but yield of C_2–C_4 hydrocarbons increased (Fig. 1b).

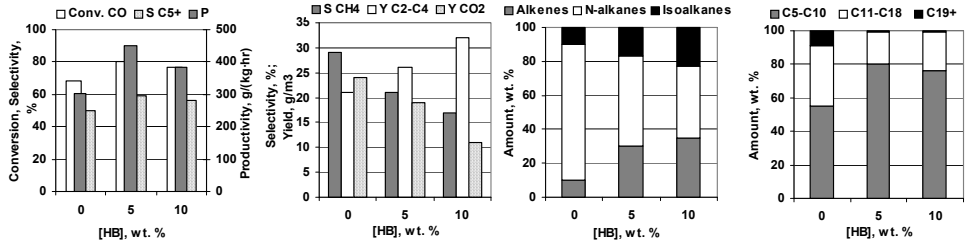

Fig. 1. The effect of the amount of HB on the basic FTS indexes (a), the byproducts formation (b), and C_5a ydrocarbons composition b ınd d). Process conditc s: 2MPa, 235°C, GHSV=d 00 h^{-1}, $H_2/CO = 2$

The composition of product obtained in the presence of the zero-zeolite sample has the highest content of n–paraffins (80%, Fig. 1c). The introduction of zeolite into catalyst and growth of its content led to decrease in content of n–paraffins to 42% at 10 wt.% HB. Content of olefins uniformly increases with stepwise introduction of zeolite from 10% was observed at HB absence to 35% at [HB] = 10 wt.%. The lowest content of iso-paraffins (10%) obtained in the presence of the zero-zeolite catalyst too. The introduction of 10 wt.% zeolite led to a significant increase up to 23%.

The fractional composition of C_{5+} hydrocarbons differed with HB introduction too; this, in the presence of zero-zeolite sample, 55% of the C_5–C_{10} fraction and 36% of the C_{11}–C_{18} fraction and C_{19+} fraction 9% were formed (Fig. 1d). The zeolite addition promoted C_5–C_{10} fraction growth to 80 % due to C_{11}–C_{18} and C_{19+} portions decreasing to 19–23 and 1% correspondently. Its amount increase has led to some decreasing of C_5–C_{10} fraction at the expense of C_{11}–C_{18} growth. This can be explained by the occurrence of bimolecular reactions on the acid sites of the zeolite.

4 Conclusions

Thus, it has been found that the introduction of H-form zeolite into a composite catalyst on skeleton Co basis has a positive effect both on the process parameters and on the composition of FTS products, namely: C_{5+} selectivity and productivity increase, and C_{19+} products are minimized. This is probably due to the processes occurring at acid sites of zeolite, where FTS products can enter various secondary reactions such as cracking, isomerization and bimolecular reactions by carbocation mechanism [4, 6–8, 11].

Keywords: ORR, catalysis, coaxial, pulsed, vacuum, arc

We have developed nano-particles formation system for catalysts by a dry process. By use of a Coaxial pulsed vacuum Arc Plasma Discharge system (CAPD), highly ionized metal plasma can be generated from a target rod without any discharge gases, and deposits on flat substrates or powders to form various catalysts. Here, we investigate the electrocatalytic activity for oxygen reduction reaction (ORR) of our PtC-5% catalyst which is prepared using CAPD, For compression, commercially available PtC-20% and commercially available PtC-5% are also tested. The half-wave potential of our catalyst is higher than those of the others. The currents of four catalysts at 0.80 V, normalized by Pt mass (mass activity) and Pt electrochemically active surface area (ECSA) (specific activity), are also investigated. In both cases, the activity is much higher than those of the others, indicating that nanosized Pt particles prepared by our method can highly improve the utilization efficiency of Pt in electro-reduction of oxygen. The polarization curves are also recorded at different rotation rates. The expected increase of the limiting diffusion current density is observed as a function of the rotation rate. Thecorresponding Koutecky-Levich (K-L) plots show the first-order reaction kinetics toward the dissolved O2 on our catalyst from 0.3 V to 0.6 V. The calculated number of transferred electrons during the reduction of oxygen was between 4.03~4.18, thereby indicating that the ORR from 0.3 V to 0.6 V is dominated by a four-electron (4e-) process and O2 is reduced to OH-.

1 Introduction

This article introduces the nanoparticle formation pulse arc plasma source. This is a kind of dry catalyst manufacturing method where the target platinum is ionized through vacuum pulse arc discharge and is then caused to collide against the carrier. This method has significant advantages. First, platinum corpuscles only several nanometers across can be formed and evenly distributed across the carrier [5-9]. Also, the process is extremely easy to perform. The catalyst material can be easily changed and it is also possible to synthesize a catalyst material. This article introduces the principles of the nanoparticle formation pulse arc plasma source and reports the first attempt to create a platinum support carbon for fuel cells using this device [10, 11] and assess its characteristics. So we have investigated the experiments of oxygen reduction reaction in this paper. We could check this catalyst activity is high by ORR. We have analyzed and investigated this catalyst by using electrochemical analyzer. We report the reason why the activity of catalyst produced by CAPD is high in this paper.

2 Experimental Details

Preparation of Pt catalysts by CAPD: The vacuum chamber in the arc plasma method nanoparticle formation device contains a cylindrical container with a diameter of about 8 cm. Put about 10 to 20 cc carbon black in this container. Rotate the container to churn the powder using the two scrapers that are on the bottom of the container. Irradiate the plasma platinum over the surface of the churning carbon black powder to support platinum nanoparticles. The arc is

pulsed, the discharge time is short (100 to 200 μs) and the current value that flows through the cathode target (support material) is 2,000 to 6,000 A. Therefore, the energy density per unit hour is extremely high. This means that the cathode material condenses, vaporizes, and becomes plasma all at once, and then as atomic ions, collides with the carrier (substrate) at a high speed forming nanoparticle. Oxygen reduction reaction (ORR) measurements. Polarization curves for ORR were carried out with a conventional three-electrode cell was used, including an Ag/AgCl electrode as a reference electrode, a platinum wire as a counter electrode, and a rotation disk electrode (RDE, 2 mm in diameter) modified by catalyst as a working electrode.

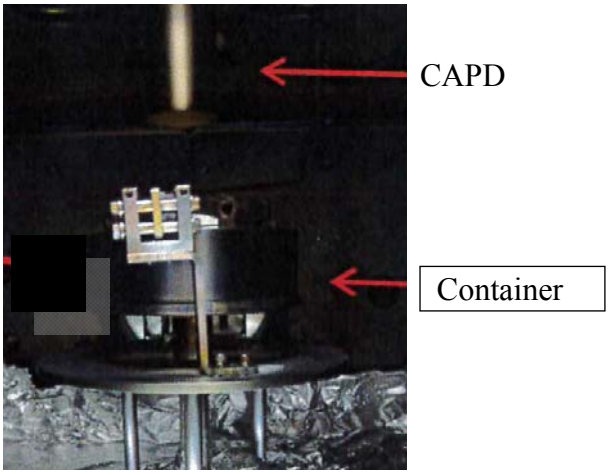

Figure 1. Experimental setup for preparation of Pt/C catalyst by CAPD.[14]

3 Experimental results

We measured a polarization test of Pt/C catalyst to investigate the performance of ORR. Measurement of Pt/C catalyst used the Pt/C-5wt% formed in CAPD,available commercially Pt/C5wt% and Pt/C20wt%. We changed the rotating speed of the rotationg disk and measured polarization characteristic to measure ORR electron-transfer pathway. A figure of (Koutecky-Levich K-L) plots was made from the above-mentioned polarization characteristic. Electron-transfer pathway of this Pt/C catalyst was 3.88 from the inclination of this figure. This result indicates hat our PtC sample catalyzes the ORR mainly through a four-electron process.

4 Conclusion

Surface area per unit of Pt/C catalyst generated by CAPD is almost same as surface area per 1g of commercially available Pt catalyst. But, the value of electron-transfer pathway of the Pt/C catalyst formed in CAPD is 3.88. In this result shows that this process is almost all four-electron reduction.

The Use of Heteropolyanions and Chelating Agents for Designing TMS Catalysts for Hydroprocessing of Oil Cuts and Residues

Nikulshin P.*, Pimerzin A.

Samara State Technical University, Samara, Russia

* p.a.nikulshin@gmail.com

Keywords: hydroprocessing, heteropolyanion, CoMoS, KCoMoS, NiWS, ULSD

1 Introduction

Stricter environmental requirements for commercial oil products, as well as the need to expand the resources for their production stimulate the development of new high-effective hydrotreating (HDT) catalysts. The report presents the results of the research and development of new hydrotreating catalysts for hydroprocessing of various hydrocarbon raw feeds (FCC gasoline, diesel cuts, and vacuum gas oil (VGO).

2 Experimental

Catalysts were synthesized using the following precursors: (i) the $[Co_2Mo_{10}O_{38}H_4]^{6-}$ and cobalt complexes with chelating agents Co(*Chel*)-$Co_2Mo_{10}S/Al_2O_3$, where *Chel* were NTA, EDTA, citric acid (CA), tartaric acid with *Chel*/Co ratio equal to 1:1 [1]; (ii) the Keggin type heteropolyacid $H_3PMo_{12}O_{40}$ with cobalt citrate and potassium hydroxide; (iii) the $H_3PW_{12}O_{40}$ and nickel citrate.

Catalysts were prepared by wet impregnation of the alumina with water solutions of active components with moisture capacity control. Then the samples were dried at 120 ^{0}C (8 h) and sulfided. The prepared samples were studied by N_2 adsorption, Raman spectroscopy, XRD, HRTEM, H_2-TPR and XPS methods. Catalytic properties of the catalysts were determined in model reactions in a fixed-bed microreactor in a high-pressure flow system: (i) thiophene HDS; (ii) *n*-hexene-1 HYD, (iii) 4,6-DMDBT HDS; (iv) benzene HYD; (v) naphthalene HYD; (vi) quinoline HDN. Reaction products were identified by matching retention times with commercially available standards, as well as by GC/MS analysis using Finnigan Trace DSQ equipment. We also evaluated catalytic behavior of the prepared catalysts in a bench-scale flow reactor unit during HDT of diesel fractions (straight run gas oil, their mixture with light cycle oil, light coker gas oil), FCC gasolines and VGO.

3 Results and discussion

The CoMoS active phase was formed more selectively when using Co_2Mo_{10}HPA and Co-chelate complexes simultaneously during catalyst preparation [2]. Adding the Co-chelate significantly changed the active phase morphology due to the different interactions between the precursors and carrier surfaces in each catalyst. The catalytic activities of the Co_3[*Chel*]-Co_2Mo_{10}/Al_2O_3 samples depended strongly on the *Chel*. The CA-containing catalyst showed the highest HDS and HYD activities and the best selectivity factor.

Some structure-activity relationships were found in the HDS and HYD reactions (Figs. 1 and 2). A size effect that depended on an S-organic molecule was observed. During HDS of DBT and 4,6-DMDBT, the TOF values decreased with the grow of the particles of active phase. In HDS of DBT-derived molecules over a multi-slab CoMoS active phase, the average length of the CoMoS phase and the promoter ratio strongly affect the catalytic activity.

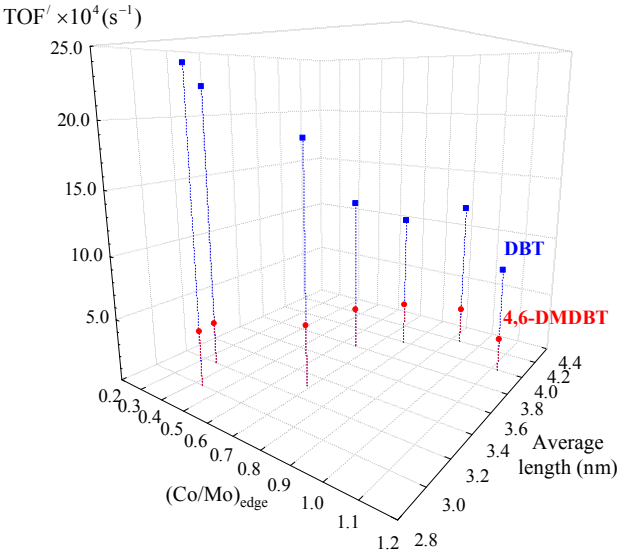

Fig. 1. 3D dependences of TOF/ number in HDS of DBT and 4,6-DMDBT over $CoMo/Al_2O_3$ catalysts on average length of CoMoS phase and $(Co/Mo)_{edge}$ ratio

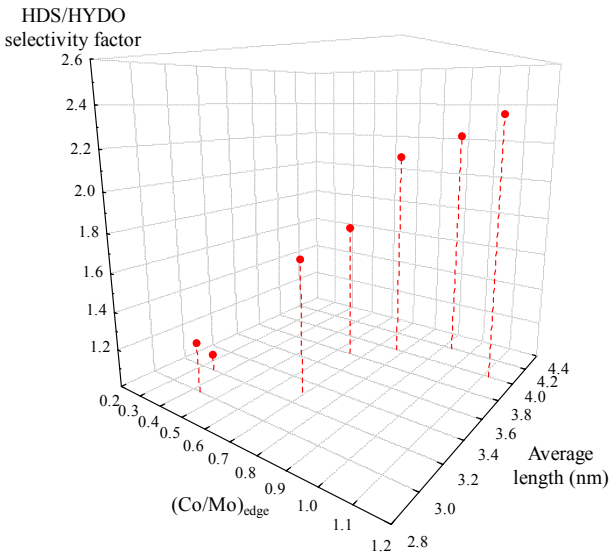

Fig. 2. 3D dependence of selectivity factor of $CoMo/Al_2O_3$ catalysts in the HDT of a mixture of thiophene and *n*-hexene-1 on average length of CoMoS phase and Co/Mo edge ratio in the CoMoS edges

The HDS/HYDO selectivities linearly depended on the number of CoMo sites on the slab edges. The selectivity increased as the average length of the active phase and the $(Co/Mo)_{edge}$ ratio increased. Further improvements in the HDS/HYDO selectivity was achieved by modifying the active CoMoS phase with the largest $(Co/Mo)_{edge}$ ratio of alkali metals. Promoting catalysts with potassium led to the partial poisoning of both types of the active sites and increased selectivity factor 4 times.

Optimization of the size and Ni/Mo(W) ratio in NiMo(W)S active phase species allowed to develop new catalysts for deep hydrotreating of VGO. NiW and NiMo catalysts supported on a mesostructured alumina provided the removing sulfur content to 500 ppm (from 2 wt .% in the feedstock) at 360 ºC, H_2 pressure of 5 MPa, LHSV 1.0 h^{-1} and H_2/feedstock 800 NL/L. The catalysts exhibited a lesser degree of deactivation and coke content after the tests.

4 Conclusions

New approaches for creating TMS catalysts were developed. Simultaneous use of Co_2Mo_{10}HPA and chelating agents allowed to change significantly the promotion ratio and morphology of CoMoS active phase type II and, thereby, catalyst properties in HDS and HYD reactions. New catalysts for (i) deep diesel hydrotreating, (ii) selective hydrotreating of FCC gasoline with saving octane number, and (ii) deep VGO hydrotreating were developed.

1 Introduction

Bioethanol, i.e. ethanol from fermentation, can be a useful source of biohydrogen by catalytic ethanol steam reforming, ESR, which is a complex and widely studied reaction [1,2]. Noble metal based catalysts are reported to be needed to efficiently convert real bioethanol [3], however less expensive catalytic materials are still under investigation. Nickel based catalysts are reported to allow high hydrogen yield at high reaction temperature (>600°C), although drawbacks such as deactivation by sulphur poisoning, coking and metal particles sintering are reported [4]. Alternatively, catalysts containing Cobalt, a less reducible metal, have been proven to be effective in the same reaction mainly at low temperature [5]. In this work we report our recent results on characterization and activity in ESR of Ni and Co containing catalysts based on ceria-zirconia support with an atomic ratio Ce:Zr=9:1.

2 Experimental.

Catalysts were prepared from aqueous solution of $Ce(NO_3)_3.6H_2O$, $ZrO(NO_3)_2$, $Ni(NO_3)_2.6H_2O$ and/or $Co(NO_3)_2.6H_2O$. The resulting suspensions were left to settle overnight, then centrifuged and washed with deionized water. The samples were dried overnight at 80°C and then calcined in air flow up to 973 K for 5 h (3° min^{-1}). The catalyst samples were identified by acronyms CZ91X (X= Co and/or Ni) and have been fully characterized by ICP analysis, XRD, H_2-TPR, FT IR and UV-Vis. NIR spectroscopies (table 1). The catalytic experiments were carried out in a fixed-bed tubular quartz flow reactor, operating isothermally. ESR has been tested in the following conditions: liquid mixed feed of ethanol and water with molar ratio of 1:6 was fed to the line by a pump and heated at 500 K before feeding to the reactor (He as carrier gas). Ethanol Steam Reforming (ESR) reaction was performed from 300°C to 800°C. Analysis of reactants and products was carried out by GC equipped with TCD and FID detectors.

Table 1. Catalysts studied.

sample	Composition w/w	Surf. area $m^2\ g^{-1}$	H_2 uptake* (mmol $H_2\ g^{-1}$)	H_2 theor.* consumption (mmol $H_2\ g^{-1}$)	%red
CZ91Ni	Ni 7.6%	13	-	-	95.3
CZ91Co	Co 3.9%	12	1.23	1.29	79.5
CZ91NiCo	Ni 7.6%, Co 3.9%	12	0.70	0.88	100

* H_2 uptake for the reduction of the Ni, Co or both Ni-Co ions.

3 Results and discussion

The comparison of catalytic results of CZ91NiCo and CZ91Ni and CZ91Co shows that the bimetallic formulation significantly increases both ethanol conversion, which reaches 90% above 500°C, and hydrogen yield, which is near 80% at temperatures above 600°C K (figure 1).

These results can be explained by the synergetic effect occurring between Ni and Co in a

temperature range where the corresponding oxides are reduced by the same reaction mixture. Following previous results on bimetallic NiCo catalysts supported on stabilized zirconia we could possibly suggest that some alloying is also occurring in the bimetallic particles [5]. TPR and IR data of adsorbed probe molecules CO and methanol (namely, the easier oxidation of adsorbed methoxy species to formate species in the bimetallic formulation) also suggest the high reducibility of active phase oxides, possibly also enhanced by the availability of surface oxygen from the support [6]. Alcohols mainly adsorb dissociatively at the catalyst surfaces, pointing out the key role of the alkoxy species in reactants activation.

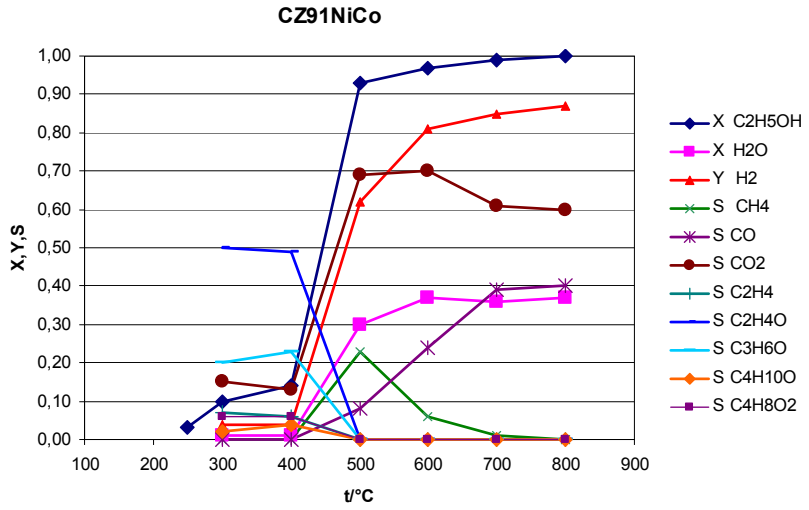

Fig. 1. Ethanol conversion (X), hydrogen yield (Y) and selectivities (S) to reaction products over CZ91NiCo, as function of temperature.

On the other side, the CZ support, mainly characterized by the ceria basic character, limits the formation of dehydration products such as ethene, in comparison to similar catalysts formulations over different supports. No deactivation phenomena were detected for the whole duration of the reactivity tests.

4 Conclusions

CZ91NiCo catalyst has proven to be very active in ESR reaction. The bimetallic formulation shows a synergic effect resulting in increased ethanol conversion and hydrogen yield (above 80% from 600°C). The basic character of Ceria-based support limits the formation of ethene, likely precursor of coke formation.

Keywords: Fischer-Tropsch synthesis, precipitated iron-based catalysts, activation study, carburizability

1 Introduction

Fischer-Tropsch synthesis (FTS) has attracted much attention as a promising route to produce clean fuels or chemicals from syngas (H_2 + CO) derived from coal/biomass gasification or natural gas reforming. Iron-based catalysts are highly promising for the FTS due to their high activity and low cost. Furthermore, the iron-based catalysts have a great merit when they are used in the FTS using syngas with a low H_2/CO ratio (≤ 1.0), due to their potential activity for a water-gas shift (WGS) reaction. For low-temperature FTS (≤ 280 ºC), a precipitation technique is known to be the most practical preparation method of iron-based catalysts [1]. In general, iron carbides such as ε`-$Fe_{2.2}C$ and χ-$Fe_{2.5}C$ are reported to be active sites for the low-temperature FTS. Thus, the as-prepared precipitated iron-based catalysts, which are usually composed of iron oxides, need to be pre-activated into iron carbides in a CO-containing atmosphere prior to the FTS [2]. During the FTS over iron-based catalysts, considerable amounts of H_2O and CO_2 are inevitably produced as by-products, which can lead to oxidation and decarburization of active iron carbides into inactive iron oxides, respectively. Therefore, it is worth developing highly reducible and carburizable iron-based catalysts for enhanced catalytic performance in the FTS. In this study, we report highly reducible and carburizable iron-based FTS catalysts, which can be spontaneously activated in the FTS condition.

2 Experimental/methodology

The catalysts used in this study were prepared through a combination of a co-precipitation technique and a spray-drying method, in a process similar to that described previously [2,3]. In brief, a Na_2CO_3 solution was added to a solution containing both $Fe(NO_3)_3$ and $Cu(NO_3)_2$ in the desired ratio at 80 ± 1 °C until the pH reached 8.0 ± 0.1. The precipitate slurry was filtered, washed with distilled water, and subsequently re-slurried in distilled water. After completing the washing process, the required amount of K_2CO_3 solution and colloidal suspension of SiO_2 were added to the precipitate slurry, and the final mixture was spray-dried. Then, the dried sample was calcined at 400 °C for 8 h. The calcined catalysts were pressed into pellets and then crushed and sieved to obtain 300-600 μm particles for a test in a fixed-bed reactor. The chemical composition of the as-prepared catalysts was analyzed by X-ray fluorescence spectroscopy (XRF) using a Rigaku model ZSX Primus II. The Brunauer-Emmett-Teller (BET) surface area, the single point pore volume, and the average pore diameter of the as-prepared catalysts were analyzed by means of N_2 physisorption using a Micromeritics model Tristar II 3020. The FTS was carried out in a fixed-bed reactor composed of stainless steel. Using either as-prepared catalysts or pre-activated catalysts, the FTS was performed with syngas (H_2/CO=1.0, 2.8 NL/$g_{(cat)}$-h) at 275 °C and 1.5 MPa. The pre-activated

catalysts were prepared in situ with syngas (H_2/CO=1.0, 2.8 NL/$g_{(cat)}$-h) at 280 °C and 0.1 MPa for 20 h. The composition of the outlet gases was analyzed using an online gas chromatograph (GC; Agilent, 3000A Micro-GC) equipped with molecular sieve and plot Q columns. The flow rates of the gases were measured by means of a wet-gas flow meter.

3 Results and discussion

The chemical composition of the as-prepared catalysts analyzed by XRF was 100Fe/5.29Cu/4.86K/19.4SiO_2 in part per weight. The BET surface area, the single point pore volume, and the average pore diameter of the as-prepared catalysts were 203 m^2/g, 0.436 cm^3/g, and 8.60 nm, respectively. The pre-activated catalysts showed a high and stable CO conversion (83-85%) during the entire reaction time (~ 114 h), indicating that the catalysts prepared in this study are reducible and carburizable enough to maintain the active iron carbides during the FTS. Interestingly, the as-prepared catalysts also displayed a CO conversion higher than 60% at the beginning of reaction, and the CO conversion showed a slight increasing trend with increased time. This implies that the catalysts prepared in this study can be spontaneously activated during the FTS. The overall catalytic performance of pre-activated catalysts (denoted as PAC) and spontaneously activated catalysts (denoted as SAC) were comparatively evaluated during 66-114 h of reaction. While the CO conversion of SAC was lower than that of PAC (SAC: 64.1%, PAC: 84.5%), SAC showed much higher selectivity of C_{5+} hydrocarbons than PAC (SAC: 79.6 wt% in total hydrocarbons, PAC: 57.9 wt% in total hydrocarbons). Also, the CO_2 selectivity of SAC was slightly lower than that of PAC (SAC: 41.2%, PAC: 44.5%). As a result, SAC showed higher productivity of C_{5+} hydrocarbons than PAC (SAC: 0.271 g/$g_{(cat)}$-h, PAC: 0.218 g/$g_{(cat)}$-h).

4 Conclusions

The catalysts prepared in this study can be spontaneously activated during the FTS. The spontaneously activated catalysts showed high catalytic performance in terms of C_{5+} hydrocarbon productivity, which is even higher than that of pre-activated catalysts.

Selectivity in the Liquid-Phase Hydrogenation of 5-Hydroxymethyl Furfural over Ni-Al Catalysts

Perret N.*, Grigoropoulos A., Manning T., Claridge J., Rosseinsky M.J.

University of Liverpool, Liverpool, UK

* noemie.perret@liverpool.ac.uk

Keywords: 5-Hydroxymethylfurfural, Ni-Al catalysts, hydrogenation, biomass-derivatives, selectivity

1 Introduction

As the worldwide reserves of non-renewable fossil diminish, there is a growing demand on the development of sustainable feedstock. While the production of biofuels and bioenergy are still economically a challenge, the coproduction of value added chemicals could render the process cost-effective. Hemicelluloses can easily be broken down and converted to monosaccharides. The following dehydrations of sugars generate platform chemicals, such as 5-hydroxymethyl furfural (HMF) [1].The hydrogenation of HMF can produced a wide variety of valuable compounds [2]. However, selectivity in terms of targeted C=C or C=O reduction is challenging. Moreover, while most research focused on the combined hydrogenation/ hydrogenolysis of 5-HMF towards alcohols, really few studies dealt with the successive hydrogenation of 5-HMF with etherification or ring rearrangement [3].

The calcination and reduction of Ni-Al hydrotalcite-like compounds can generate catalysts with higher metal loading than Ni/Al_2O_3 synthesised by more traditional impregnation method; they can also exhibit distinct products selectivities which have yet to be fully exploited. In this study, we investigated the hydrogenation of HMF over $Ni_{1-x}Al_x$ catalysts ($0.2 \leq x \leq 0.45$) based on hydrotalcite like compounds. The effects of temperature (80-140°C), pressure (20-60bars) and solvent (water, methanol) on the catalytic response were investigated.

2 Experimental

Four hydrotalcites $Ni_{(1-x)}Al_x(OH)_2(CO_3)_{x/2}.mH_2O$, with $0.2 \leq x \leq 0.45$ and $0.3 \leq m \leq 0.7$, were prepared by precipitation of mixed aqueous solutions of $AlCl_3$ and $NiCl_2$ with solid urea. After aging for 60h at 95°C, all precipitated materials were left in suspension with NH_4HCO_3 for 5h (to remove any residual Cl), then filtered, washed and dried at 120°C for 3h. The catalysts $Ni_{1-x}Al_x$ were obtained by successive calcination (under air; 75mL min^{-1}) and reduction (under H_2, 100mL min^{-1}) at 500°C for 5h, followed by passivation at room temperature for 3h.

The crystallographic structures were confirmed by XRD. Bulk and surface Ni/Al ratios were obtained by elemental analysis (ICP) and SEM-EDX, respectively. Ni metal particles sizes were determined by TEM and XRD. Temperature-programmed reduction (TPR), H_2 chemisorption, temperature-programmed desorption (TPD), BET surface area and total pore volume were measured with a Chem-BET quantachrome and a Tristar II micromeritics.

The hydrogenation of 5-hydroxymethyl furfural was carried out in a batch stirred stainless steel reactor under constant pressure (P_{H2}= 20-60 bar) and agitation (600rpm) at temperature in the range 80-140°C. In a typical experiment 0.03g-0.09g of catalyst and a 45 mL aqueous or methanolic solution of 5-hydroxymethyl furfural reactant (C = 0.02-0.04M) were charged in the reactor. Liquid samples were analysed by GC and NMR.

3 Results and discussion

Characterisation showed that the catalysts obtained exhibit well dispersed Ni nanoparticles

(11-15nm) on the surface. The catalytic hydrogenations of HMF were conducted over $Ni_{1-x}Al_x$ ($0.2 \leq x \leq 0.45$) where an increase in Ni loading was associated with an increase in activity.

Table 1. Yields (Y) for the hydrogenation of HMF over $Ni_{0.8}Al_{0.2}$ catalysts after 20h reactions

T (°C)	P_{H2} (bars)	Solvent	X_{HMF}	Y_{FDM}	Y_{THF}	Y_{MF}	Y_{HCPN}	Y_{others}
80	60	water	1.00	0	1.00	0	0	0
140	20	water	1.00	0.04	0.10	0	0.75	0.10
140	20	Methanol	0.80	0.15	0.02	0.52	0	0.11

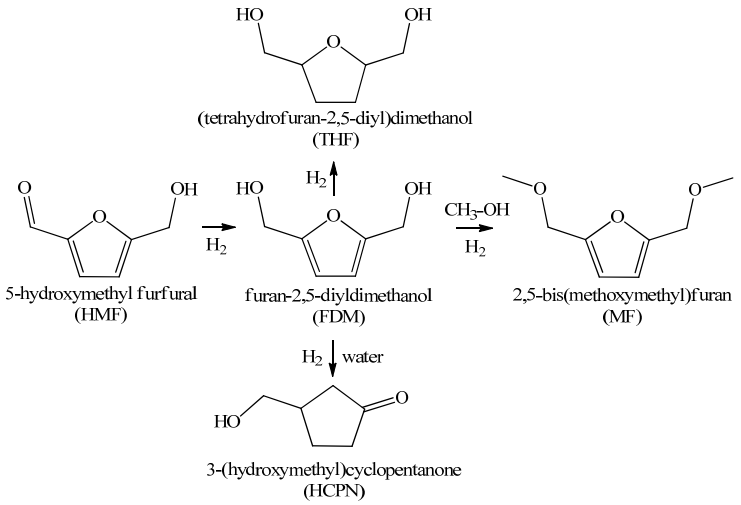

Fig. 1. Observed reaction pathway for the hydrogenation of 5-hydroxymethyl furfural

At low temperature and pressure (80°C, 20bar), successive reduction of C=O and C=C occur with formation of furan-2,5-diyldimethanol (FDM) and (tetrahydrofuran-2,5-diyl)dimethanol (THF, see Figure 1). By adjusting the reaction conditions (80°C, 60bar), 100% yields towards (tetrahydrofuran-2,5-diyl)dimethanol was obtained (Table 1). Increasing the temperature to 140°C had a drastic effect on selectivity. In water, the combined hydrogenation and ring rearrangement generated the formation of 3-(hydroxymethyl)cyclopentanone (HCPN) where 75% yield was achieved at 100% conversion (Table 1). When working in methanol, we observed the etherification of the intermediate furan-2,5-diyldimethanol with formation of 2,5-bis(methoxymethyl)furan (MF, Figure 1).

4 Conclusions

Temperature and solvent were shown to have a strong effect on the selectivity. The liquid phase hydrogenation of HMF over $Ni_{0.8}Al_{0.2}$ catalyst generated 100% yield of THF at 80°C. An increase in temperature was associated with a shift of selectivity towards HCPN and MF when working in water and methanol, respectively. We observed for the first time the formation of ether furan and cyclopentanone derivative over Ni catalysts.

Keywords: furfural, benzaldehyde, hydrogenation, palladium catalysts, ruthenium catalysts, carbon supports

1 Introduction

Catalytic hydrogenation is widely used to reduce functional groups in various organic compounds. Selective hydrogenation of carbonyl compounds over supported metal catalysts is one of the methods of obtaining alcohols. Among the proposed hydrogenation catalysts, those based on noble metals have some advantages, since their high activity under mild reaction conditions and reusability. The nature of metallic component and its state in the catalyst are of key importance for hydrogenation processes. It is known that hydrogenation of aldehydes is a structure-sensitive reaction, since the particle size of supported metal affects catalyst activity. To provide the desired activity and selectivity of hydrogenation catalyst, the choice of support is also very important because features of the support affect the state of supported metal, the adsorption of reagents, and mass transfer processes. The goal of this work was to elucidate the effect exerted by the nature of carbon support on the formation of metallic sites in Pd/C and Ru/C catalysts for the liquid-phase selective hydrogenation of benzaldehyde and furfural.

2 Experimental

As the catalyst supports, we chose the carbon materials, multi-wall carbon nanotubes (CNT) and carbon black (CB), in principle differed in preparation method, structure and physicochemical characteristics such as texture and acid-base properties. The supported Ru catalysts were obtained by incipient wetness impregnation of the carbon supports with aqueous solutions of ruthenium(IV) chloride complexes. The Pd catalysts were prepared by the adsorption of palladium(II) chloride complexes from excess solution. The metal content in the catalysts was equal to 0.3, 1.0 and 1.5 wt. %. The formation of metal sites in the samples was examined by H_2-TPR. Metal dispersion in the reduced Pd/C and Ru/C samples was estimated by pulse chemisorption of CO or O_2 and directly by TEM. XPS was used to estimate the oxidation state of supported metal in the reduced catalysts. Hydrogenation of benzaldehyde in the presence of synthesized catalysts was performed in ethanol at 40 and 60 ^{o}C and a hydrogen pressure of 0.5 MPa in steel autoclave. The composition of reaction products was determined every hour by GC. Hydrogenation of furfural was carried out in aqueous solution at a temperature of 50 and 90 ^{o}C and a hydrogen pressure of 0.5 and 2.0 MPa. In this case, the reaction was controlled by measuring the volume of consumed hydrogen. The products of furfural hydrogenation were determined by GC after completion of the reaction and cooling.

3 Results and discussion

The adsorption of palladium(II) chloride complexes on CNT is less strong than their adsorption on CB. As a result, Pd complexes supported on CNT are reduced at a lower temperature with the formation of highly dispersed particles and a lower Pd^0:$Pd^{\delta+}$ atomic ratio. The adsorption capacity of CNT and CB with respect to ruthenium(IV) chloride complexes is very low. The reduction of a precursor in the Ru/CB sample led to the formation of ruthenium

particles having a higher dispersion as compared to Ru/CNT.

Hydrogenation of benzaldehyde. In the series of studied Pd/C catalysts, the highest selectivity for benzyl alcohol (98 %) with complete conversion of benzaldehyde was demonstrated by the 1 % Pd/CNT sample (40 °C, 0.5 MPa). For the Pd/C samples containing 0.3 % of palladium, the number of active sites is insufficient for accomplishing the reaction with high conversion. In this case, there is an increased fraction of products of the reaction between benzaldehyde and ethanol formed with participation of acid sites of the support. Increasing the palladium content up to 1.5 % leads to a significant increase in the toluene fraction (up to 92 %) in the reaction products.

The Ru/C catalysts are less active as compared to the palladium samples. Under the chosen reaction conditions, the presence of Ru/C samples does not provide a complete conversion of benzaldehyde. A maximum conversion of 71 % was attained in the presence of 1.5 % Ru/CNT (60 °C, 0.5 MPa). Hydrodeoxygenation into toluene is completely suppressed irrespective of the reaction conditions and ruthenium content in the catalyst; thus, high selectivity for benzyl alcohol is maintained. Among the Ru/C catalysts, most active in the formation of benzyl alcohol are the catalysts containing CNT.

Hydrogenation of furfural. The nature of carbon support was shown to affect the catalytic properties of Pd/C and Ru/C catalysts in the aqueous-phase hydrogenation of furfural (Fig. 1). The 1.5 % Pd/CB catalyst demonstrated a high selectivity (no less than 98 %) for furfuryl alcohol during hydrogenation of furfural at a temperature of 50 °C and hydrogen pressure of 0.5 and 2.0 MPa (the furfural conversion of 29 and 46 %, respectively). The 1.5 % Pd/CNT catalyst was not active under mild conditions of the reaction (50 °C, 0.5 MPa), but had a greater tendency to reduce the furan ring under severe conditions (90 °C, 0.5 or 2.0 MPa) as demonstrated by an increased yield of tetrahydrofurfuryl alcohol.

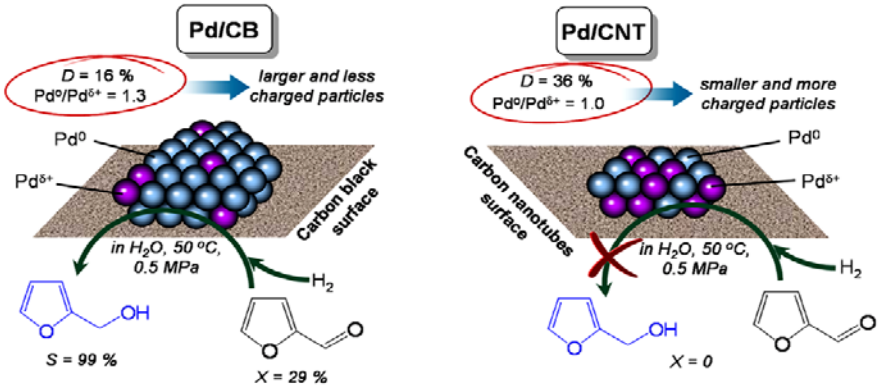

Fig. 1. Proposed effect of electronic and dispersion state of supported palladium on the catalytic properties of Pd/C in furfural hydrogenation

The ruthenium samples have a low activity in aqueous-phase hydrogenation of furfural irrespective of the support nature and reaction conditions, possibly due to irreversible adsorption of water on the active sites.

4 Conclusions

The study has revealed that the nature of carbon support affects the formation and state of supported metal in the Pd/C and Ru/C samples as well as its catalytic properties in hydrogenation of benzaldehyde and furfural.

Sustainable "Hydrogen Free" Catalytic Hydrogenation: from Concept to Reality

Li M., Cárdenas-Lizana F.*, Keane M. A.

Heriot-Watt University, Chemical Engineering, Edinburgh, UK

* f.cardenaslizana@hw.ac.uk

Keywords: gas phase, coupling reactions, alcohol, dehydrogenation-hydrogen transfer, Cu/SiO_2, supported Au catalysts

1 Introduction

Hydrogenation is a core catalytic operation in synthetic organic chemistry, accounting for 30-40% of the chemical processes in the manufacture of fine chemicals.[1] Commercial hydrogenation processes are typically operated in excess of pressurised gaseous H_2 in order to maximise product yield. Hydrogen is not a naturally occurring feedstock and production, storage and transport represent serious constraints. Over 95% of global H_2 production is fossil fuel based, notably by methane steam reforming and coal gasification and issues of sustainability now demand alternative sources with enhanced efficiencies.[2] A step change in catalytic hydrogenation must tackle H_2 utilisation and a completely new approach is called for.

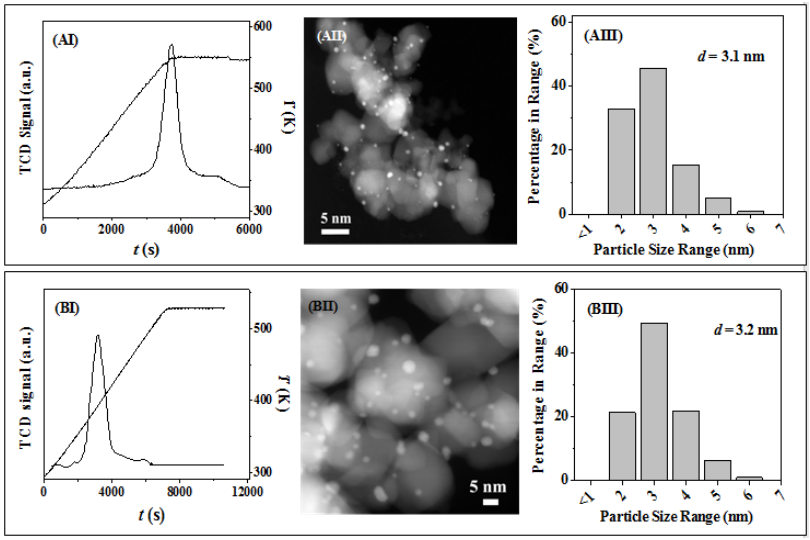

Fig. 1. (I) Temperature programmed reduction profiles, **(II)** representative STEM images and **(III)** associated metal particle size distribution histograms for **(A)** Cu/SiO_2 and **(B)** Au/TiO_2.

2 Experimental/methodology

Cu/SiO_2 and (CeO_2 and TiO_2) supported Au catalysts were prepared by deposition precipitation and/or impregnation. The catalysts were characterised in terms of elemental analysis/AAS, BET/pore volume, TPR, H_2 chemisorption/TPD, XRD, XPS, SEM, HRTEM, STEM, TGA-DSC and XPS measurements. The coupled dehydrogenation-hydrogen transfer reactions were conducted in continuous gas flow (fixed bed vertical glass reactor; P_{H2}=1 bar; T=423-593 K). The gases (H_2, N_2, Ar, O_2 and He) were of ultra high purity. The composition of the reaction/product mixtures was determined by capillary GC analysis.

3 Results and discussion

We have established the viability of continuous *in-situ* hydrogen generation (from 2-butanol dehydrogenation) and direct utilisation (in nitrobenzene hydrogenation) over (15.9% and 1.8% wt.) Cu/SiO_2 for the sustainable "hydrogen free" synthesis of commercially important products, *i.e.* 2-butanone and aniline. Dehydrogenation of 2-butanol is structure-sensitive with higher TOF over 15.9% wt. Cu/SiO_2 bearing larger (mean size=7.9 nm) Cu^0 nanoparticles. Enhanced TOF in

the hydrogenation of nitrobenzene has been demonstrated over 1.8% wt. Cu/SiO_2 that exhibited smaller Cu nanocrystals (mean = 3.1 nm) with greater H_2 uptake capacity. Exclusive production of both 2-butanone and aniline at full conversion has been achieved in the coupling of 2-butanol dehydrogenation with nitrobenzene hydrogenation over Cu/SiO_2 (conducted in N_2 as carrier). Hydrogen utilisation efficiency was appreciably greater (by a factor of up to 50) in the coupled system relative to conventional stand alone hydrogenation using pressurised H_2, a response that can be attributed to the generation of reactive hydrogen associated with the Cu sites (Cu-H) that is effectively transferred for nitro-group reduction. This circumvents the limitations associated with H_2 activation/dissociation by Cu.[3]

This approach has been further exploited with the combination of Cu/SiO_2 as a physical mixture with Au/TiO_2 (as a chemoselective hydrogenation catalyst)[4] for the gas phase coupling of benzyl alcohol dehydrogenation with nitrobenzene hydrogenation for "hydrogen-free" imine (*N*-benzylideneaniline) production. Post-activation both catalysts exhibited a narrow particle size distribution (1-6 nm) and similar nanoparticle size (3.1-3.2 nm) (see Fig. 1). Dehydrogenation of benzyl alcohol over Cu/SiO_2 delivered a ten-fold higher rate than Au/TiO_2 where the latter was appreciably more active in nitrobenzene hydrogenation . The coupled reaction generated the target imine over Cu/SiO_2, which suffered severe a severe temporal loss of activity and selectivity. Incorporation of Au/TiO_2 with Cu/SiO_2 resulted in a catalytic synergy (explained on the basis of XPS analysis combined with TGA-DSC measurements) resulting in overall enhanced imine production and full hydrogen utilisation.

The potential of this "hydrogen free" hydrogenation strategy is further demonstrated in a fully sustainable (hydrogen free, aqueous solvent, biomass reactant) process for the production of furfuryl alcohol and 2-butanone (from furfural hydrogenation using the hydrogen released from 2-butanol dehydrogenation) over Cu/SiO_2+Au/CeO_2 in continuous operation under mild reaction conditions. We demonstrate that this is the most effective among a series of strategies directed at enhancing surface availability of reactive hydrogen (see Fig. 2).

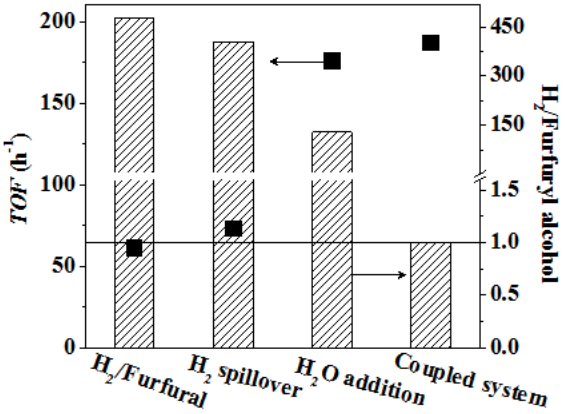

Fig. 2. Furfural turnover frequency (*TOF*;■) and H_2 utilisation with respect to furfuryl alcohol produced (H_2/Furfuryl alcohol, hatched bars) over Au/CeO_2 using different hydrogen supply strategies.

4 Conclusions

The results from this work demonstrate the feasibility of innovative coupling and cross-coupling of catalytic dehydrogenation (as a source of reactive hydrogen) with hydrogenation. Cu/SiO_2 is effective in the dehydrogenation step and we demonstrate catalytic synergy between Au and Cu in the coupled system with orders of magnitude enhanced H_2 utilisation, elevated selective hydrogenation rate and the simultaneous production of a range of high value products. Our coupled system circumvents the use of compressed H_2 from non-renewable sources with important safety and long term supply implications for large scale production.

Keywords: furfural, 2-Methylfuran, biomass, Pd catalyst

1 Introduction

One of the most plentiful resources of renewable energy that exists in the world is biomass. The current challenge for researchers in both industry and academia is the development of efficient technologies that utilize biomass or biomass-derived chemicals to a large extent.[1] Furan derivatives are considered to be important intermediates because of their rich chemistry with carbohydrates being the most dominant source of these platform molecules.[2] Furfuryl alcohol is an important bio-derivative obtained from cellulose and hemicellulose hydrolysis. Almost all the reported work on FA hydrogenation is performed using harsh reaction conditions. In the current work we report an application of Pd-supported catalyst synthesized by wet impregnation method in selective biomass hydrogenation and we discuss the catalytic performance of Pd catalysts under different reaction conditions such as variation in pressure, solvent and amount of catalyst on the hydrogenation of FA into 2-Methylfuran (2-MF)at room temperature.

2 Experimental/methodology

Catalyst Preparation

Incipient Wetness Impregnation method

Catalysts supported on titania were prepared by a wet impregnation method. The preparation procedure is as detailed as follows. $PdCl_2$ was dissolved in water and stirred under heating and added to the support and the resulting paste formed was dried in an oven at 110°C for 16h. The powder was calcined in static air at 400°C for 3h at a ramp rate of 20°C per minute.

Characterization

XRD, TEM, and XPS have been used in order to characterize the catalysts used for current study.

Catalytic Testing

The reactor was charged with Fufuryl alcohol (1g), dichloroethane (20 ml) and catalyst (0.1g). The autoclave was sealed, pressurised with hydrogen (1-3 bar, continuously controlled or constant pressure), and stirred (1000 rpm) for 30-120 min at room temperature. The reaction mixture (after centrifuging the sample to isolate the catalyst) was analysed by GC (Varian 3800 fitted with CP wax column). Products were identified by comparison with authentic samples. For the quantification of the amounts of reactant consumed and products generated, an external calibration method was used. External standard was acetonitrile.

3 Results and discussion

Various loadings of palladium metal supported on titania have been studied and a variation in activity of catalysts is observed with respect to conversion and selectivity both. The results are

presented in table 1.

Table 1. Effect Palladium loading on catalysis for hydrogenation of furfuryl alcohol

Catalysts	Conversion (%)	Selectivity (%)	
		2-Methylfuran	Tetrahydrofurfuryl alcohol
1% Pd/TiO_2	21.4	49	51
2.5% Pd/TiO_2	46.2	92.5	7.5
5% Pd/TiO_2	65.1	85.2	13.8

Reaction conditions:- substrate (1g), catalyst (100mg), $C_2H_4Cl_2$ (20 ml), 25 °C, 3h, 1000 rpm, 1Bar H_2

A comparison among different solvents was conducted. Dichloroethane gives the best catalytic performance, and is very selective to 2-MF with very low production of tetrahydrofurfural alcohol. Very limited reduction was observed when using actonitrile and toluene as solvents. Increasing the amount of catalyst improved the overall catalytic performance. The reaction was found to be very selective to 2-MF, when we used 100 to 125 mg 5wt% Pd/TiO_2. The conversion kept increasing, but selectivity decreased when 150 mg of catalyst was used. This can be attributed to a further reduction of Pd cation, or side reactions due to the excess amount of catalyst since yield of 2-methytetrahydrolfuran and tetrahydrofurfuryl alcohol also increased associated with the higher amount of catalysts.

4 Conclusions

We have demonstrated that FA can be converted selectively into 2-MF at room temperature using very low pressure of hydrogen with Pd supported catalysts. In this work highly active Pd catalysts with an abundance of very small particles (<2nm) were prepared via a very simple impregnation method. By using these Pd catalysts, only O-H hydrogenated deoxygenation happened, C=C was very less reduced under these reaction conditions, wherein the only byproduct detected was tetrahydrofurfuryl alcohol <6%.

Keywords: MexOy, nanoparticles, functionalized, nitroarene, catalytic transfer, hydrogenation

1. Introduction

Functionalized anilines are broadly used as intermediates for the production of fine chemicals. Selective and more environmentally friendly catalytic hydrogenations have replaced their conventional production processes (Béchamp's process, reduction by sulphides) . The benchmark catalysts, consisting mainly of noble metals (Pt, Ir, Ru, etc.), are usually used under H_2 pressures up to 150 bars. Catalytic transfer hydrogenations (CTH) relying on alternative hydrogen sources (2-PrOH, HCOOH, N_2H_4, etc.) allow avoiding such high pressures . Non-precious metal (Ni, Fe, Ce, etc.) based catalysts have shown to be an alternative to noble metals when the active phase is sufficiently dispersed .

Herein, we report catalysts based on transition metal oxides supported on activated carbon fibres (ACF) developed for selective CTH of substituted nitroarenes (NAr) into corresponding anilines (An) under mild conditions using N_2H_4 as a reducing agent. Microporous ACF (SSA~2000 m^2 g^{-1}) allow stabilizing extremely dispersed metal oxide nanoparticles (NPs). Downstream separation of the catalyst is avoided with the use of structured ACF. A small diameter of elementary filaments (10 μm) prevents internal mass transfer limitations.The ACF regular macrostructure provides a low resistance to a fluid flow in continuous processes .

2. Experimental/methodology

The Me_xO_y/ACF catalysts were prepared as following. Activated carbon fibers (ACF-K-20, Kynol Europa GmbH) used in the form of woven fabric were impregnated by an ethanol solution of metal nitrates precursor and dried in air at room temperature. Prior to catalytic testing the Me_xO_y/ACF catalysts were activated in an Ar flow at 623 K (ramp – 10 K min^{-1}) during 1 h followed by a passivation at 293 K under 2% v/v air/Ar flow for 1 h.

AAS was applied to determine the metal content and possible leaching. The specific surface area and total pore volume were characterized by BET. The size, morphology and electronic properties of the NPs were investigated by SEM, STEM, XRD and XPS.

Liquid-phase CTH reactions were carried out in a commercial semi-batch stainless steel stirred reactor. The structured ACF catalyst was fixed directly on the stirrer (stirring rate ~ 2000 rpm). The composition of the reaction mixture was monitored by GC.

3. Results and discussion

Electron microscopy revealed that highly dispersed Fe_2O_3 and Co_3O_4 NPs were formed within ACF micropores (Fig. 1). The NP size is controlled by the pore size (d_{pore} <2 nm).

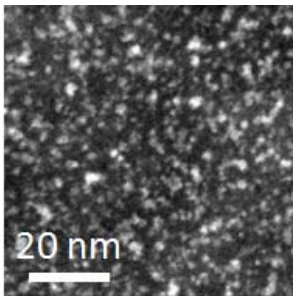

Fig. 1. STEM-HAADF image of 5%Fe_2O_3/ACF.

All catalysts were active in CTH of *para*-chloronitrobenzene (*p*CNB). Fe_2O_3/ACF and Co_3O_4/ACF exhibited an initial specific activity of one order of magnitude higher (3-6·10^{-2} $mol_{NAr}·mol_{Me}^{-1}·s^{-1}$) than CeO_2/ACF and NiO/ACF. While only *p*CAN was observed throughout the reaction over the Fe and Ce based catalysts, azoxy- and azoarene intermediates were detected over Co_3O_4/ACF and NiO/ACF. The further testing of two the most active catalysts in CTH of nitroaromatics with different substituents (-OCH_3, -CH_3, -H, -Cl, -C=C) demonstrated extremely high yields (>99 %) of corresponding anilines (Table 1). It is important to note that hydrogenation of 3-nitrostyrene containing a readily reducible vinyl-group is quantitatively selective over Co_3O_4/ACF without any additives.

Table 1. CTH of functionalized nitroarenes over 8%Fe_2O_3/ACF and 5%Co_3O_4/ACF. Reaction conditions: 333 K, substrate - 0.126 M, Fe catalyst - 2.0 mol.%, N_2H_4/*p*CNB - 3, EtOH - 100 ml.

a. Substrate - 0.016 M.

4. Conclusions

Highly dispersed Fe and Co oxide NPs (2-4 nm) deposited on ACF were demonstrated to be efficient catalysts for selective transfer hydrogenation of a variety of functionalized nitroarenes under mild conditions (T = 333 K: P = 1 bar). The challenging reduction of nitrostyrene to vinylaniline was successfully achieved over Co_3O_4/ACF with a selectivity of >99 % at full conversion.

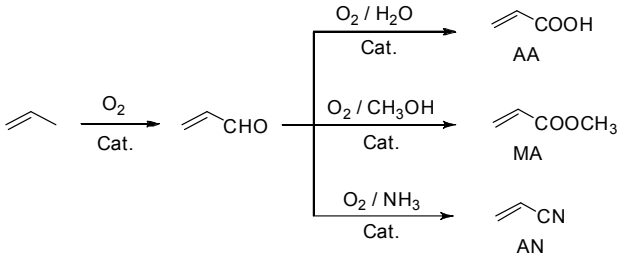
Keywords: vanadium mixed oxide catalyst, nucleophilic acyl substitution, acrolein, acrylic acid, methyl acrylate, acrylonitrile

1 Introduction

Acrylic acid (AA), methyl acrylate (MA) and acrylonitrile (AN) are important bulk chemicals. Their production is currently based on propylene oxidative transformations, while acrolein plays a key role as an isolated or in situ intermediate in these reactions. For example, aerobic oxidation of acrolein to AA over a molybdenum-vanadium oxide catalyst is a part of the two-step propylene oxidation process (Scheme 1). Notably, this reaction proceeds normally in the presence of 2 to 40 vol% of water at 250−310°C.

MA can be synthesized directly from acrolein or even propylene as a result of oxidative esterification, on condition that methanol is added to the feed (Scheme 1).

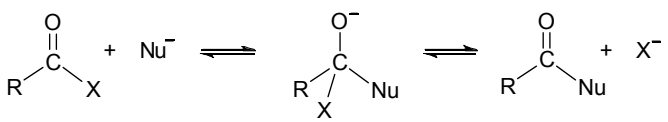
AN is mainly produced by ammoxidation of propylene over bismuth molybdate catalysts at 400−500°C (Sohio process). There is no generally accepted opinion whether this reaction proceeds via in situ formation of acrolein or not. Nevertheless, acrolein itself undergoes oxidation in the presence of ammonia to yield AN, the rate of this reaction is at least several times as high as the rate of propylene ammoxidation (Scheme 1).



Scheme 1. Oxidative transformations of propylene and acrolein.

Taking into account a striking similarity in the acrolein conversions to AA, MA and AN, it can be surmised a common mechanism for these reactions. Obviously, a general stage should be an oxidation of acrolein into the same intermediate, which will undergo different transformations depending on the reaction conditions. The evident difference in the reactions at Scheme 1 is the presence of various reagents, such as water, methanol and ammonia.

However, no general mechanism for the reactions on Scheme 1 is suggested so far. On the other hand, it is known that nucleophilic acyl substitution in the RCOX compounds (with good leaving groups X) is a fundamental and energetically favourable route to carboxylic acid derivatives. When water, alcohols and ammonia are used as nucleophiles, carboxylic acids, esters and amides (or nitriles) are produced, respectively (Scheme 2).

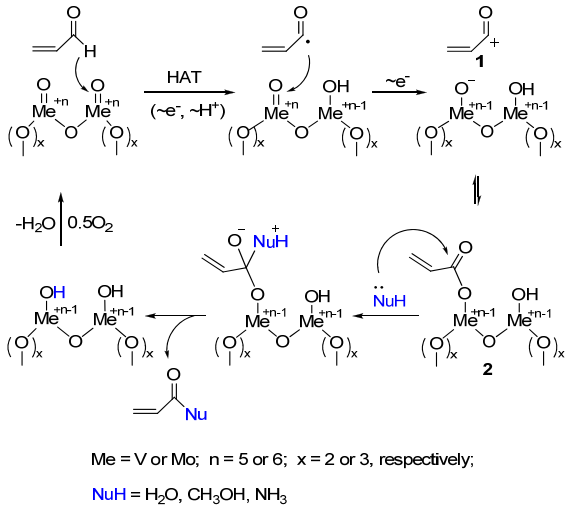


Scheme 2. Nucleophilic acyl substitution (general reaction pattern). X = halide (acid halides), acyloxy (anhydrides), alkoxy (esters), and other "good leaving" groups.

In our presentation we reasoned that catalytic oxidation of acrolein to AA, MA and AN can involve inherently nucleophilic substitution reactions with water, alcohols and ammonia. Therefore, we have shown initially that the selfsame catalyst, MoVTeNb mixed oxides, provides all three reactions, such as oxidation, oxidative esterification and ammoxidation of acrolein. The results obtained can be plausibly interpreted in terms of HAT theory and nucleophile-electrophile interactions. Recently, similar consideration was applied to catalytic oxidation of methanol over vanadia and this gave a robust explanation for predominant selectivity towards each product among formaldehyde, formic acid, dimethoxymethane and methyl formate depending on reaction conditions [1].

2 Results and discussion

The gas-phase acrolein oxidation reactions were performed using MoVTeNb oxides chosen as powerful and versatile vanadium catalyst. As expected, AA is mainly produced in the presence of water. When methanol is present in the feed, MA becomes the main product, while minor amounts of AA are also formed. When ammonia is present in the feed, AN becomes the main product. Moreover, addition of water in the feed in amount of 10 vol% practically does not influence the result of the latter reaction. Accordingly, the same catalyst provides quite efficiently oxidation, oxidative esterification and ammoxidation of acrolein (the experimental details will be disclosed in presentation). Therefore, one may propose that all these reactions are relative and, moreover, they may be happen within the same catalytic sites.



For a simplified theoretical consideration, a hypothetical sequence of the reaction steps in acrolein oxidative transformations can be outlined by the example of a monolayer dimeric metal oxide (Scheme 3). The oxidation step leads to formation of intermediates such as **1** and **2**.

Scheme 3. Proposed mechanism for oxidation of acrolein in the presence of water, methanol and ammonia over monolayer dimeric metal oxide.

Even though ion **1** does not react with a nucleophile immediately, it binds to the anion surface to form meta-stable compound **2**. Intermediate **2** is in fact a semiorganic ester, which is electrophilic enough to react with water, methanol and especially with ammonia to give AA, MA and acrylamide, respectively. Obviously, acrylamide undergoes immediate dehydration upon the reaction conditions (T > 400°C) to yield AN.

3 Conclusion

We suggest that transient acryl-vanadia/molybdenum surface complexes (formed in the oxidation stage) can react readily with typical nucleophiles, such as water, methanol and ammonia to yield the expected AA, MA and AN. The concept suggested is universal; it plausibly explains the formation of various products over the same catalyst upon oxidation conditions and is in accord with established organic and general chemistry principals.

Keywords: asymmetric catalysis, epoxidation, hydrogen peroxide, mechanism, sulfoxidation, titanium

1 Introduction

In the last decades, the development of catalyst systems for the asymmetric epoxidation of olefins and oxidation of thioethers to sulfoxides has been a challenging goal. While a number of biologically active chiral sulfoxides are known (including the bestseller anti-ulcer drugs esomeprazole and dexlansoprazole [1]), optically pure epoxides are valuable intermediates that can be readily involved in further asymmetric transformations via e.g. asymmetric ring-opening reactions [2].

In this contribution, we present a series of novel chiral titanium(IV) complexes of the salan and salalen families, capable of acting as highly enantioselective catalysts for the asymmetric epoxidation of olefins and oxidation of thioethers with "green" hydrogen peroxide. New insights into the mechanisms of those processes are reported.

2 Experimental/methodology

Chiral titanium(IV) salan and salalen complexes were prepared as reported [3,4]. ^{1}H and ^{13}C NMR spectra were measured on Bruker Avance 400 spectrometer at 400.13 and 100.613 MHz, respectively, or on Bruker DPX-250 at 250.13 and 62.903 MHz, respectively. Single-crystal diffraction characterization was performed at 150 K on a Bruker Apex Duo four-circle diffractometer equipped with an area detector (Mo-K_α, graphite monochromator, φ and ω scans). UV-Vis measurements were conducted on a Cary 60 spectrophotometer. The incorporation of ^{18}O into the oxidation products was determined using Agilent 7000B GC/MS with Triple Quad detector, EI - 70 eV, chromatograph Agilent 7890 equipped with a capillary column HP-5ms [30 m × 0.25 mm × 0.25μm, He carrier gas]. Enantiomeric excess values and absolute configurations were measured on a Shimadzu LC-20 HPLC chromatograph equipped with a set of Daicel chiral columns.

3 Results and discussion

A series of dinuclear chiral titanium(IV) salan and salalen complexes was synthesized, bearing different sibstituents at the chiral ligands (Figure 1).

Fig. 1. Structures of some salan (**1-11**) and salalen (**12-15**) complexes discussed in this work.

Complexes of both types appeared to be highly enantioselective catalysts for the oxidation of conjugated olefins to epoxides – precursors of biologically active complex molecules – and bulky thioethers – precursors of anti-ulcer drugs (and their steric models) – to sulfoxides with H_2O_2. Good efficiencies (TN 20 for epoxidations and TN 200-300 for sulfoxidations) were documented. A few examples are presented in Figure 2.

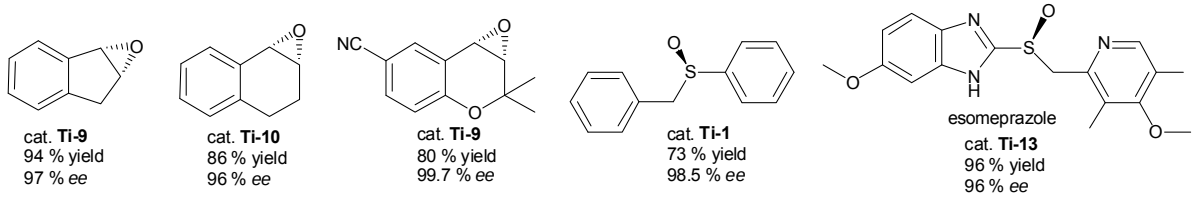

Fig. 2. Examples of asymmetric oxidations of various substrates on Ti catalysts.

Kinetic and spectroscopic studies revealed fundamental distinctions in the epoxidation and sulfoxidation mechanisms. While the active oxygen-transferring species is apparently the same for both processes ((η^2-peroxo)titanium(IV) complex), the epoxidation on Ti-salan complexes proceeds via stepwise ("Mimoun-type" [5]) mechanism, rate-limited by coordination of the olefin to the electrophilic active titanium peroxo species. In effect, variation of the olefin nucleophilicity only affects the epoxidation rate (without changing the *ee*), while the epoxidation enantioselectivity is solely determined by steric matching of the chiral ligand and the coordinated olefin.

In contrast, sulfoxidation on Ti-salalen complexes is rate-limited by generation of the titanium peroxo species upon reaction of the catalyst with H_2O_2, followed by relatively fast concerted ("Sharpless-type" [5]) oxygen transfer to the sulfide. For the asymmetric sulfoxidations, non-linear temperature dependence of the enantioselectivity has been documented, with maximum *ee*s attained at 273…283 K. This nonlinearity (*isoinversion relationship*) is indicative of the existence of two separate reaction paths, each generating two diastereomeric transition states but in varying ratios. A reaction mechanism has been proposed explaining the observed temperature dependence of enantioselectivity.

4 Conclusions

Highly enantioselective epoxidation of olefins and oxidation of thioethers with H_2O_2 on chiral titanium(IV) salan and salalen complexes is reported. The effects of steric bulk and electronic properties of chiral ligands on the enantioselectivity of oxidations have been examined. Mechanistic studies reveal distinct mechanisms operating in those processes: a stepwise mechanism for epoxidations and concerted one for sulfoxidations. For the first time, isoinversion behavior has been documented for the asymmetric sulfoxidation reactions, with T_{inv} of 273…283 K, which temperature range may be recommended for preparative reactions.

Catalytic Performance of Fluidizable Binder-Free Mo/HZSM-5 Catalyst in the Non-Oxidative Methane Conversion to Benzene at Severe Conditions

Zhang Z.-G.[1*], Xu Y.[1], Suzuki Y.[1], Ma H.[2], Yamamoto Y.[2]

1 - National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba-shi, Japan
2 - Core Research Technology Laboratories, Meidensha Corporation, Tokyo, Japan

Keywords: methane, benzene, Mo/HZSM-5 catalyst, binder-free, fluidization, fluidized-bed

1 Introduction

With a high selectivity to benzene up to 70% the non-oxidative CH_4 dehydroaromatization over Mo/HZSM-5 provides a new route of direct conversion of methane resources toward valuable chemicals. However, due to its very low equilibrium conversion (about 21% at atmospheric pressure and 1073 K), this reaction has to be performed at a temperature and a space velocity as high as possible, say, 1073 K and 10,000 mL/g/h, to gain a performance-acceptable high conversion and hourly benzene yield. Thus rapid catalyst deactivation caused by unavoidable coke formation becomes the main problem to be overcome for its practical application [1-3]. Adding a small amount of CO2 or CO into feed is helpful in improving the catalyst stability [4], but the prolonged catalyst lifetime is still short and cannot meet practical requirements. Thus, developing a practically usable, continuous catalyst-regeneration technology becomes essential, and multi-bed fluidized bed reactor systems were proposed for realization of Mo/HZSM-5's continuous regeneration [1,3]

Recently a binder-free, fluidizable Mo/HZSM-5 catalyst with a high compressive strength of 850 kgf/cm^2 was developed by Meidensha Co., Japan. In this study, this catalyst was applied to the title reaction. Its catalytic performance was evaluated in either a micro fixed-bed reactor, or a micro fluidized-bed or a two-bed type circulating fluidized bed system at the practically required severe conditions of 1073 and 10,000 mL/g/h. The results have demonstrated that this catalyst can offer a long-term stable aromatics formation activity under either periodic or continuous regeneration mode.

2 Experimental

A binder-free, spherical-shaped 6%Mo/HZSM-5(S) catalyst was used for the present study, which was manufactured by spray-drying technique and supplied by Meidensha Co. Japan. Its average particle size was measured to be about 160 μm and its minimum fluidization velocity in N2 to be 0.7 cm/s. For comparison a self-prepared 6%Mo/HZSM-5 powder catalyst was also tested in this study. All activity tests were conducted in either a micro fixed-bed reactor (10 mm i.d.) or a micro fluidized-bed one (15 mm i.d.) or a two-bed type of circulating fluidized bed reactor system (35 mm i.d.) at 1073 K and variable space velocities.

3 Results and discussion

The catalytic performance of the binder-free catalyst was first compared with the self-prepared 100% HZSM-5 based powdery catalyst in the micro fixed bed reactor at a condition of 1073 K and 10,000 mL/g/h under a periodic 5 min CH4-10 min H2 switch operation mode. The results obtained revealed that the test binder-free catalyst can exhibits the same high activity and stability as the powder catalyst does, suggesting the spray-drying shaping process brings no

negative effect to this ball-milled crystals-based, fluidizable catalyst on its performance. Comparatively, a 17% pure silica-added Mo/HZSM-5 catalyst showed a very rapid deactivation at the same condition, suggesting the necessity of developing a practically usable binder-free catalyst.

Then a three-day long test was performed in the micro fluidized bed reactor at 1073 K and 11,000 mL/g/h under a periodic 5 min CH4-20 min H2 operation mode for the binder-free catalyst to confirm its long-term activity stability. This was a daytime test without any catalyst sample removed out the reactor during three days' test, and the second and third day's test was started at heating the catalyst sample in a H2 stream up to the reaction temperature and holding it at the temperature for one hour for its full regeneration. For this operation three well-repeated performance-time dependence curves were obtained, confirming that the catalyst can maintain its long-term stability as long as it is operated in a proper regeneration mode.

To obtain a most effective regeneration mode for maintaining its high activity a six-day daytime fluidized bed test was also conducted for the binder-free catalyst at variable daily regeneration cycles. The results revealed that rather than shortening the reaction duration of reaction-regeneration cycle extending the regeneration duration is more effective for keeping the initial high activity of the catalyst and also these results suggested that the reaction duration should be shortened within 30 min and the corresponding regeneration duration extended over 60 min.

Finally, the stable performance of the catalyst was confirmed in the self-developed, two-bed type of circulating fluidized bed reactor system at 1073 K and variable space velocities under continuous regeneration mode. Typical performance-time dependences obtained are shown in Fig. 1. A stable benzene yield of about 10% was obtained in a three-day test at 1073 K and under a continuous regeneration mode.

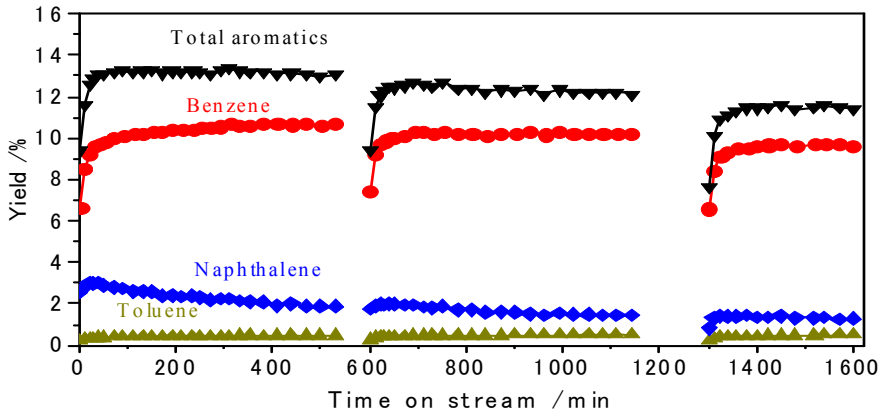

Fig. 1. Aromatics production yields reached over the fluidized binder-free catalyst in a three-day test under a continuous regeneration mode. Reactor T: 1073K and Regenerator T: 1073 K.

4 Conclusions

The fluidizable binder-free Mo/HZSM-5 catalyst enables a very high and stable aromatics production yield to be realized at 1073 K and under a continuous regeneration mode.

* Hilde.J.Venvik@ntnu.no

Keywords: DME, methanol synthesis, methanol dehydration, direct synthesis

1 Introduction

Dimethyl ether (DME) can be synthesized directly from synthesis gas using a dual catalyst system that permits both methanol synthesis (Cu-based catalyst) and dehydration (acidic catalyst) in a single process unit. While syngas conversion to methanol is thermodynamically limited, further conversion of methanol to DME allows higher single-pass conversion.

The objective of this work is to study the effect that combining methanol synthesis and methanol dehydration in a single reactor, can have on the catalytic performance. In order to do so, the influence of operating conditions (space velocity, temperature, pressure, time on stream and syngas composition) on the activity, selectivity and stability of the catalyst was studied and compared for the methanol synthesis, methanol dehydration and direct DME synthesis.

2 Experimental

The experiments were conducted in a stainless steel micro packed bed reactor-heat exchanger. The reactor consists of a 6 cm long reaction slit with rectangular cross section of 8.8×1.5 mm^2, sandwiched between cross flow channels for circulation of heat transfer oil. The reactor has already been tested under similar operating conditions for methanol [1] and direct DME [2] synthesis, and is established as practically isothermal, isobaric and free from mass transfer limitations, and to have a narrow residence time distribution. Catalyst, either conventionally prepared Cu-ZnO-based methanol synthesis catalysts, a commercial H-ZSM-5 or γ-alumina methanol dehydration catalyst, or a physical mixture of these, was packed into the reactor in a particle size range of 80-125 μm. Products were analyzed online using a gas chromatograph equipped with a TCD and a FID. Experiments were conducted at temperature, pressure and space velocity ranges of 210-270°C, 10-50 bar and 150-800 Nml/(min×gr catalyst), respectively.

3 Results and discussion

Figure 1 illustrates the product yields for methanol synthesis and direct DME synthesis under identical operating conditions. The direct DME synthesis experiment was performed using a hybrid catalyst with excess amount of the dehydration component. Therefore, almost all the methanol formed was converted further to DME, i.e. the overall synthesis was controlled by methanol formation. Accordingly, the space velocity is based on the weight of the methanol synthesis catalyst for both experiments. As expected, at higher temperatures, syngas conversion and product yield are limited thermodynamically in the methanol synthesis experiment, while product yield continues to increase with temperature in the direct DME synthesis, for which the equilibrium product yield is much higher.

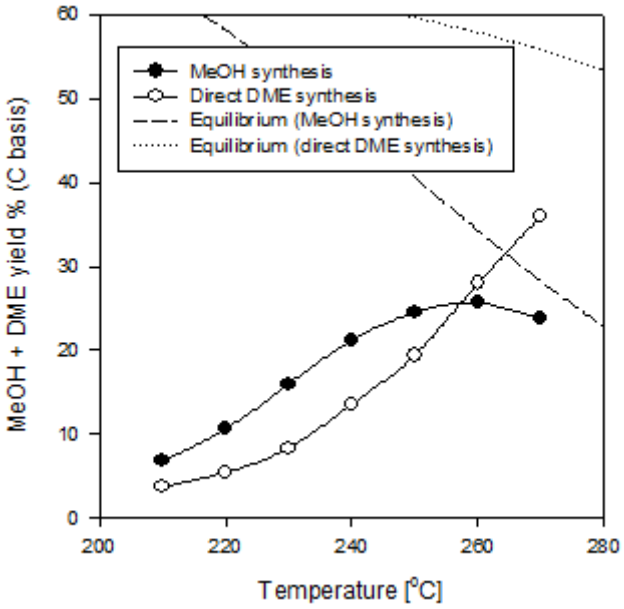

Fig. 1 Product yields against reaction temperature for methanol synthesis and direct DME synthesis, under identical SV (based on methanol synthesis catalyst weight), P=50 bar, and syngas composition $H_2/CO/CO_2/CH_4/N_2$: 56/28/5/6/5 mol%.

Apart from the apparent synergistic benefit when thermodynamics is a limiting factor, the results suggest that combining methanol synthesis and dehydration in a single reactor has a negative effect on the methanol formation kinetics. That can be observed as a lower product yield in the direct DME experiment (also lower methanol formation rates, as space velocities are identical) at lower temperatures where the effect of the reverse reaction on methanol synthesis is smaller. The apparent activation energy of methanol formation seems, however, similar for both experiments in the kinetic regime and have been estimated to 85-86 kJ/mol. Similar conclusions can be drawn using different dehydration catalyst and also under a synthesis gas with a H_2/CO molar ratio of 1.

The origin of the observed phenomena will be further discussed and investigated, including the possible inhibition by the dehydration products. Such effects are being studied by introducing DME and water to the feed of the methanol synthesis reaction.

Methanol to Hydrocarbons over ZSM-5: Diffusion and the External Particle Surface

Erickson J.K.[1], Baucherel X.[2], Gladden L.F.[1*]

1 - University of Cambridge, Department of Chemical Engineering and Biotechnology, Cambridge, United Kingdom

2 - Johnson Matthey Technology Centre, Chilton, Billingham, United Kingdom

Keywords: ZSM-5, methanol-to-hydrocarbons, MTO, external surface, diffusion, zeolites

1 Introduction

The methanol to hydrocarbons process (MTH) is a valuable means by which to balance the use of fossil and renewable resources, providing a wide range of hydrocarbons from either renewable or fossil-derived methanol. MTH technology can contribute to addressing the current global propene shortage associated with shale gas growth and the expansion of coal-to-liquid in China, whilst also being an integral part of a future renewable methanol-based economy as proposed by Olah et al. [1]. ZSM-5 is the most extensively used catalyst for MTH. The reaction has been shown to proceed via the hydrocarbon pool mechanism, where polyalkylated aromatics and larger olefins form within zeolite pores and combine with acid sites to form a hybrid catalyst [2]. The mechanism consists of two catalytic cycles: one in which olefins are repeatedly methylated to form branched species, and another involving the methylation and dealkylation of aromatics to form light olefins. The selectivity towards certain products such as ethene can be used to measure the propagation of these olefin and aromatic-based cycles [3].

An established modification of ZSM-5 catalysts is the deactivation of non-shape selective acid sites on the external particle surface, commonly achieved via post-synthesis deposition of silicon alkoxides. This work describes for the first time the effect of chemical liquid deposition of tetraethyl orthosilicate (TEOS) on ZSM-5 for use as a catalyst in the MTH reaction. We have studied the roles of the external zeolite surface and diffusion in affecting the conversion, selectivity and deactivation of the MTH reaction.

2 Experimental

ZSM-5 zeolites H-Z41 and H-Z81, with similar crystallite sizes of ~70nm but different SiO_2:Al_2O_3 ratios (41 and 81, respectively) were supplied by Johnson Matthey plc. H-Z41 was silylated with TEOS in three cycles to give Sil-Z41, using the chemical liquid deposition method reported elsewhere [4]. In addition to standard techniques such as temperature-progammed desorption of ammonia and collidine, ^{29}Si and ^{27}Al MAS NMR, N_2 soprtion, and infrared spectroscopy, the effect of silylation on adsorption capacity and access of reactants to the internal pore structure was investigated using a tapered element oscillating microbalance and pulsed field gradient NMR. MTH catalyst testing was performed using a 3 mm inner-diameter quartz microreactor at 350 °C with a WHSV of 24 h^{-1} and monitored with online gas chromatography.

3 Results and discussion

Silylation of H-Z41 caused a 18 % decrease in acidity primarily due to the loss of external acid sites, while H-Z81 had a 44 % lower acidity compared to H-Z41 due to its reduced aluminium content (Table 1). In MTH catalyst testing, selectivity to ethene was the same for H-Z41 and H-Z81 but was doubled in the case of Sil-Z41, representing a shift towards the

aromatic-based mechanism. While the catalytic lifetime of H-Z81 was almost double that of H-Z41, silylation caused the lifetime of H-Z41 to decrease by approximately half (Figure 1).
In addition to reducing acidity, silylation has been shown to cause narrowing of zeolite pore mouths [5]. This will cause a shift towards smaller products by restricting the diffusion of larger molecules leaving the pores, and also a decrease in lifetime by making pores more susceptible to blockage by polyaromatics and coke deposits. Through a variety of characterisation techniques, we have found that the diffusion of larger hydrocarbons in silylated ZSM-5 is inhibited and that the MTH reaction proceeds in the absence of active sites on the external zeolite surface.

Table 1. Properties of ZSM-5 catalysts used for MTH

Zeolite	Form	Acidity (mmol/g)	Ethene selectivity
H-Z41	activated H+	0.63	9 %
Sil-Z41	silylated	0.52	18 %
H-Z81	activated H+	0.35	9 %

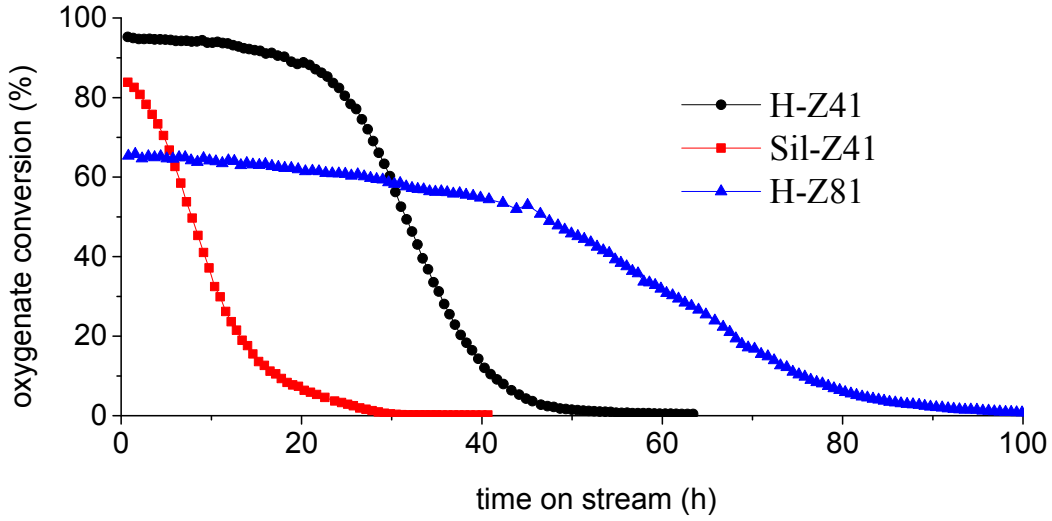

Fig. 1. Oxygenate conversion in the MTH reaction as a function of time on stream, catalysed by zeolites H-Z41, Sil-Z41 and H-Z81.

4 Conclusions

These findings suggest that catalytic activity in the MTH reaction is confined to the internal pore space of ZSM-5, while pore mouth narrowing shifts the product distribution towards smaller products and increases the rate of deactivation due to coke formation.

Insights in the Reaction Mechanism for HMF Oxidation to FDCA over Bimetallic Au/Pd Nanoparticles

Cavani F.[1*], Lolli A.[1], Utili L.[1], Amadori R.[1], Lucarelli C.[1,2], Albonetti S.[1]

1 - Dipartimento di Chimica Industriale "Toso Montanari", Università di Bologna, Bologna, Italy
2 - Università dell'Insubria, Como, Italy

* fabrizio.cavani@unibo.it

Keywords: HMF, 2,5-Furandicarboxylic acid, Pd–Au nanoparticles, Cannizzaro reaction

1 Introduction

Furandicarboxylic acid (FDCA) has been suggested as an important renewable building block for the synthesis of polymers, alternative to those obtained from terephthalic acid. As an example, the Avantium Company is using FDCA to produce polyethylene furandicarboxylate. The exact route for producing FDCA has not yet been disclosed but the current technology for terephthalic acid production using metal/bromide catalysts is probably being evaluated [1]. One drawback of these systems is the use of corrosive and dangerous compounds, which make the process polluting. Moreover, there are concerns regarding the purity of both the product and the final polymer. Recently Au-supported catalysts have been found to be very active for 5-hydroxymethylfurfural (HMF) oxidation to FDCA [2,3]. So far, catalyst stability and productivity on this type of catalysts are low but the possibility to obtain high product purity and process sustainability makes this approach highly interesting for the future.

2 Experimental part

Au/TiO_2, Pd/TiO_2, and $Au\text{-}Pd/TiO_2$ catalysts were prepared by the immobilization on the TiO_2 surface of the preformed monometallic and bimetallic colloids [4]. Core-shell nanoparticles were prepared from a monometallic system (Au or Pd) which had been used as seed for the nucleation of the second metal. The oxidation of 5-hydroxymethyl-2-furfural (HMF) was carried out using an autoclave. The reactor was charged with an aqueous solution containing the appropriate amount of HMF, base (NaOH), and catalyst (HMF/metal molar ratio = 100).

3 Results and Discussion

The attention has been mainly focused on the role played by the active phase in the reaction mechanism. The comparison of the activity of systems with different Pd/Au molar ratio indicated that the production of FDCA and different intermediates was strongly dependent on Pd and Au content (Figure 1). $Pd\text{-}TiO_2$ was poorly selective to FDCA because of its inability to transform the 5-hydroxymethyl-2-furancarboxylic acid (HMFCA) intermediate. Conversely, an increase in FDCA selectivity was observed increasing the gold content, especially for the sample which has Pd/Au molar ration of 1:6. Therefore, a small quantity of Pd seems to be adequate to strongly change the electronic properties of gold phase and to enhance the catalytic activity in alcohol oxidation. The catalytic activity of Pd-Au catalysts was strongly affected by thermal treatments, suggesting some modifications on the Pd-Au alloy. The segregation of Pd on the outer part of bimetallic nanoparticles might explain the modification of the path for FDCA formation, making it more similar to the one observed with the monometallic Pd. Indeed, calcined Pd/Au material was unable to transform molecules containing the –COOH functional group, such as HMFCA and 5-formyl-2-furancaboxylic acid (FFCA) intermediates. PVP-protected Pd-Au nanoparticles with different structures (alloy and core-shell) were tested in the

reaction in order to confirm the different HMF oxidation mechanisms depending on whether the active phases preferentially expose Pd or Au atoms (Figure 2A and 2B). Moreover, the Cannizzaro-type disproportionation was demonstrated to be involved in FDCA formation with some of the studied systems, indicating that this reaction must be taken in account when studying the furanic aldehydes reactivity.

Noble Metal Nanoparticles Supported on Carbon-Based Materials as Catalysts for 5-HMF Oxidation to FDCA

Nese V., Schüth F.*

Max-Planck-Institut für Kohlenforschung, Mülheim an der Ruhr, Germany

* schueth@mpi-muelheim.mpg.de

Keywords: 5-HMF, FDCA, oxidation, noble metals, polyacrylate

1 Introduction

2,5-furandicarboxylic acid (FDCA) has been identified as a building block chemical for the production of bio-based polyesters and polyamides [1]. In fact, this molecule can be produced by 5-hydroxymethylfurfural (5-HMF) oxidation, which is obtained from sugars like fructose and glucose through a dehydration step.

The selective oxidation of 5-HMF to FDCA with molecular oxygen in water is a green alternative to the use of stoichiometric oxidants and processes occurring in organic solvents. The addition of a base is often necessary to achieve high FDCA yields, since the presence of hydroxide ions in the reaction mixture facilitates the oxidation of both the aldehyde and methyl-alcohol groups of 5-HMF. Additionally, it improves the solubility of the final product.

2 Experimental/methodology

In the present study, 5-HMF oxidation was performed in a 50 mL stainless-steel autoclave, in the presence of noble metal (Pt, Pd, Ru, Au) catalysts supported on porous carbon and polymeric materials. The standard reaction conditions used were 100°C, 8 bar O_2, and $NaHCO_3$ was added to the reaction mixture as the base (pH 9).

3 Results and discussion

In a first series of experiments, commercial Pt(5%)/C, Ru(5%)/C and Pd(5%)/C were used as catalysts for 5-HMF oxidation: the highest reaction rate was observed in the presence of Pt(5%)/C (full conversion was reached after 2 hours) and 91% of FDCA was obtained after 24 hours reaction time. Using Pd(5%)/C, high selectivity towards the intermediates of HMF oxidation was achieved, but the conversion and FDCA yield were 87% and 13% after 24 hours, respectively. Ru(5%)/C yielded large amounts of unidentified by-products from the early stages of the reaction.

Two Au(5%)/C catalysts were prepared with two different methods that resulted in different particle size distributions: when the carbon was impregnated with a solution of the metal precursor and subsequently reduced, very small particles were observed in the TEM images; when the metal nanoparticles were pre-formed in solution using PVA as stabilizer and deposited on the carbon support, Au particles with a diameter between 2 and 5 nm were achieved. As shown in Fig. 1, only particles with dimensions above a certain size are active for 5-HMF oxidation: only the material with bigger particles was showing a high reaction rate and yielding 95% FDCA after 8 hours.

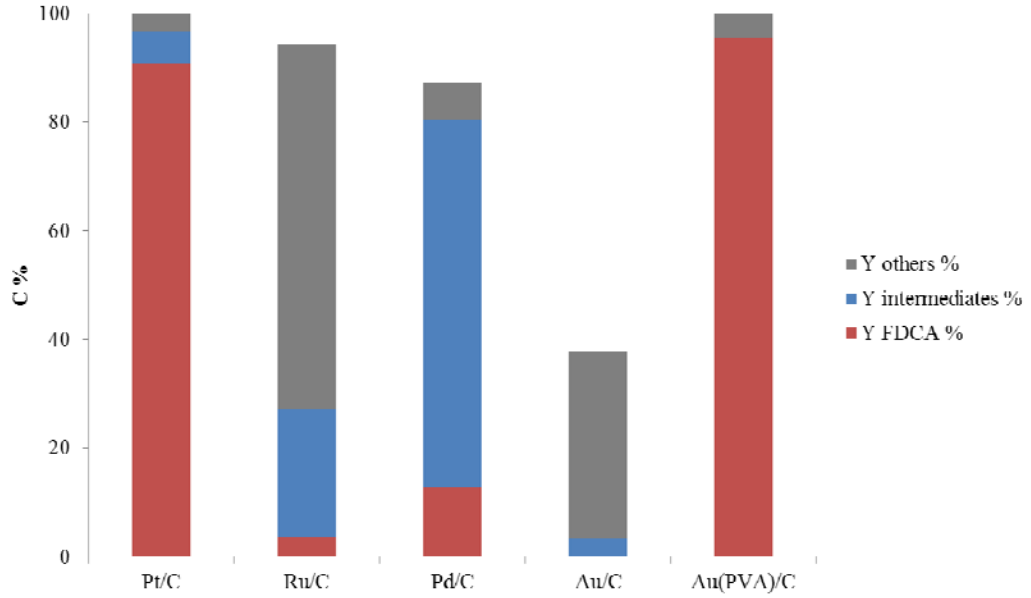

Fig. 1. Conversion of 5-HMF and yield of products after 24 hours of reaction

Two metal precursors ($Pt(NH_3)_4(NO_3)_2$ and $Ru(NH_3)_6Cl_3$) were ion-exchanged on commercial PS-DVB sulfonated polymers (Amberlyst 35 and Amberlyst 70) and the reduction of the noble metal was performed with $NaBH_4$ solution or under H_2 pressure, yielding particles with dimensions above 15-20 nm in all the materials. The low activity of these catalysts pointed out once again the importance of the metal particle size.

Since 5-HMF is an unstable product formed by the dehydration of hexoses, it would be desirable to perform FDCA synthesis in one-pot reaction starting from sugars like fructose and glucose. Unfortunately, direct oxidation of these two reactants can occur already at room temperature in the presence of noble metals like Au or Pd [2]. A study on fructose dehydration revealed that a series of highly hydrophilic sulfonated polyacrylates (DAE25) is inaccessible to the reactant, but at the same time it suppresses further degradation of 5-HMF to levulinic acid, one of the most abundant side products. As a matter of fact, no levulinic acid was formed when these polymers were present, while 44% of this by-product was obtained when Amberlyst 35 was used, the most active among a series of commercial PS-DVB sulfonated polymers. Therefore, these polyacrylates materials could be ideal supports for the preparation of catalysts suitable for the one-pot reaction from fructose to FDCA.

4 Conclusions

Pt, Pd and Au supported on carbon showed high selectivity towards the products of 5-HMF oxidation. Among them, Au(PVA)/C with particle size between 2 and 5 nm gave the best performance, yielding 95% FDCA after 8 hours of reaction. The study underlines the importance of particle dimensions in the preparation of an active catalyst. A study on fructose dehydration showed that a series of polyacrylates polymers (DAE25) could be a suitable support for the synthesis of a catalyst for the production of FDCA directly from fructose.

Catalytic Applications of Palladium Nanoparticles-Supported Nanocomposites in Carbonylation Reactions

Zhu Y.*

Institute of Chemical and Engineering Sciences, Singapore

* zhu_yinghuai@ices.a-star.edu.sg

Keywords: nanocatalyst, palladium nanoparticle, nanocomposite, carbonylation

1 Introduction

Supported palladium nanoparticles (Pd NPs) have been widely used as efficient catalysts in organic conversions such as Suzuki-Miyaura cross-coupling reactions due to their high activity and recyclability [1,2]. We have successfully loaded Pd-NPs on metal organic frameworks (MOF), cyclic poly(*L*-lactide)-clay, carbon nanotubes and graphene oxides to form Pd-NPs-supported nanocomposites [3-7]. The as-prepared nanocomposites have been used as catalysts for carbonylation of various aryl halides to form corresponding amides and ketones, repectively (see Eqs 1-2). These catalysts show high activity and good recyclability. Detail synthesis methods and activity will be presented.

$$Ar–X\ (X = Cl, Br, I) + CO + HNRR' \rightarrow Ar–CO–NRR' \quad \text{(Eq 1)}$$

$$Ar–I + CO + Ar'–B(OH)_2 \rightarrow Ar–CO–Ar' \quad \text{(Eq 2)}$$

2 Experimental

Pd NPs-supported catalysts were synthesized via reduction precursors of M_2PdCl_4 (M = H,K) or $PdCl_2(PhCN)_2$ by sodium borohydride, hydrazine or ethylene glycol, respectively [3-7] in the presence of corresponding supports. The supported catalysts were dried in vacuum to a constant weight before using. The resultant catalysts were fully characterized by XRD, TEM, XPS, TGA, FT-IR and ICP to identify the catalyst morphology, oxidation state and loading amount.

Aminocarbonylation reactions between aryl halides and amines were carried out at a temperature of 105°C, 120°C and 130°C, respectively. Various CO feeding pressures (1.0, 10.0, 10.3 and 12.4 bar) were examined [3-7]. K_2CO_3 (1~2eq) was used to promote the reactions.

Carbonylation reactions between arylboronic acids and aryl halides were carried out in anisole in the presence of base K_2CO_3 at a CO pressure of 6.9 bar [3].

All the products were separated either by flash chromatography or by thin layer chromatography and characterized by ^1H, ^{13}C NMR spectroscopy.

3 Results and discussion

Pd NPs-supported catalysts were easily prepared by conventional reducing processes. In general, the obtained Pd NPs were small, less than 5nm, and well dispersed according to TEM images as shown in **Figure 1**. Aminocarbonylation of aryl halides were carried out catalyzed by above supported palladium catalysts. Some results are listed in **Scheme 1 (a)** [6]. The catalysts showed high activity for aryl iodides, up to 98% yield was reached. Aryl bromides and chlorides are relatively inert. Amides products were obtained in medium to high yields under the same conditions. The carbonylation of aryl iodides lead to the formation of new carboranylaryl ketones in 51-83% isolated yields as summarized in **Scheme 1 (b)** [3].

4 Conclusions

Supported Pd NPs based heterogeneous catalysts are stable and recyclable with high activity for aminocarbonylation and carbonylation reactions to form corresponding amides and ketones. The catalysts are able to tolerate a wide scope of functional groups to synthesize various carbonyl compounds which are potentially important in pharmaceutical industry and fine chemistry. We are expecting their wide applications in industry.

Keywords: green nanoparticles, lignin, palladium, platinum, isomerization, hydrogenation

1 Introduction

Chemoselective catalytic hydrogenation of α,β-unsaturated alcohols, aldehydes/ketones or alkenes is a demanding task for the flavour, fragrance and pharmaceutical industries. Metal nanoparticles (NPs) are good candidates as catalysts for this purpose thanks to their peculiar properties such as the high surface-to-volume ratio and the size-dependent electronic structure.

Pd and Pt NPs, synthesised in water by a simple and green way (20 °C, 1 atm), employing lignin as stabilizing/reducing agent, are able to catalyse oxidation, reduction and C-C cross coupling reactions.[1,2] Lignin is a widely available by-product of wood and paper industry.

2 Experimental

Lignin stabilized Pd and Pt nanoparticles were prepared and characterized in accordance with our previous work[1].

For the hydrogenation reactions we operated as follow: 15 mL of water was placed into an hermetically closed 20 mL vial; after a purging step with H_2, 0.3 mmol of the substrate was added and then 100 µL of Pd NPs (0.56 µmol of Pd) or Pt NPs (0.97 µmol of Pt) solution was introduced. The reaction mixture was left under static H_2 atmosphere at room pressure and temperature (20 °C) and stirred for 24 h.

3 Results and discussion

We prepared and characterized a series of twelve NPs using two metals (Pd and Pt) with different water-soluble lignins: Kraft lignin (KrLig), ammonium lignosulphonate (AmLig), calcium (CaLig) and sodium (NaLig) lignosulphonates and the corresponding low-sugar ones (CaROLig and NaROLig).

Pd NPs have spherical shape (15-25 nm) while Pt NPs are irregular and smaller (7-12 nm), as revealed in TEM images.

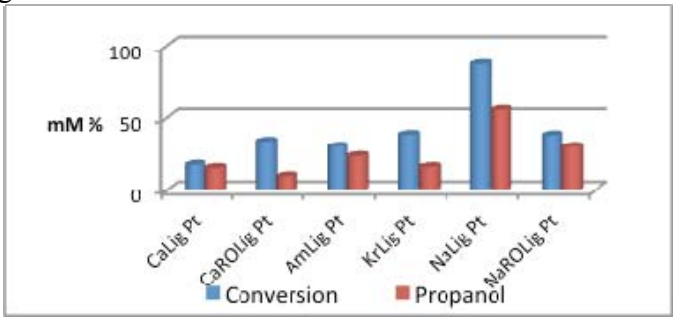

Fig. 1. Conversion of allyl alcohol and products formation in presence of Pd NPs

We investigated the different catalytic activity of Pt and Pd NPs towards the hydrogenation

of allyl alcohols in mild conditions (water media, room T and P, H_2 atmosphere).

The conversion of allyl alcohol with Pd NPs was quantitative unless with NaLig Pd (47% conversion). However, the main reaction product was propionaldehyde, the isomerization product[3] (Fig. 1).

At the contrary, when we put allyl alcohol with Pt NPs, 1-propanol was the only detectable product inside the aqueous solution (by ^{1}H NMR) (Fig. 2). However, analysing the headspace of the reaction vessels (by GC-MS) we found both hydrocarbons, namely propene and propane.

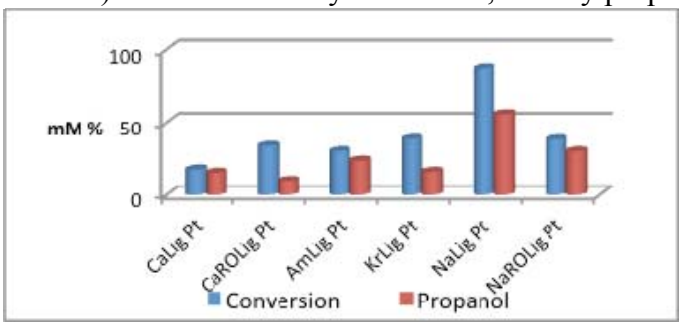

Fig. 2. Conversion of allyl alcohol and product formation in presence of PtNPs

To best understand if and how the substitutions on the sp^2 carbon of allyl alcohols address the reaction to isomerization or to the double bond hydrogenation, we tested also crotyl alcohol and 3-methyl-2-buten-1-ol. Comparing the data, with both metal NPs, we observed lower conversions when allyl alcohol is the reactant, while 3-methyl-2-buten-1-ol always showed the higher reactivity (Fig. 3).

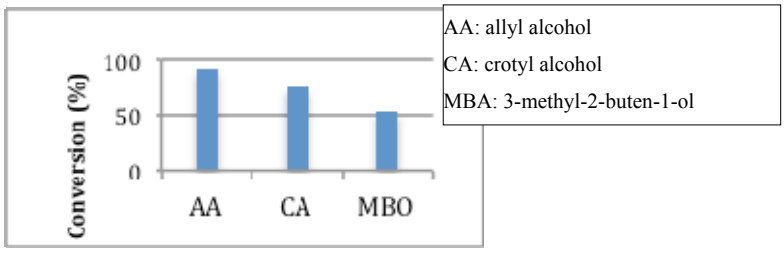

Fig. 3. Conversions of alcohols in presence of PdNPs

4 Conclusions

In presence of Pd NPs, we observed always C=C hydrogenation, isomerization and double bond migration products; in the case of Pt NPs only saturated alcohols and hydrocarbons were detected.

We are extending our work testing NPs for hydrogenation of unsaturated non-allyl alcohols, like butenol and pentenol, to obtain important saturated alcohols, useful for chemical industry as well as promising alternative fuels.

Keywords: carbohydrate, biomass, diffusion, limitations, Sn-zeolites, sustainable chemistry

1 Introduction

Lignocellulosic biomass is expected to become an important future feedstock for sustainable production of chemicals and fuels. The isomerization of carbohydrates is a key transformation in all selective glucose conversion schemes. Such reactions can be catalyzed using Lewis acidic materials. To date, Sn-BEA zeolite has been identified as one of the most promising catalysts for aldose to ketose isomerization. The origin of the unique reactivity of this catalyst is not well understood yet. A recent theoretical study has indicated that the topology of zeolite catalyst does not influence the intrinsic activity of Sn-centers in its framework, while it may strongly influence the transport of reagents and products through the micropores to and from the active sites [1]. Here, we present the first experimental study on the role of transport phenomena on the catalytic activity of Sn-BEA in sugar isomerization by in situ solid state ^{13}C MAS NMR spectroscopy complemented by kinetic experiments. To validate the theoretical predictions and understand the role of zeolite topology, the catalytic performance of Sn-functionalized BEA, MOR, and MCM-22/ITQ-2 for isomerization of 1,3-dihydroxyacetone (DHA) and D-glucose was investigated.

2 Experimental/methodology

Hydrothermal synthesis of Sn-BEA zeolites (Sn-BEA-HF) was carried out according to the procedure reported by Corma et al. [2]. Post-synthetic modification of zeolites with framework Sn was done following a procedure recently developed in our laboratory [3]. Prior to Sn introduction, the zeolite (MOR, MCM-22/ITQ-2, BEA) was dealuminated by treatment with 65% HNO_3 at 110°C overnight. After drying (3h, 170°C), Sn-functionalization was carried out by dry impregnation with anhydrous $SnCl_4$ at 100°C for 16 h. Excess $SnCl_4$ was removed by extensive washing with methanol. The materials were calcined at 550°C for 5 h (1 K/min). In-situ NMR measurements were carried out by impregnation of the zeolite with a solution of $^{13}C_1$-labeled glucose in D_2O (Sugar:Sn ratio = 5) followed by evacuation for 15 min.

3 Results and discussion

We compared the conversion of $^{13}C_1$-labeled glucose by in-situ solid state ^{13}C NMR in a time-resolved manner directly after impregnation of the reactant in dehydrated and hydrated Sn-BEA. The NMR results are shown in Figure 1. The reaction occurs already at room temperature when the sugar was brought into contact with the dehydrated zeolite (Fig 1a). On contrary, when labelled glucose was brought into contact with a hydrated Sn-BEA zeolite, the reaction proceeded much slower (Fig. 1b). It is interesting to mention that the reaction rate was negligible, when this reaction was carried out in a batch reactor using water as the solvent. These findings strongly indicate that the exchange of the solvent molecules in the micropores with the glucose reactant molecules is slow and to some degree limits the reaction rate. Accordingly, we argue that counter-diffusion limits the catalytic reactivity of Lewis acid zeolite catalysts for glucose activation.

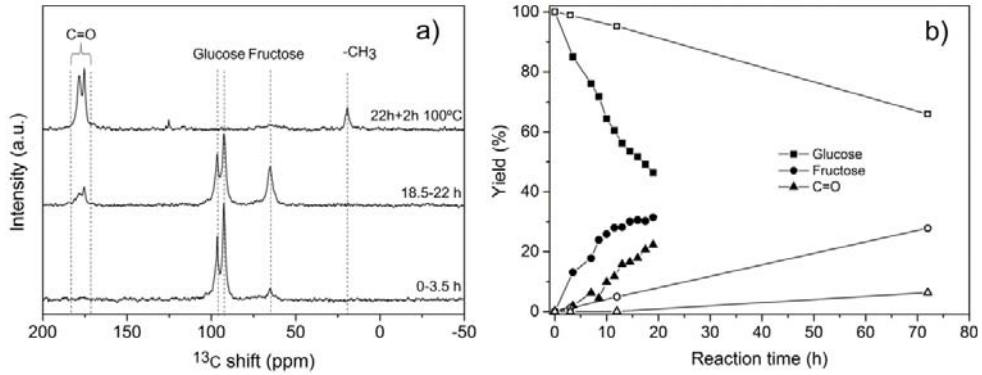

Figure 1. a) Conversion of $^{13}C_1$-glucose over Sn-BEA at room temperature; b) Conversion of $^{13}C_1$-glucose over dehydrated (closed symbols) and hydrated (open symbols) Sn-BEA.

We further investigated the importance of diffusion limitations by evaluating the catalytic reactivity of a series of Sn-modified zeolites with different topologies in the conversion of dihydroxyacetone and D-glucose. The results summarized in Table 1 show that the activities of Sn-containing 10MR zeolites (MCM-22 and ITQ-2) are lower than those of Sn-BEA and Sn-MOR. This can be correlated to the difference in pore diameter. Compared to the negligible rate of glucose conversion in the 10MR zeolites, the smaller 1,3-dihydroxyacetone is more readily converted in Sn-MCM-22 and Sn-ITQ-2, albeit at a lower rate than in Sn-BEA.

Table 1. Assessment of the catalytic performance of selected Sn-functionalized zeolites

Catalyst	d_{pore} (Å)	Si/Sn	$Yield_{ML}$ (%)[1)]		Glucose isomerization[2)]		
			70°C	90°C	Glucose (%)	Fructose (%)	Mannose (%)
Sn-MCM-22	5.5	70	25	69	>99	<1	<1
Sn-ITQ-2	5.5	36	32	71	>99	<1	<1
Sn-MOR	6.5	35	<1	14	90	10	<1
Sn-BEA-PS	6.7	80	92	98	31	29	5

[1)] Conversion of 1,3-dihydroxyacetone in methanol. 2h, 2.5 mL 0.25 M solution, 40 mg cat.
[2)] Glucose conversion at 100°C for 6h, 2.5 mL 125 mM in water, 40 mg cat.

4 Conclusions

^{13}C NMR measurements show that glucose isomerization can take place in the micropores of Sn-BEA at room temperature. Under practical conditions, the catalytic reaction rate is limited by the exchange of the solvent molecules for reactant molecules. Thus, we conclude that diffusion limitations may play a much more important role in glucose isomerization than assumed before. In keeping with this, framework Sn Lewis acid sites in 10MR zeolites such as MCM-22 convert glucose at much lower rate than in 12MR zeolites such as MOR and BEA. Compared to glucose, 1,3-dihydroxyacetone is more readily converted in the 10MR zeolites.

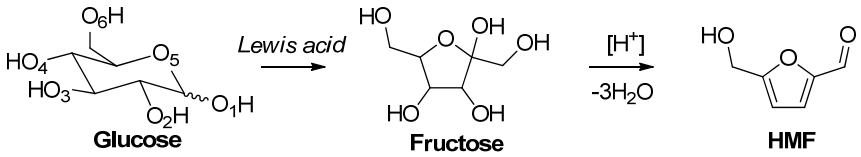
Keywords: biomass, reaction mechanism, zeolites, metal oxides, bifunctional catalysis, DFT calculations

1 Introduction

Efficient utilization of cellulosic biomass as a feedstock for future more sustainable chemical industry requires the development of new technologies for the selective conversion of carbohydrates to platform chemicals such as 5-hydroxymethylfurfural (HMF). While a number of homogeneous and heterogeneous catalysts can be used to selectively convert fructose [1], the activation of the more abundant glucose isomer is much more difficult. To achieve high HMF yields, glucose has to be selectively isomerized to fructose before the dehydration starts (Scheme 1). Recently, a number of catalytic systems capable of promoting such a reaction sequence has been introduced [1,2]. These include homogeneous ionic liquid-mediated Cr (II) and (III) chlorides [2,3] and heterogeneous Sn-BEA zeolite and WO_3 oxide catalyst [1,4]. The fundamental factors that determine the high reactivity of these very different systems have not been clarified yet. In this work we carried out a comprehensive computational study of the mechanism of glucose activation by these systems aiming at elucidation of the common features that render them efficient catalysts for the conversion of carbohydrates.



Scheme 1. Glucose conversion to HMF.

2 Experimental/methodology

Periodic DFT calculations on glucose conversion by zeolite and bulk oxide catalysts were carried out using the DFT plus damped dispersion (DFT-D3) approach with PBE exchange-correlation functional and plane-wave basis set as implemented in VASP 5.2 program. Explicit solvent (H_2O) molecules were introduced in the model to evaluate the impact of solvent-assisted reaction routes. The electron-ion interactions were described by the projected augmented wave (PAW) method. The energy cut-off was set to 400 eV. A complete unit cell of BEA zeolite and a slab model of modified WO_3 oxide surface were used as the models [5]. A detailed description of the computational methodologies used can be found in ref. [5].

3 Results and discussion

DFT calculations show that the selective sugar paths by Sn-BEA and WO_3-based catalysts are initiated by the reversible deprotonation of the O1H hydroxyl group of glucose by basic lattice oxygen centres adjacent to the catalytically active Lewis acid site. The latter binds the

activated sugar residue and directs its further transformations along the catalytic cycle. Because of only a minor energy difference between different possible glucose coordination modes, they rapidly interconvert under the reaction conditions.

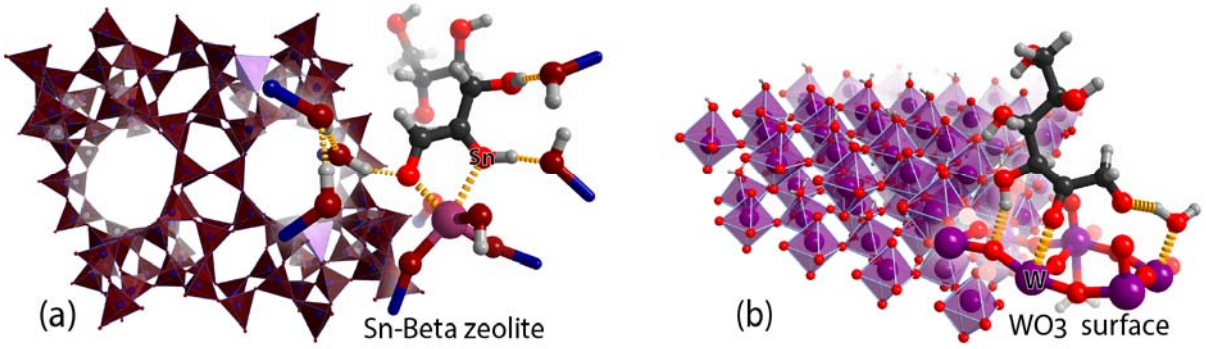


Figure 1. Representative structures of the key intermediates in glucose isomerization by (a) Sn-BEA zeolite and (b) WO_3 oxide.

The subsequent H-shift reaction upon which the aldose intermediate is transformed into the keto form is identified as the rate-determining step in the isomerization reaction. DFT calculations demonstrate that the unique reactivity of Sn-BEA zeolite and WO_3 catalyst stems from the dynamic and cooperative action of their active sites towards selective sugar transformations (Figure 1). The concerted action of lattice Sn site and neighbouring proton donors (adsorbed water or silanol groups) confined in Sn-beta micropores is essential to establish a favourable path for glucose to fructose isomerization [5]. A similar cooperative mechanism involving a synergetic action of surface hydroxyls and Lewis acid sites on WO_3 surface provides a low energy path for glucose isomerization.

4 Conclusions

A comprehensive DFT study of the mechanism of glucose isomerization by Sn-BEA zeolite and surface of WO_3 oxide reveals the crucial role of active site coopearativity for the efficient sugar transformations by these systems. The favourable reaction mechanisms involve a synergetic action of the Lewis acidic sites and neighbouring proton donors at the rate-determining H-shift step. The proposed mechanisms closely resemble the way homogeneous catalysts and enzymatic systems promote such a reaction. The activation of glucose by bio- and chemocatalysts involves the dynamic and cooperative action of their active sites towards selective glucose transformation. These fundamental insights pave the way towards a generic reactivity concept of carbohydrate activation.

Keywords: Sn-Beta, zeolites, heterogeneous catalysis, biomass, alkali effect, mesoporous materials

1 Introduction

Tin-containing silicates have interesting catalytic properties in a variety of reactions relevant for biomass conversion such as the isomerization of glucose to fructose and the conversion of sugars to methyl lactate (ML).[1-2] Sn-Beta is often reported as being one of the most active stannosilicate catalysts; however the main challenge in the utilization of Sn-Beta is that the yield of desired products is often quite low. The presence of alkali ions is known to greatly influence the synthesis of metallosilicate materials and has been shown to change the catalytic properties of the resulting zeotype catalyst depending on the reaction system.[3-5]

2 Experimental/methodology

Conversion of carbohydrates to ML was performed in a stainless steel autoclave. Reaction conditions: 0.450 g sucrose, 0.150 g catalyst, 15 g methanol containing K_2CO_3, 170˚C, 16 hours.

3 Results and discussion

Here is reported that the presence of alkali salts during conversion of sugars with stannosilicates have a drastic impact on the resulting yields of ML.[6] Sn-Beta prepared either by hydrothermal synthesis (HT Sn-Beta) or by post-treatment of dealuminated Beta zeolite (PT Sn-Beta) in the absence of alkali metal salts, results in a poor ML yield of 20-30 % (Fig. 1). When adding small amounts of alkali salts either during synthesis or directly to the reaction media, the yield increases to 66-75%.

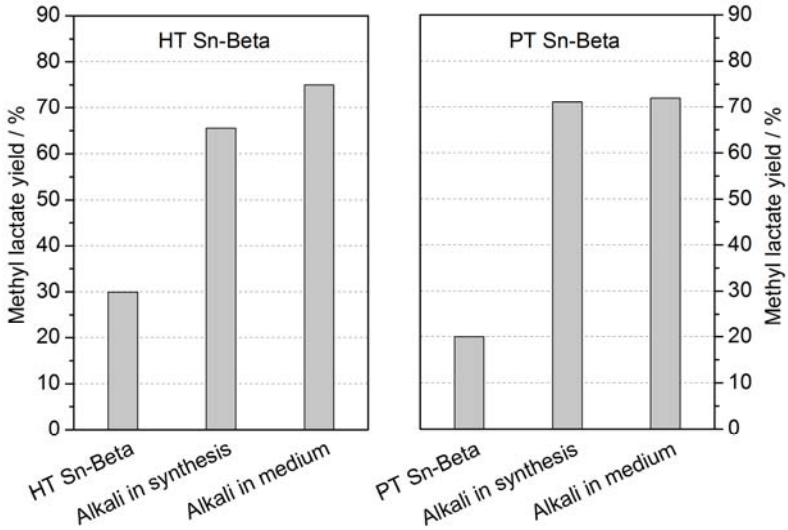

Fig. 1. Yield of methyl lactate obtained from sucrose in the presence and absence of alkali metal salts when using Sn-Beta zeolites prepared by hydrothermal synthesis (HT Sn-Beta) or by post-treatment of a dealuminated commercial zeolite (PT Sn-Beta).

It was observed that all alkali salts improve the selectivity of ML. The specific concentration of alkali salt is important, as a clear optimum is seen at distinct concentrations, varying for different samples of Sn-Beta (Fig. 2). Furthermore, it was found that the effect could be expanded to non-zeolithic stannosilicates such as Sn-MCM-41 and Sn-SBA-15.

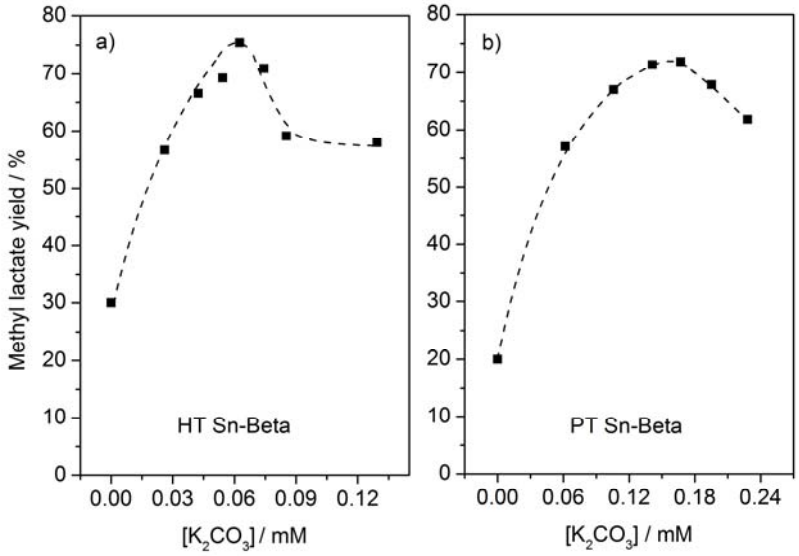

Fig. 2. The methyl lactate yield obtained from sucrose using HT Sn-Beta (a) or PT Sn-Beta (b) versus the concentrations of K_2CO_3 in methanol.

4 Conclusions

The experiments show that the total amounts of alkali metal ions present in the reaction, both in the catalyst and in solution, is essential to reach a high ML yield. The effect is not exclusive to hydrothermally prepared Sn-Beta, but can be applied to both materials prepared by post-synthesis and expanded to other non-zeolithic structures. These findings make it possible to expand on the catalyst portfolio and get a better understanding of the reaction system.

Mg-Al Hydrotalcites with Tailored Structure as Efficient Catalysts for Glucose Isomerization into Fructose

Delidovich I., Palkovits R.*

Chair of Heterogeneous Catalysis and Chemical Technology, RWTH Aachen University, Aachen, Germany

* palkovits@itmc.rwth-aachen.de

Keywords: hydrotalcite, glucose, fructose, solid base, isomerization

1 Introduction

Cellulosic biomass is an attractive renewable resource that can be converted into value-added products via hydrolysis giving glucose (Glu). A further efficient valorization of Glu requires its isomerization into fructose (Fru) in order to increase the reactivity of the carbohydrate feedstock [1]. Isomerization of Glu into Fru is a catalytic process with the yield of Fru in water thermodynamically limited to ca. 50%. The maximal yield attainable to date in the presence of a solid catalyst is ca. 30%. In this work we consider one of the most promising solid catalysts for isomerization, namely Mg-Al hydrotalcite (HT) in carbonate form. HTs are layered double hydroxides with the general formula $[Mg_{1-x}Al_x(OH)_2]^{x+}(CO_3)_{x/2}\cdot mH_2O$ where Mg^{2+} ions are partially substituted by Al^{3+} in the brucite-type layers; $0.17<x<0.34$. This work aims at elucidating correlations between structure and catalytic performance of HTs [2].

2 Experimental part

HTs were prepared by co-precipitation of solutions containing $Al(NO_3)_3$+$Mg(NO_3)_2$ and $NaOH$+Na_2CO_3 at constant pH. We varied: (1) the molar Al content; (2) the pH of precipitation; (3) the aging temperature and (4) H_2O or H_2O-EtOH mixtures as solvent. Catalysts were characterized by ICP-OES, N_2 sorption, sorption of acrylic acid, XRD, TG-DSC, and SEM. In a typical experiment, 100 mg catalyst were dispersed in 5 mL 10wt.% aqueous Glu solution and stirred for 1.5 h at 110 °C. Afterwards, the reaction solution was filtered and analysed by HPLC.

3 Results and discussion

Characterization of the HTs showed that the prepared materials consist of agglomerated primary platelet-like particles (40-200 nm in diameter and *ca.* 20 nm thickness) of polycrystalline nature. The size of the primary particles as well as their agglomeration depends on the preparation conditions. Interlayer carbonate anions are catalytically active sites for the isomerization of Glu, therefore, their accessibility is essential to enable high catalytic activity. These active sites are located on (i) edges of the primary HT particles and (ii) defects of the HT crystals, e.g. the places of noncoherent coalescence of the crystallites.

The best yields of Fru were obtained over catalysts with a molar content of Al $0.23<Al/(Mg+Al)<0.3$, while catalysts with $0.3<Al/(Mg+Al)<0.34$ were less active. We assign this observation to blockage of active sites with aluminium hydroxide forming in minor amounts during catalyst preparation.

Preparation conditions significantly influence the properties and catalytic activity of HTs. Aging of HTs at 150°C results in coalescence of primary particles and decrease of the defect concentrations. As a result, the basic sites of the materials aged at high temperature are hardly accessible leading to lower catalytic activity as compared to HTs aged at room temperature.

In addition, the pH of co-precipitation in aqueous solutions has a clear influence on the catalytic performance of the prepared HT materials. When precipitated at the isoelectric point

(pH 10), the primary particles of HTs are assembled into agglomerates with a "sand-rose" structure. This facilitates easy access towards the basic sites located on both basal and non-basal planes of the HTs. Preparation of HTs at pH 9.0-9.5 (i.e. below isoelectric point) gives rise to materials with less regular morphology: In this case the agglomeration takes place by stacking of the basal planes of primary particles. Consequently, catalysts prepared at pH 10 possess a greater amount of basic sites and demonstrate higher catalytic activity compared to materials synthesized at pH 9.5.

Moreover, activity of the catalysts can be improved by conducting the preparation in aqueous-ethanol solvent instead of aqueous medium. Dispersion of the primary particles of HTs increases upon addition of ethanol, enhancing basicity of the materials.

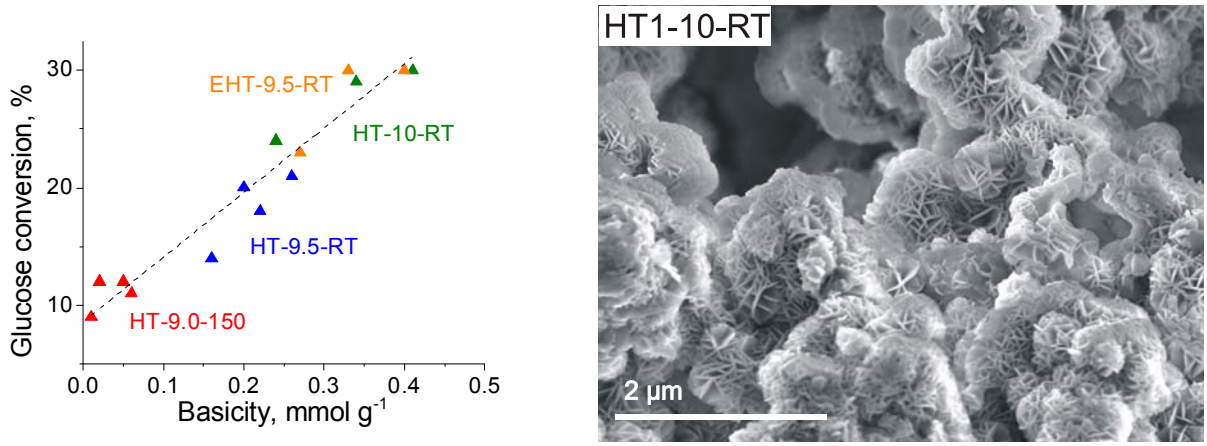

Fig.1. (Left) Glucose conversion vs. basicity of hydrotalcites. Reaction conditions: 5 mL 10wt.% aqueous glucose solution, 100 mg catalyst, 110°C, 1.5 h, 750 rpm; (right) SEM micrograph of a HT precipitated in aqueous medium at pH 10 and aged at room temperature.

In summary, basicity of the HTs correlates with the catalytic activity (Fig. 1). The best results were obtained for the most basic catalysts precipitated at pH 10 and HTs prepared in an aqueous-ethanol medium. The yield of Fru reaches up to 30% with 89% selectivity when conducting the reaction under typical conditions but for 4 hours. Although some leaching of Mg^{2+} was observed, the reaction takes place heterogeneously, as shown by a filtration test. The HT was successfully recycled 4 times without loss of activity and selectivity.

Liquid Phase Oxidation of Glucose to Gluconic Acid over Supported Metal Catalysts

Padovani A., Schüth F.*

Max Planck Institut für Kohlenforschung, Mülheim an der Ruhr, Germany

* schueth@kofo.mpg.de

Keywords: glucose, gluconic acid, supported metals catalysts

1 Introduction

During recent years, the metal catalyzed liquid-phase oxidation of glucose to gluconic acid has received much attention, since the latter is a fine chemical used as water soluble cleansing agent and additive for food and beverages.

2 Experimental/methodology

In this study the oxidation of glucose to gluconic acid is carried out both with pure oxygen and with air as oxidizing agent under pressure, at 70°C and at room temperature, under basic or neutral conditions without pH control. Although in this study the reaction is typically run either for seven or three hours, with this system the highest values of conversion are usually reached within the first 50 minutes of reaction. The chemical oxidation of glucose to gluconic acid with nickel group metals – especially Pd and Pt, on carbon and metal oxides has been investigated for a long time [1]. As alternative to nickel group metals, Au-based supported catalysts have received much attention [2-3].

3 Results and discussion

In this work, at alkaline pH and at 70°C using pure oxygen as oxidizing agent Au(1wt%) was tested supported on metal oxides, i.e. on ZnO, Al_2O_3, TiO_2,. The conversions obtained are around 60-70%, but the selectivities to gluconic acid are low, and only a minor yield of gluconic acid is obtained (7-14%). Au was also tested on carbon as support. Instead of a microporous material, two mesoporous carbons named CA1 and SX with different surface areas were used. In general, the SX carbon supported catalyst gives better results in terms both of conversion (90-100%) and yield of gluconic acid (~90%). Au/SX carbon was also tested under alkaline conditions at room temperature: the reaction is slower with ~100% conversion and ~80% selectivity. On a micro-mesoporous carbon support, the performance is not as good, with ~90% conversion and ~60% of gluconic acid produced. Pd and Pt at 1wt% were inferior under the same conditions compared to the best gold systems. Pd/C as catalyst is the best system, with full conversion and selectivities around 70%. Pt seems to work better using the ordered structure of CMK-5 as support: the only oxidation product formed during the reaction is gluconic acid in ~68% yield and ~70% selectivity, while on the SX carbon only ~80% conversion and ~40% yield of gluconic acid are obtained.

If the noble metal content of the catalysts is increased, the performance is substantially improved: with 3% Au on SX carbon, full conversion and ~90-100% yield of gluconic acid were obtained, at 5wt% the system is not improved further (Fig.1).

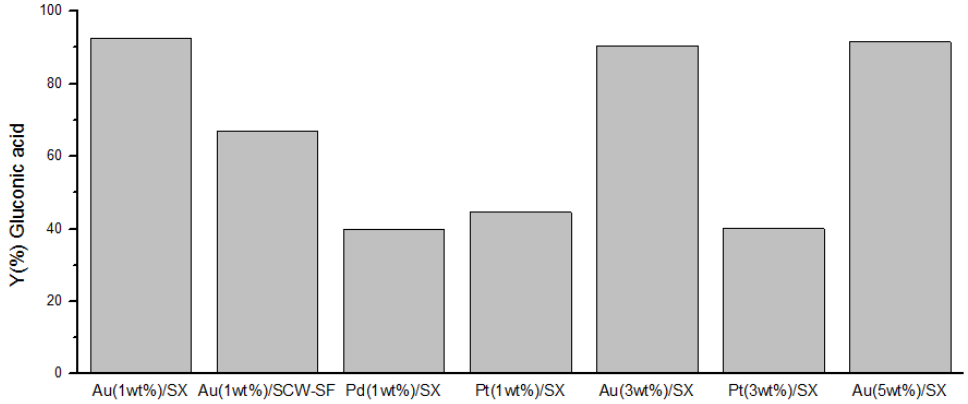

Fig. 1. Best catalysts in glucose oxidation to gluconic acid, alkaline pH, O_2, 3 bar.

The catalysts were also tested with air as oxidizing agent instead of oxygen. In this case the best results are obtained with Au(3wt%)/SX and Au(5wt%)/SX giving full conversion and ~100% and ~40% yield of gluconic acid respectively.

It would be attractive to carry out the reactions without base, and thus some catalyst systems were also tested at neutral pH, using pure oxygen as oxidizing agent. With Au(1wt%)/ZnO at 70°C the conversion is ~55% with a selectivity of ~90%, while at room temperature the values of conversion and selectivity to gluconic acid are, respectively, ~40% and ~80%, with lower amount of gluconic acid produced (~30%). Ru(1wt%)/C was also tested, but it shows no selectivity to gluconic acid.

4 Conclusions

In alkaline pH the best catalysts are Au/SX carbon, which give high conversion and yield of gluconic acid both under oxygen and air as oxidizing agent.While alkaline conditions favor the formation of gluconic acid, with the right catalyst systems reasonable yields can also be obtained at neutral pH, with Au/ZnO reaching almost 60%.

Efficient Carbon Based Catalysts with Acid Sites and Magnetic Properties for Starch Valorization to Bio-chemicals

Anita F., Podolean I., Parvulescu V.I., Coman S.M.*

University of Bucharest, Faculty of Chemistry, Bucharest, Romania

* simona.coman@g.unibuc.ro

Keywords: carbons, magnetic nanoparticles, acid sites, starch, levulinic acid, lactic acid

1 Introduction

Along with cellulose, starch is an important raw material for the synthesis of platform molecules. However, studies conducted to date in homogeneous acid catalysis, show that the yields are relatively low (19-35%, in HCl) [1, 2]. In addition, the use of mineral acids presents a series of drawbacks related to the corrosive nature of the catalyst, the difficulty of separation at the end of reaction and hazardous waste generated. An alternative to such systems are those using solid acid catalysts, but progress is still insignificant, new active and selective solid catalyst systems waiting to be discovered and developed. An explanation for this situation is the special nature of the bio-polymer raw material and their low solubility in most of organic solvents.

Nanocatalysis represents a viable alternative to create high-performance catalysts able to convert biomass into bio-chemicals. However, the isolation and recovery of such tiny particles from the reaction mixture is not simple using conventional techniques. To overcome this problem, the use of magnetic nanoparticles (MNP) has emerged as a viable solution. Their insoluble paramagnetic nature allows an easy and efficient separation of the catalyst from the reaction mixture with an external magnet. Such a solution is very practical at the industrial level, where the separation processes represent more than half of total investments in specific equipment chemical industry.

Based on these, the main objective of this work was the design and development of carbon based catalysts (i.e., MWCNT and graphene) with acid sites and magnetic properties, suitable for the starch conversion into bio-chemicals. Commercially corn starch was used as raw material.

2 Experimental/methodology

Both graphene and MWCNT were oxidized by treating with HNO_3 at temperature. Then, the resulted graphene oxide was treated with concentrated triflic acid at 80°C for 10h resulting in GO@ SO_3CF_3, and MWCNT was modified with sulfuric acid leading to MWCNT-SO_3H. Fe_3O_4 nanoparticles were inserted into MWCNT-SO_3H using a simple protocol in which iron sulphate (II) ammonium chloride hexahydrate was dissolved in a deionized solution of hydrazine hydrate [3]. The resulted suspension of NPM@MWCNT-SO_3H particles was ultrasonicated, and the pH adjusted to 11-13. Then the catalysts were washed and dried. Their characterization was made by a number of techniques such as X-ray diffraction (XRD), Dynamic Light Scattering (DLS), Infrared Diffuse Reflectance spectroscopy with Fourier transform (DRIFT) and Elemental Analysis. Activity tests were carried out in a glass-pressure autoclave (Top 45 model, Top Industrie), at 130-180°C for 2-8h. After reaction the catalyst was recovered and the water-soluble products were separated by distillation under vacuum. The recovered products were sylilated and analysed by a GC-MS Carlo Erba Instruments QMD 1000 equipped with a Factor Four VF-5HT column.

3 Results and discussion

Compared with the oxide carriers, such as zeolite or alumina, catalysts based on carbon supports showed better performances, especially due to their higher tolerance to water and better dispersion of the catalytically active species. The functional groups of the GO/MWCNT (-OH, -COOH, etc.) works as docking centers for the active catalytic species thus providing an advanced dispersion of the active species.

This work valorizes as well this property by docking triflate and sulfate groups. The XRD patterns and DRIFT spectra of GO and MWCNT confirmed the functionalization with acid groups. On the other hand, the elemental analysis showed a higher percent of triflate grafted on the GO surface (10.32% S) by comparison with the sulfate groups grafted onto the MWCNT support (0.077% S).

Table 1 compiles the main results in the starch degradation. The GO@SO_3CF_3 catalyst is more active and selective in the process probably due to the much higher loading of acid sites. Both catalysts display Lewis/Brønsted acidity but in different proportions. Interesting enough, the selectivity to lactic or levulinic acid is not controlled by the L/B acid sites ratio but by the reaction conditions. Thus, in the presence of GO@SO_3CF_3, at 150°C, levulinic acid was preponderantly formed (60.0%) in 4h, while at 180°C lactic acid was formed in high amounts (56.6%). Differently, the MNP@MWCNT-SO_3H catalyst become active only at 180°C, and after 6h led to a small selectivity in lactic acid (49.0%). However, the advantage of using this catalyst is its simple isolation and recovery from the reaction mixture by applying an external magnetic field.

Table 1. Catalytic performances of the carbon-based materials in starch degradation

Catalyst	T (°C)	Time (h)	C (%)	Product distribution (S %)
GO@SO_3CF_3	130	4	100	Humines
GO@SO_3CF_3	130	6	100	Humines
GO@SO_3CF_3	150	2	83.8	Lactic acid (15.5), glycolic acid (7.5)
GO@SO_3CF_3	150	4	100	Lactic acid (62.9), levulinic acid (21.8)
GO@SO_3CF_3	150	6	100	Lactic acid (7.8), levulinic acid (60.0)
GO@SO_3CF_3	180	4	100	Lactic acid (56.6), glycolic acid (43.4)
MNP@MWCNT-SO_3H	150	4	0	-
MNP@MWCNT-SO_3H	180	4	0	-
MNP@MWCNT-SO_3H	180	6	100	Lactic acid (49.0), glycolic acid (28.0)

4 Conclusions

In conclusion, the synthesized carbon-based materials showed a promising behavior for catalytic applications in the recovery of municipal food wastes (rich in starch) as bio-chemicals.

New Cross-Dehydrogenative Coupling Reactions with Selective C-O Bond Formation

Terent'ev A.O.*, Krylov I.B., Vil' V.A., Zdvizhkov A.T., Sharipov M.Yu.

N. D. Zelinsky Institute of Organic Chemistry, Moscow, Russia

* alterex@yandex.ru

Keywords: oxidation, peroxides, coupling, dicarbonyl, compounds, C-O bond

1 Introduction

The cross-dehydrogenative C-C coupling was studied in most detail; the C-N, C-P, and C-O cross-coupling reactions are less well developed. It is difficult to achieve high selectivity in the cross-dehydrogenative C-O coupling because the starting compounds are prone to side oxidation and fragmentation reactions giving, for example, alcohols and carbonyl compounds. This gives rise to a problem of searching for oxidizing agents and reaction conditions suitable for the cross-coupling of different types of substrates.

2 Results and discussion

In this work we found cross-dehydrogenative C–O coupling of 1,3-dicarbonyl compounds and their heteroanalogs with oximes, hydroxyamides, and peroxides (Fig. 1 and 2). The best results in coupling with peroxides were obtained with the use of the widely available copper, iron, manganese or lantanide salts as catalysts or oxidants (Fig. 1).

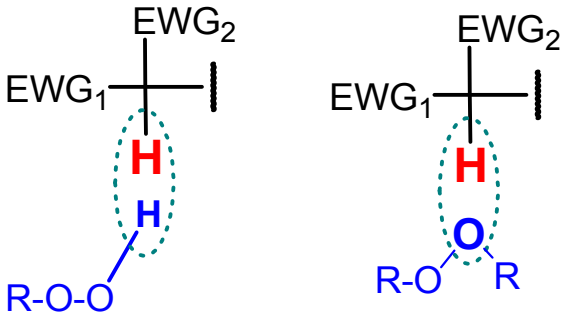

Fig. 1. Cross-dehydrogenative C–O coupling of 1,3-dicarbonyl compounds and their heteroanalogs with peroxides.

In the past decades, organic peroxides have got attention from researchers in the fields of medicinal chemistry and pharmacology because these compounds, particularly ozonides and tetraoxanes, were found to exhibit marked antimalarial, anthelmintic, and antitumor activities. Organic peroxides have been widely used for more than half a century as radical polymerization initiators in the industrial synthesis, for example, of such polymers as polystyrene, polyvinyl chloride, polyacrylates, and high-pressure polyethylene. Organic peroxides are also used for the crosslinking of silicone, acrylonitrile-butadiene, and fluorinated rubbers.

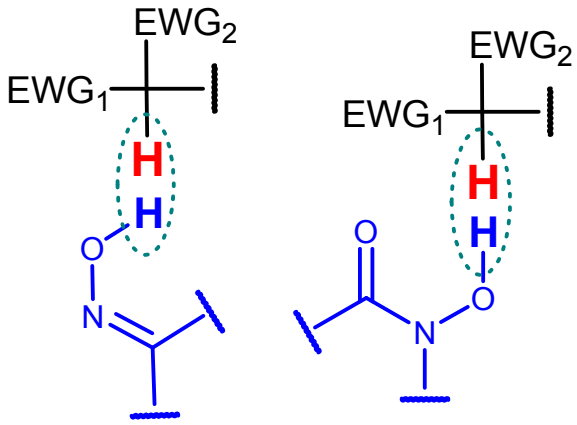

Fig. 2. Cross-dehydrogenative C–O coupling of 1,3-dicarbonyl compounds and their heteroanalogs with oximes and hyroxyamides.

In the case of Fig. 2, apparently, the reaction proceeds *via* the radical mechanism, in which the oxidizing agent serves to generate O-centred radicals from oximes and hyroxyamides. The formation of O-centred radicals was confirmed by ESR spectroscopy. The coupling described in the present study is the first example of the selective intermolecular reaction involving O-centred radicals generated in situ.

Generally speaking this work is a new approach to the solving of problem for selective oxidation of carbon atom with sp^3 hybridization.

Keywords: carbonylation, dimethyl ether, methyl acetate, mordenite

1 Introduction

Recently, a novel route to ethanol (EtOH) from synthesis gas has been demonstrated, in which dimethyl ether (DME), formed from synthesis gas, reacts with CO to methyl acetate (MA), which in turn is hydrogenated to EtOH and methanol (MeOH) [1]. Mordenite has been identified to be the most active catalyst for DME carbonylation [2, 3]. The framework of Mordenite contains two types of cavities: eight-membered ring (8-MR) side pockets and 12-MR main channels. 8-MR are the active sites for MA synthesis and formation of acetyl groups as surface intermediates is the rate limiting reaction step [4]. In this study, we present unprecedented insights into formation of acetyl on Mordenite in the steady-state phase, including the DFT energies and energy barriers for all reaction steps, and present experimental evidence of the theoretical model by showing that ketene is a reaction intermediate as predicted by the DFT calculations.

2 Experimental/methodology

All calculations were performed using the GPAW [5] DFT program with the BEEF-vdW functional [6]. Ketene was detected experimentally in an experiment, in which the DME carbonylation was given 5.7 h to approach steady-state, where D_2O was introduced to the CO/DME feed. Gas-phase ketene is the only species in the system which forms a doubly deuterated acetic acid, in a reaction with D_2O. The other pathways to acetic acid: acetyl hydration, MA hydrolysis and MeOH carbonylation all result in acetic acid isotopes with, at most, a single deuterium atom. This analysis is possible because the methyl groups are not deprotonated on acidic zeolites by MeOH, DME or D_2O [3, 7].

3 Results and discussion

Our DFT calculations show that ketene is a reaction intermediate in both the 8-MR and the 12-MR (Figure 1). Additionally, formation of acetyl is significantly faster in the 8-MR than in the 12-MR, by a factor of about 5 at 438 K. Figure 2 shows the mass ratio between m/z = 62 (CH_2DCOOD) and m/z = 61 (CH_3COOD) as a function of time on stream during the experiment. Before the addition of D_2O in the system, the ratio between the signals from doubly and singly deuterated acetic acid isotopes corresponded to noise, but as D_2O was introduced, a well-defined peak emerged, showing that ketene is a reaction intermediate. Upon the introduction of D_2O the carbonylation reaction was still running and ketene intermediates were

available for conversion to CH_2DCOOD, whereby the m/z = 62 signal became prominent.

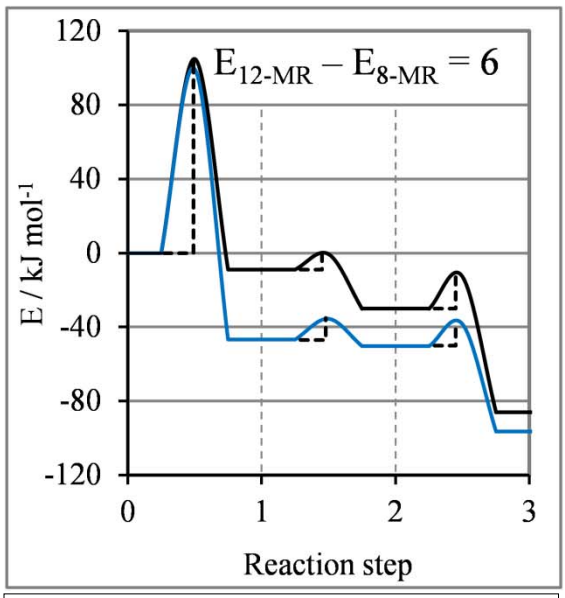

Fig.1. Reaction paths for formation of acetyl on Mordenite. Reaction steps: 0 CO in vacuum, methyl group on the zeolite; 1 Acetyl carbocation; 2 Ketene physisorbed on a Brønsted acid site; 3 Acetyl group on zeolite. Black line: reaction steps in the main channel; Blue line: reaction steps in the side pocket.

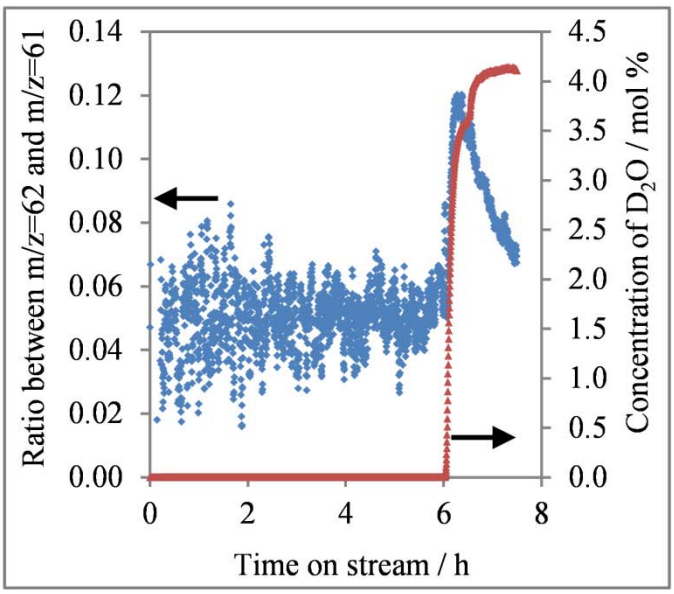

Fig.2. The ratio between the MS signal at m/z=62 (doubly deuterated acetic acid) and m/z=61 (singly deuterated acetic acid). Conditions: 9.8 bar CO, 0.2 bar DME, 300 Nml/min, 3.0 g catalyst, 438 K.

4 Conclusions

The present work shows that ketene is an intermediate in the DME carbonylation over Mordenite. Ketene undergoes base catalyzed polymerization to poly-ketones already at very low temperatures and may be involved in the build-up of the larger carbonaceous structures that lead to deactivation of the zeolite catalyst [8]. The presence of ketene is also of importance for the ongoing studies of the formation of the initial C-C bonds in acidic zeolites.

On the Mechanism for the First C-C Bond Formation in MTO Reaction

Liu Y.*, Müller S., Sanchez-Sanchez M., Lercher J.

Department of Chemistry and Catalysis Research Center, Technische Universität München, München, Germany

* yue.liu@tum.de

Keywords: MTO, H-ZSM-5, methanol, mechanism

1 Introduction

Catalytic conversion of methanol to hydrocarbons (MTH) on solid acids, especially on H-ZSM-5 and SAPO-34, has attracted great attention and effort in the past decades in respect of methane and syn-gas transformation as well as gasoline (MTG) and olefin (MTO) production [1]. A large amount of work has been focused on this process, but till now the full mechanism of methanol conversion is unclear. It is widely accepted that a "hydrocarbon pool" is formed which includes olefin and aromatic cycles [2]. However, how the first olefin or the first aromatic molecules are originated solely from methanol is still under debate. Diverse distinctive proposals on the first olefin or first C-C bond formation make it hard to reach a uniform consensus. These proposals can be classified by their key intemediate as oxonium ylide mechanism, carbene mechanism, carbenium ion mechanism, free radical mechanism, surface alkoxy mechansim and CO involved mechanism [3].

In this work, we study the first surface and gas products formed on acidic zeolite by reaction of methanol and some potential C_1 intermediates followed by IR spectroscopy and a mass spectrometer. We detected tens of ppm of acetic acid and methyl acetate prior to the appearance of olefin in MTO, which were assigned to the first species containing a C-C bond. A promotion of MTO reaction rate was observed as well when cofeeding CO with methanol. Based on these findings, a new reaction mechanism network is proposed involving carbonylation, aldol condensation and decarboxylation. Ethylene and propylene arise simultaneously as first olefin products but it is found that they originate from two different routes.

2 Experiments

Reactions were performed in a quarz tube reactor under ambient pressure. A commercial H-ZSM5 catalyst was pressed and sieved into 200-280 μm particles and diluted (1:20 wt.) in 355-500 μm SiC. For comparison, H-MOR catalyst was also tested. Prior to reaction, catalyst was activated in 25 mL/min He flow at 450 ^{o}C for 1h. Methanol and methylal were fed by passing 25 mL/min He through an evaporator and partial pressure was controled by modulating evaporator temperature. Reaction products were dectected on line by MS. For temperature programmed reaction, a temperature rising rate of 10 ^{o}C/min was applied.

3 Results and discussion

Steady state reaction of methylal on H-ZSM-5 was performed at 450 ^{o}C. With time on stream, the yield of olefins decreased and the DME/methanol increased correspondingly, due to deactivation of the catalyst. Between the two species, a weak peak of methyl acetate and acetic acid appeared as reaction intermediate (Figure 1). Similar trend was observed for the methanol reaction on the less stable H-MOR. Therefore, we propose that C_1 molecules including methanol, DME, methylal, formaldehyde and CO are converted to olefins via methyl acetate and

acetic acid. The latter species is formed by DME/methanol carbonylation and proposed to be the first intermediate containing a C-C bond.

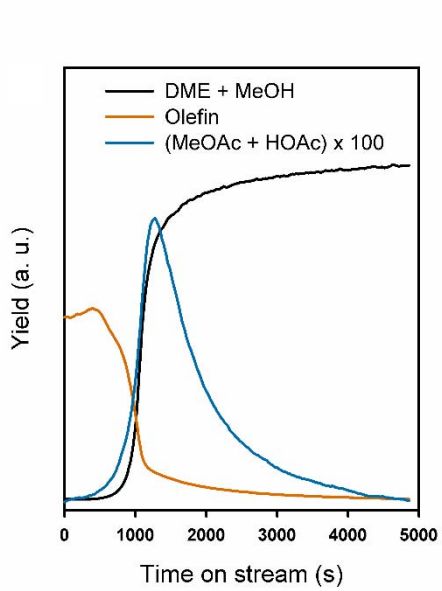

Fig. 1. Methylal to olefin conversion on H-ZSM-5 as a function of time on stream.

An obvious reaction rate increase was observed when cofeeding CO with methanol on H-ZSM-5. This promotion effect is difficult to detect under typical reaction conditions because this pathway is strongly inhibited by the presence of water, similar to the effect of water reported for DME carbonylation [4]. Even though water is generated from methanol dehydration to dimethyl ether at the initial stage, carbonylation still proceeds at a rate slow but sufficient to trigger the formation of the "hydrocarbon pool". The very low rate of this step explains the need for a certain space time, known as the induction period in MTH. A reaction mechanism is proposed based on these findings. First C-C bond is formed by carbonylation of methanol / DME, generating acetyl species as methyl acetate and acetic acid, which further transforms into ethylene and propylene.

4 Conclusions

Acetic acid and methyl acetate was for the first time observed as relevant intermediates in MTO reaction and a new mechanism for the first C-C bond and first olefin formation in MTO was proposed. The first C-C bond is generated by carbonylation of surface methoxy group, forming surface acetyl group, which further reacts into olefins.

Activity Control of Supported Catalysts with Tailored Ru Nanoparticles for Non-Oxidative Propane Dehydrogenation

Otroshchenko T., Stoyanova M., Rodemerck U., Sokolov S., Linke D., Kondratenko E.V.*

Leibniz Institute for Catalysis, Leibniz, Germany

Keywords: propane, dehydrogenation, nanoparticles, zirconia

1 Introduction

Propene is one of the most important petrochemicals mainly used as a feedstock for the production of various polymers. It is industrially produced as a by-product of steam cracking of naphtha or fluid catalytic cracking of heavy oil fractions. Therefore, it is difficult to tune its selectivity. Since demand for propene is continuously growing, non-oxidative propane dehydrogenation (PDH) was commercialized for on-purpose propene production over supported Pt- or CrO_x-based catalysts, which show high propene selectivity and long lifetime . However, Pt-based catalysts are quite expensive and CrO_x-based catalysts are toxic and lead to environmental issues. Recently, supported VO_x-based materials were demonstrated to catalyze the PDH reaction with propene selectivity similar to industrial analogs [2]. Nevertheless, they are less active than Pt-based materials.

Here, we present novel supported catalysts possessing well-defined (1 nm) Ru nanoparticles with an overall metal loading as low as 0.05 wt.%. Their PDH performance determined under industrially relevant conditions surpassed that of VO_x- and Pt-based catalysts. The high activity together with the tiny Ru content makes our materials attractive from an industrial viewpoint.

2 Experimental

Ru nanoparticles (NP) were synthesized by reduction of $RuCl_3 \cdot nH_2O$ in ethylene glycol solution [3]. SiO_2, Al_2O_3-SiO_2 with SiO_2 content of 40 and 10 wt.% (Siral 40 and Siral 10, respectively), La_2O_3-ZrO_2 ($LaZrO_x$) and Al_2O_3 were used as supports. All catalysts were synthesized by impregnation of the supports with either colloidal solutions of Ru NP in CH_3OH or with a toluene solution of vanadium acetylacetonate to attain the metal loading of 0.05 or 4 wt.%, respectively. PDH tests were carried out at 550°C in a multichannel setup consisting of 15 plug-flow fixed-bed quartz reactors. The catalysts were pre-reduced in H_2 (30 vol.% in N_2) at 550°C for 1 h, flushed with N_2 and then exposed to a feed containing 40 vol.% C_3H_8 in N_2. The feed components and the reaction products were analyzed by an on-line gas-chromatograph.

3 Results and discussion

The size and distribution of Ru NP in ethylene glycol solution and after their deposition from this solution onto grid was determined by small angle X-ray spectroscopy and transmission electron microscopy, respectively. It amounted to approximately 1 nm. As shown in our previous study [3], the size did not significantly change after deposition of NP on supports.

Propene was the main product formed over all catalysts, while CH_4, C_2H_6, C_2H_4 and C_4-olefins were minor by-products. To compare the PDH activity of prepared catalysts, we determined the rate of propene formation at a propane conversion below 10%. The values obtained are shown in Fig.1. This figure also contains the corresponding value for an industrial analogue (Pt-Sn/Al_2O_3) tested under the same reaction conditions [2].

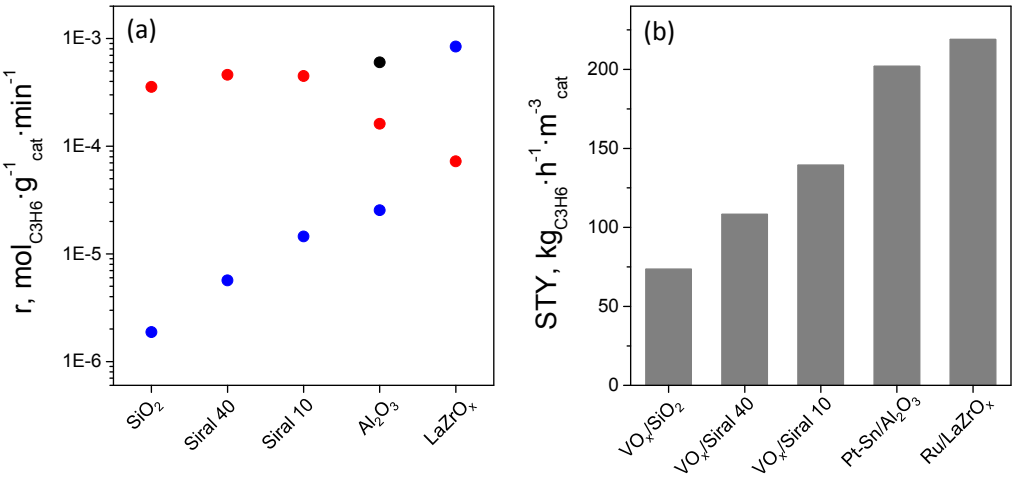

Fig. 1: Rates of propene formation (a) over Pt-Sn- (●), VO_x- (●) and Ru-based (●) supported catalysts and maximal space-time yield (STY) of propene (b) over the most active catalysts determined at 550°C.

It is obvious that the catalysts strongly differed in their activity depending on the kind (VO_x vs. Ru) of active species and support. For SiO_2-Al_2O_3-based catalysts, surface VO_x species showed significantly higher activity than Ru NP and their activity did not significantly depend on the content of SiO_2 (0-100 wt.%). Contrarily, the activity of Ru-based catalysts strongly increased with a decrease in this content. When using $LaZrO_x$ as support, VO_x species became significantly less active than those supported on SiO_2-Al_2O_3, while Ru/$LaZrO_x$ showed the highest rate of propane formation. For example, it was 450 or 2 times higher than those over Ru/SiO_2 or over the most active VO_x-based catalyst, respectively. Moreover, industrially relevant Pt-Sn/Al_2O_3 was less active than Ru/$LaZrO_x$. Since Ru loading and particle size was same for all supported catalysts, such strong difference in the activity of Ru-based catalysts can be referred to the metal-support interaction and its effect on the reaction.

It is worth mentioning that Ru/$LaZrO_x$ also performed superior to all other catalysts in terms of space-time yield (STY) of propene formation at industrially relevant propane conversion (>25%). The highest achieved value was 220 $kg_{C3H6} \cdot h^{-1} \cdot m^{-3}_{cat}$. The selectivity to propene was around 90%. This high performance was stable over 10 PDH/regeneration cycles thus proving that no structural changes occurred upon reductive/oxidative catalyst treatments.

Our contribution will discuss the trends observed during the catalytic tests together with the results of catalyst characterization by complementary methods to highlight the role of metal-support interaction and the kind of active components for propene formation. Similarities and differences in the mechanism of propane dehydrogenation over catalysts possessing VO_x species or Ru NP will be also discussed.

4 Conclusions

We have demonstrated that simple deposition of tailored Ru NP on commercial supports results in active, selective and stable catalysts for non-oxidative propane dehydrogenation even at metal loading as low as 0.05 wt.%. Such results appear promising from an applied viewpoint and provide the fundamental basis for developing active and selective PDH catalysts.

Methylation Reaction of Aromatic NH-heterocycles with Using Supercritical Methanol: Competitive Homogeneous and Heterogeneous Catalysis by Si-Containing Compounds

Martyanov O.N.[1,2*], Chibiryaev A.M.[1,2], Kozhevnikov I.V.[1]

* oleg@catalysis.ru

Keywords: supercritical methanol, NH-heterocycles, methylation, Si-containing compounds, catalysis

1 Introduction

The catalytic properties of Si-containing compounds are investigated quite thoroughly for various organic reactions. But the top-level of these researches is the study of Lewis acid properties of silicas or its promotion effect (assistance) as catalyst supports. There is still a lack of reliable data on the catalytic activity of other Si-containing compounds, for example tetraalkyl orthosilicates. Recently, we have demonstrated the pronounced catalytic effect of tetramethyl orthosilicate (TMOS) on the methylation reaction of some aromatic azaheterocycles in supercritical (*sc*) methanol at 350 °C without additional methylating reagents [1,2]. The starting reagent was not commercial TMOS, but some SiO_2-containing materials (quartz, silica gel, etc.) which were reacted with *sc*-methanol to produce *in-situ* the equilibrium concentration of methyl orthosilicates by following scheme: $\mathbf{SiO_2 + CH_3OH \rightarrow Si(OCH_3)_4 + (CH_3O)_6Si_2O +}$ **(methyl oligosilicates)** $\mathbf{+ H_2O}$. It was shown that TMOS catalyzes the heterocycles methylation as homogeneous catalyst. At the same time there is indirect evidence that the solid SiO_2-surface works as heterogeneous catalyst for the methylation reaction of some aromatic azaheterocycles in *sc*-methanol. Thus, the methylation reaction in *sc*-methanol can be considered as an example of competing homogeneous and heterogeneous catalysis by Si-containing compounds.

2 Experimental

All runs were performed at 350°C and ~ 215 atm. in a batch reactor made from corrosion-resistant Hastelloy® C-276 alloy and repeated three times. The reactor was equipped with mechanical agitator MagneDrive® (Autoclave Engineers) and spinning catalytic basket Harshaw® (Autoclave Engineers), which was preliminary charged by solid SiO_2-containing material. The critical parameters of methanol are T_{cr} = 240°C, P_{cr} = 80 atm., and ρ_{cr} = 0.27 g cm^{-3}. The calculated density of the reaction mixtures were around ρ = 0.33 g cm^{-3} in supercritical phase at 350°C. The samples of the reaction mixture were collected every hour and analyzed with using the GC–MS and GC–AED.

3 Results and discussion

We have found that SiO_2 or TMOS enhance the reaction regioselectivity of heterocycle methylation in *sc*-methanol at 350 °C (**Fig. 1**), for instance up to 96–97% of 3-methylindole formation for indole reaction. The main catalytic effect is determined by the presence of TMOS that forms from the solid SiO_2-containing materials (quartz, Pyrex glass and silica gel) and methanol at these reaction conditions. Unusually, aromatic NH-heterocycles significantly accelerate the reaction of silica with methanol at 350 °C.

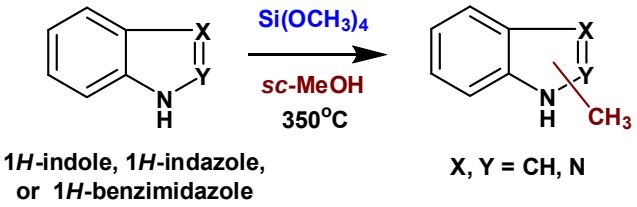

Fig. 1. Scheme of methylation reaction of some heterocycles with *sc*-methanol catalyzed by TMOS.

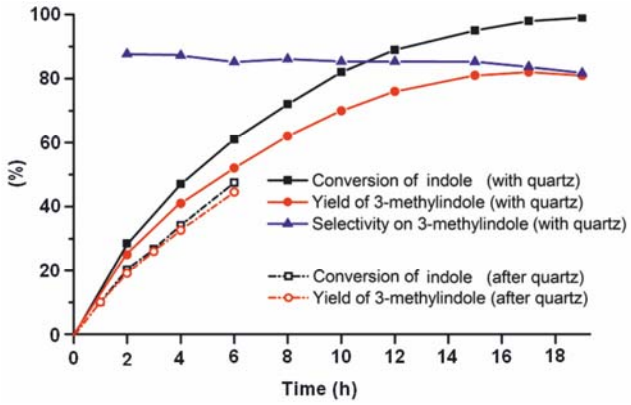

Fig. 2. Comparison of indole reaction in *sc*-methanol with using quartz sand and after its removal from the reactor.

So, we observed the cooperative concerted influence of reacting components: heterocyclic compound both provides a nucleophilic assistance to the reaction "SiO_2 + methanol" resulting in the *in-situ* formation of TMOS and is alkylated by methanol. The last reaction is catalyzed by TMOS.

But this simplified interpretation of experimental data obtained does not take into account the possible catalytic effect of the solid SiO_2-surface. In **Fig. 2** one can observe the difference in the indole conversion for the reaction in the presence of quartz (i.e. there is a solid SiO_2 in the reactor during the total reaction time) and after the removal of quartz (the last case implies the "quartz + methanol" reaction was carried out for 2 hours at 350 °C without indole, afterwards the unreacted quartz was removed out from the reactor. After the addition of the indole to the obtained solution of TMOS in methanol, the indole reaction was continued by the usual way.) It can be assumed that the difference observed is due to the extra catalytic effect of solid SiO_2-surface.

4 Conclusion

Our experimental data point to the mixed and competitive heterogeneous–homogeneous catalytic effect of Si-containing compounds (solid SiO_2 and liquid TMOS) for the methylation reaction of some aromatic NH-heterocycles with *sc*-methanol.

Keywords: bimetallic catalyst, nickel, cobalt, methane dry reforming, hydrogen production, SBA-15

1 Introduction

Dry reforming of methane (DRM) to syngas has attracted much attention in the last years for the great benefit to both environment and economy [1,2]. Nickel based materials are excellent catalysts for DRM reaction [3,4]. However, they suffer from deactivation due to Ni sintering and carbon deposition, which may also plug the reactor [5,6]. It was reported that alkali addition (Na and Mg) to the Ni based catalysts caused some decrease in carbon formation [7,8]. The type of support plays also a role, e.g., using SBA-15 as a support with its ordered mesoporous structure, narrow pore size distribution, and high surface area can anchor nanoparticles and restrain the mobility of species which otherwise might lead to metal sintering [9]. In this study, DRM was investigated over Co-Ni bimetallic supported on Sc, Mg, and La-SBA-15 catalyst with the aim to minimize carbon deposition.

2 Experimental

SBA-15 was synthesised using hydrothermal synthesis method. The prepared SBA-15 was modified by addition of the proper amount of $Sc(NO_3)_3.5H_2O$ or $Mg(NO_3)_2.6H_2O$, $La(NO_3)_3.6H_2O$ using incipient wetness impregnation. The catalysts were dried at 120 °C for 2 h and then calcined at 600 °C for 4 h. After that, they were co-impregnated with solutions of $Ni(NO_3)_2 \cdot 6H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$, dried and calcined at 600 °C for 4 h. The catalysts prepared without and with modifiers were designated e.g. as Co-Ni/SBA-15 and Co-Ni/Mg-SBA-15, respectively. The total Co-Ni loading was 10 wt% (1:1) and 5 wt% for Mg, La and 2.5-10 wt% for Sc. The fresh and spent catalysts were characterized using N_2-adsorption, XRD, TGA, TEM and TPR. DRM was investigated using a stainless steel fixed bed reactor in a temperature range of 700-800 °C at atmospheric pressure. The effect of the chosen promoters on the catalytic activity and stability was studied up to 33 h time-on-stream (TOS).

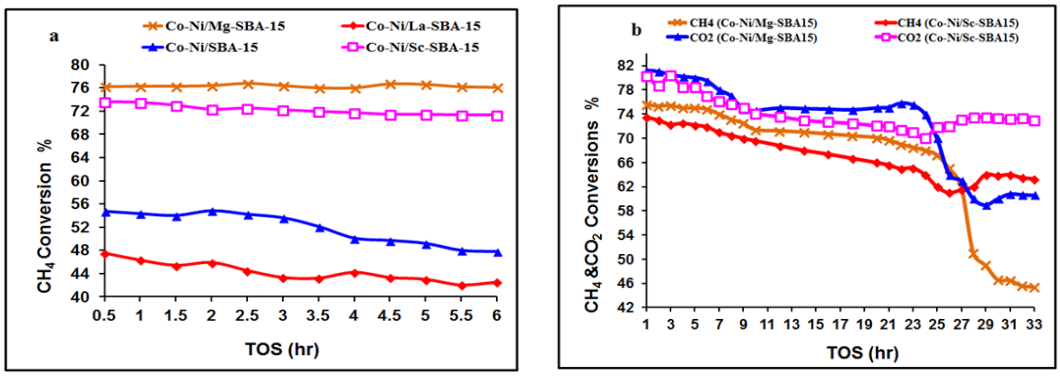
3 Results and discussion

Surface areas (SA) for the bare support, fresh and spent catalysts are shown in Table 1. Upon co-impregnation of Co-Ni and subsequent loading of the promoters a loss in SA of SBA-15 in the range of 30-50% was observed with a slight change in pore volume and diameter. This indicates that active metals were embedded into the SBA-15 pore system. The results for CH_4 conversion for all catalysts showed that Sc and Mg modified SBA-15 were far more active than the rest (see Fig. 1a). The entire catalysts showed slight deactivation over 24 h TOS, but then Co-Ni/Mg-SBA-15 showed a fast deactivation compared to Sc (see Fig. 1b). CO_2 conversion is higher than CH_4 due to consecutive reactions such as reverse water gas shift reaction (r-WGS). The carbon deposition on the catalysts showed a decrease as follows: Co-Ni/Mg-SBA-15 > Co-Ni/Sc-SBA-15 > Co-Ni/SBA-15 > Co-Ni/La-SBA-15.

Table 1: Surface area measurement for fresh and spent samples and carbon deposition data.

Catalyst	Fresh			Spent (700 °C, 6 h TOS)			Carbon content[(a)] (wt.%)
	S_{BET} (m^2/g)	Pore volume (cm^3/g)	Pore diameter (nm)	S_{BET} (m^2/g)	Pore volume (cm^3/g)	Pore size (nm)	
SBA-15	819.0	0.72	5.4	-	-	-	-
Co-Ni/SBA-15	468.9	0.53	5.6	397.6	0.48	5.57	11.2
Co-Ni/La-SBA-15	584.2	0.59	5.5	504.8	0.56	5.70	7. 5
Co-Ni/Sc-SBA-15	527.8	0.55	5.4	424.3	0.51	5.96	13.7
Co-Ni/Mg-SBA-15	426.0	0.49	5.3	318.1	0.45	6.29	20.6

[(a)]Estimation of the carbon deposition by TGA analysis after 6 h reaction



2 **Fig. 1:** CH_4 conversion vs. TOS for all catalysts under study (a) and long-term experiment over Co-Ni/Sc SBA-15 and Co-Ni/Mg-SBA-15 (b); T = 700 °C; total flow rate= 40 ml/min CH_4: CO_2: N_2 = 1: 1: 0.67.

4 Conclusions

Mg, Sc, and La promoted SBA-15 mesoporous materials were prepared and it can be seen that their addition decreases the surface area of SBA-15 but didn't block the pores. Afterwards, Co and Ni were co-impregnated on these solids; final Co-Ni/Sc- or Co-Ni/Mg-SBA-15 catalysts showed a CH_4 conversion of 73 and 76%, respectively, during the first 6 h and a slight decrease during 25 h to 66 and 73%, respectively. It seems that the stability of the Sc catalyst could be due to the generation of non-deactivating carbon deposits. The type of carbon deposition and/or location of carbon might be the reason for the deactivation of the catalysts.

New Chiral Cage Phosphines for Homogeneous Asymmetric Catalysis

Zagidullin A.A.[1*], Miluykov V.A.[1], Oshchepkova E.S.[1], Sinyashin O.G.[1], Hey-Hawkins E.[2]

Keywords: chiral cage phosphines, ligand, asymmetric catalysis

1 Introduction

The increasing demand to produce enantiomerically pure pharmaceuticals, agrochemicals, flavours and other fine chemicals has advanced the field of asymmetric catalytic technologies. Ligands with optically active phosphorus(III) centres have been used to some extent in transition metal-catalysed enantioselective reactions. Chiral cage phosphines are characterised by the presence of a chiral non-racemizable phosphorus atom situated at the bridgehead of a bicyclic system. The effectiveness of cage phosphines as weak, bulky ligands have been demonstrated in different asymmetric homogeneous catalysis with *ee*'s > 99% [1].

2 Experimental/methodology

From a synthetic standpoint, cycloaddition reactions of phosphacyclopentadienes (phospholes) are a convenient tool of molecular design of these chiral cage phosphine ligands [2, 3]. So, the [4+2] cycloaddition reaction of 1-neomenthyl-1,2-diphosphole with maleic acid deriatives proceeded under mild conditions with high diastereoselectivity (*d.e.* up to 88%) resulting in the corresponding enantiopure 1,7-diphosphanorbornadiene. The observed diastereoselectivity may be explained by the transition states showing one attractive and one repulsive pathway of Diels-Alder reaction and thermodynamic control of the reaction. This is the first example of a diastereoselective Diels-Alder reaction in a series of 1,2-diphospholes. The enantiopure cage phosphines show high activity and moderate enantioselectivity as ligands in Pd-catalyzed asymmetric allylic alkylation (ee = 15%) and as catalysts in [3+2] organocatalytic cycloaddition (*ee* = 68%).

Catalytic Conversion of Cellulose to C_2-C_3 Glycols Using Heterogeneous Platinum Catalysts Supported on Cerium Oxide

Girard E.*, Delcroix D., Cabiac A.

IFP Energies Nouvelles, Rond-Point de l'Echangeur de Solaize, Solaize, France

* etienne.girard@ifpen.fr

Keywords: biomass, cellulose, glycols, dual catalysis, cerium, oxide

1 Introduction

Cellulose, the most abundant and non-food carbohydrate source on earth, has attracted considerable attention for the production of bio-sourced platform molecules. In particular, the interest for C_2-C_3 glycols has been driven by the increasing demand for ethylene glycol and bio-based polyethyleneterephtalate (PET) in the packaging industry. The conversion of cellulose to C_2-C_3 glycols is usually achieved under hydrothermal and reducing conditions -above 100°C and 1 bar of H_2- via a cascade pathway including depolymerization of cellulose to glucose, subsequent retro-aldol reactions and hydrogenation of the resulting glycolaldehyde and glyceraldehyde molecules. Multifunctional catalytic systems are thus necessary to achieve a selective formation of C_2-C_3 glycols. Depolymerization being achieved through water autoprotolysis at high temperatures, the ideal catalytic system should combine a retro-aldol active species and a hydrogenation component. In literature, most studies were dedicated to Group 6 species and particularly tungsten homogeneous catalysts associated with a hydrogenation catalyst such Ru/Ac and Raney Nickel.[1,2] In the search of replacing tungsten, original dual catalytic systems combining homogeneous and heterogeneous catalysts based on basic oxides were screened in a preliminary study. This dual approach associates the advantages of a homogeneous catalyst –selectivity and enhanced solid substrate-catalyst contact– and those of a heterogeneous one –stability and recyclability. Higher selectivities in C_2-C_3 glycols were thus obtained with a $CeCl_3.7H_2O$ homogenous salt and transition metal catalysts supported on light rare earth oxides.[3] This communication aims to illustrate the great potential of such catalytic systems to achieve high selectivities in ethylene and propylene glycols (EG and PG) from cellulose. A specific focus on a cerium oxide-based catalytic system and its role in reaction mechanisms will be presented.

2 Experimental/methodology

The heterogeneous catalysts were prepared by dry impregnation and tested as powders sieved under 150 microns. Catalysts were reduced under a H_2 flow. Catalytic tests were performed in a high throughput apparatus possessing six 100mL autoclaves working in parallel. In a typical experiment, cellulose (1.3g), cerium chloride (500 ppm) and the heterogeneous catalyst (550 mg) were dispersed in degassed water (50mL). The autoclave was sealed and thoroughly degassed. A hydrogen pressure was set at room temperature before heating and stirring at 500 rpm.

3 Results and discussion

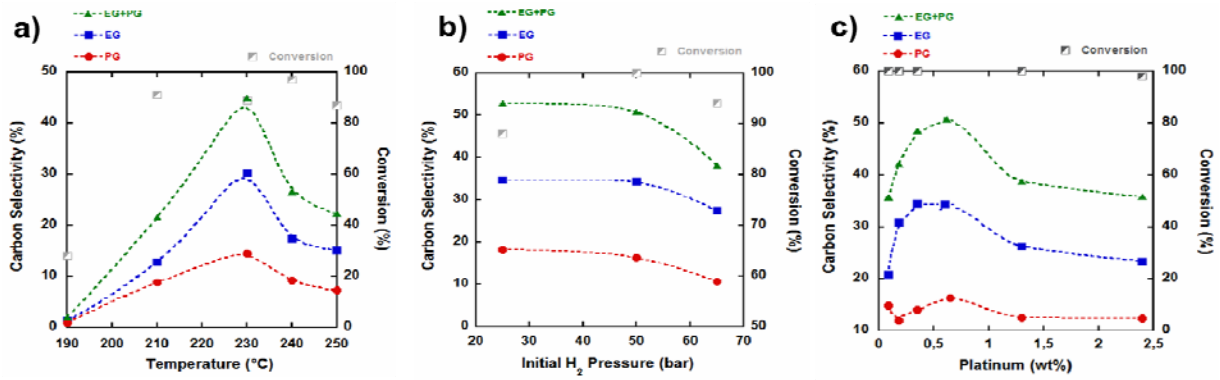
A temperature study on the selective conversion of cellulose to C_2-C_3 glycols was first conducted with $CeCl_3.7H_2O$ and Pt(0.63wt%)/CeO_2 as catalysts (see Figure 1.a)). Temperature was varied from 190 to 250°C with an initial pressure of 25 bar H_2 at room temperature. Reaction time was 12 hours. Cellulose conversion was only 28% at 190°C but was superior to

85% from 210°C. From 190°C to 230°C, an increase in EG and PG selectivities was observed with a preferential formation of EG (see Figure 1.a)). The total C_2-C_3 glycol selectivity was 44% at 230°C. A tendency shift was observed from 240°C. Selectivity in EG+PG decreased from 44% to 22% at 250°C as a result of the enhanced formation of dehydration-hydrogenation products –mostly ethanol and 1-propanol– in this temperature range. Glycol selectivities could be finally enhanced to 52% with a reduction in reaction time from 12 to 6 hours.

Pressure effects were then studied. Hydrogen pressure was then varied from 25 to 65 bar to study the influence of pressure on the formation of C_2-C_3 glycols from cellulose (see Figure 1b)). A maximum in cellulose conversion was noted at 50 bar. While results were constant between 25 and 50 bar, a decrease in selectivity was noted since the selectivity in glycols was lowered to 37% by setting an initial pressure of 65 bar.

Considering the complex cascade reactions implied in the transformation of cellulose to glycols, a sharp balance between acidic, basic and hydrogenation catalytic sites seems required to achieve a high selectivity in glycols. The platinum content was thus varied between 0.09 and 2.4% to attempt to maximize this selectivity (see Figure 1c)). An optimum in platinum content was actually observed in the 0.35-0.63% range. In parallel, the formation of degradation products -ethanol and 1-propanol- constantly increased with metal percentages, thus limiting the selectivities in EG and PG

Figure 1. Experimental results for cellulose conversion (2.5wt% in water) with $CeCl_3.7H_2O$ (500 ppm) and Pt/CeO_2 (42.5%wt/cellulose).



4 Conclusions

Original combinations between a $CeCl_3.7H_2O$ homogeneous catalyst and hydrogenation heterogeneous catalyst supported on cerium oxide were explored for the selective conversion of cellulose to C_2-C_3 glycols under hydrothermal conditions. The selection of a light rare earth support, *i.e.* cerium, was a key result in this study. This was actually confirmed by a recent study which evidenced the high catalytic activity of light rare earth compounds in the retro-aldol reaction and especially in the epimerization reaction.[4] Concerning the multifunctional catalytic system presented herein, temperature and platinum content were primary factors to achieve high selectivities in C_2-C_3 glycols. Thus, a total selectivity of 52% in ethylene and propylene glycols could be obtained.

Conversions of Cellulose and Its Derived Carbohydrates into Lactic Acid in Water Catalyzed by Al(III) and Sn(II) Dual Cations

Wang Y.L., Deng W.P., Zhang Q.H., Wang Y.*

State Key Laboratory of Physical Chemistry of Solid Surfaces, Collaborative Innovation Center of Chemistry for Energy Materials, National Engineering Laboratory for Green Chemical Productions of Alcohols, Ethers and Esters, Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, China

Keywords: biomass, cellulose, lactic acid, homogeneous catalysis, Al(III) and Sn(II) cations

1 Introduction

The direct transformation of cellulose into high-valued chemicals is of great importance for establishing sustainable chemical processes. Although limited success has been achieved for the hydrogenation or hydrogenolysis of cellulose into polyols, the consumption of hydrogen is required in these reactions. Lactic acid, an important building-block chemical, can be obtained by the transformation of cellulose without consuming hydrogen. A few recent reports disclosed that Sn^{IV}-beta and Sn^{IV}-grafted mesoporous carbon-silica composite could catalyze the conversion of carbohydrates, such as glucose, fructose and sucrose, in an alcohol medium into alkyl lactate [1,2]. However, these Sn^{IV}-based catalysts are limited to the transformation of mono or disaccharides. Recently, we reported that lactic acid could be directly produced from cellulose with high efficiency in the presence of diluted Pb^{II} in water [3]. However, the toxicity of Pb^{II} would hinder the practical application of this system. Herein, we report an environmental benign and efficient homogeneous catalytic system for the direct conversion of cellulose into lactic acid. We demonstrate that the combination of Sn^{II} and Al^{III} cations is very efficient for lactic acid formation. The mechanism of the formation of lactic acid and the roles of the two cations in each step will also be discussed through both experimental and theoretical studies.

2 Experimental

Catalytic conversions of cellulose, hexose and triose intermediates and other biomasses were performed in a batch-type Teflon-lined stainless-steel autoclave reactor. The liquid products were analyzed by high-performance liquid chromatography (HPLC, Shimazu LC-20A) equipped with UV-vis and RI detectors and a Shodex SUGARSH-1011 column. The theoretical calculations were performed with the Gaussian 09 software package.

3 Results and discussion

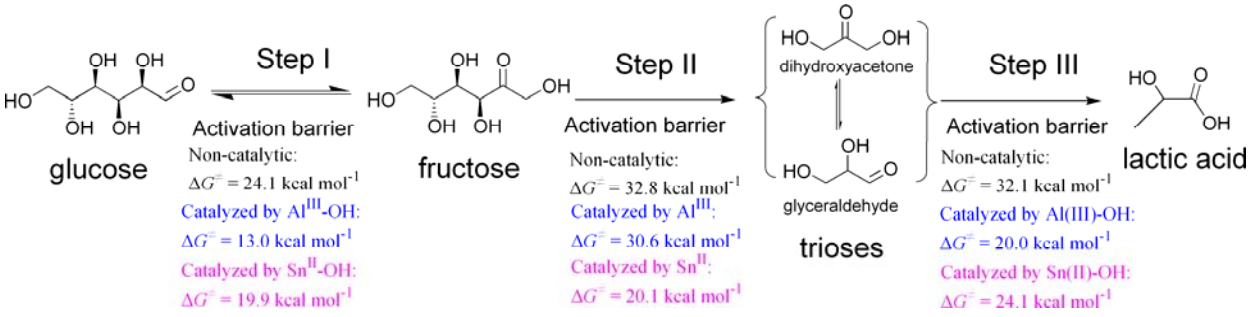
We firstly examined the catalytic performances of various non-toxic metal cations including Al^{III}, Ga^{III}, Fe^{III}, In^{III}, Bi^{III}, Cu^{II}, Ni^{II}, Zn^{II}, Co^{II}, Fe^{II}, Mn^{II} and Sn^{II} for the conversion of fructose, which was demonstrated to be a key intermediate in the formation of lactic acid [3], at 463 K. Among these cations, Al^{III} exhibited the highest yield to lactic acid (41%), whereas In^{III} and Sn^{II} afforded lactic acid yields of 38% and 38%, respectively. We observed a significant enhancement on the yield of lactic acid by combining two cations with a molar ratio of 1/1. Among various combinations, the Al^{III}-Sn^{II} combination showed the highest yield of lactic acid (90%) for the conversion of fructose at 463 K. It was confirmed that the counter anions in aqueous solution did not significantly influence the catalytic behaviors, and thus the dual cations

played the true catalytic roles. We further clarified that the Al^{III}-Sn^{II} combination could catalyse the conversions of cellulose and other biomasses such as starch and inulin. The yield of lactic acid was 66% for the ball-milled cellulose in water at 463 K for 4 h. The conversion of starch and inulin provided lactic acid yields of 70-80%.

Our reaction path studies clarified that the conversion of glucose to lactic acid underwent the following three tandem reactions: (I) isomerization of glucose to fructose; (II) retro-aldol fragmentation of fructose into trioes (e.g. dihydroxyacetone and glyceraldehydes); and (III) the isomerization of trioes into lactic acid (Scheme 1).

We investigated the roles of Al^{III} and Sn^{II} in the conversion of glucose. Our studies revealed that Al^{III} alone could efficiently catalyze the isomerization of glucose into fructose (Step I) and also the isomerization of trioses into lactic acid (Step III). With increasing the the ratio of Sn^{II}/Al^{III} from 0 to 1/1, the selectivity to fructose decreased and that to lactic acid increased. This indicates that Sn^{II} is responsible for the retro-aldol fragmentation of fructose into trioses. However, a higher ratio of Sn^{II}/Al^{III} rather decreased the selectivity to lactic acid. We clarified that Sn^{II} catalyzed the conversion of trioses into polymeric by-products in the absence of Al^{III}.

Our DFT calculations for the conversion of glucose showed that the Al^{III}–OH species significantly lowered the Gibbs energy barriers for the isomerization of glucose to fructose and that of trioes to lactic acid (Scheme 1). On the other hand, Sn(II) reduced the Gibbs energy barrier for the retro-aldol fragmentation. These results further confirm that Al^{III} is responsible for the isomerization reactions (Steps I and III), while Sn^{II} plays a significant role in the selective cleavage of C-C bond in fructose into C_3 intermediates.



Scheme 1. Reaction pathways for conversion of glucose into lactic acid and the catalytic functions of Al^{III} and Sn^{II} in each step.

4 Conclusions

We discovered that the combination of Al^{III} and Sn^{II} dual cations worked efficiently for the direct conversion of cellulose into lactic acid in water. A lactic acid yield of 66% was attained from cellulose at 463 K. The formation of lactic acid underwent three key tandem reaction steps from glucose, i.e., the isomerization of glucose to fructose, the retro-aldol fragmentation of fructose into trioes, and the isomerization of trioes to lactic acid. We clarified that Al^{III} was responsible for the isomerization of both glucose and trioes, while Sn^{II} played a significant role in the retro-aldol fragmentation of fructose to trioes.

OSDA-Free Beta Zeolite with High Al Content as Efficient Catalyst for Biomass Conversion

Otomo R, Yokoi T.*, Tatsumi T.

Tokyo Institute of Technology, Tokyo, Japan

* yokoi.t.ab@m.titech.ac.jp

Keywords: OSDA-free zeolite, synthesis, glucose

1 Introduction

Beta zeolite can be synthesized by a variety of methodologies typically using tetraethylammonium (TEA) cation as organic structure-directing agent (OSDA). In 2007 Xiao *et al.* reported the OSDA-free synthesis of Beta zeolite [1]. Since this pioneering work, other groups have also reported the OSDA-free synthesis of Beta zeolite [2] and its applications [3] Today, OSDA-free synthesis is one of the hottest topics in zeolite science, and it has attracted considerable attention because OSDA-free synthesis has several advantages compared to conventional ones using OSDAs. Therefore, OSDA-free synthesis of zeolites will certainly contribute to development of potential green chemical processes if thus prepared zeolites exhibit a high catalytic performance.

It has long been recognized that 5-hydroxymethylfurfural (HMF) is a bio-based "platform" material for producing useful chemicals [4]. Increasing research interest has been paid to the synthesis of HMF from sugars, particularly glucose because it is the most abundant component of woody biomass. However, this reaction is still a challenging subject because it is a multi-step reaction by way of fructose as an intermediate.

Herein, we first demonstrate an effective conversion of glucose to HMF over OSDA-free Beta zeolite whose acid properties are tuned by a simple method making the best use of its high Al content.

2 Results and discussion

First, we evaluated the catalytic performance of OSDA-free Beta zeolite (Si/Al atomic ratio = 5.5) prepared by calcination of the NH_4-form zeolite at 500 ºC, designated as Beta(OF)-Cal500 (Figure 1). The amounts of Brønsted and Lewis acids of Beta(OF)-Cal500 were 0.71 and 0.20 mmol/g, respectively, with the B/L ratio of 3.6. In the early stages of the reaction, fructose was produced through the intramolecular hydride transfer over Lewis acid sites and the yield of fructose was increased along with the glucose conversion up to the maximum (10 %) at the conversion of 44 %. Then the yield of fructose was continuously decreased and simultaneously the HMF yield was increased. This behavior confirmed that the conversion of glucose proceeded through the tandem reaction in the presence of Beta(OF) zeolites. The yield of HMF reached to the maximum of 72 % at 6 h, which is more or less the best performance that has so far been reported for a heterogeneous reaction system. At further prolonged reaction time, the

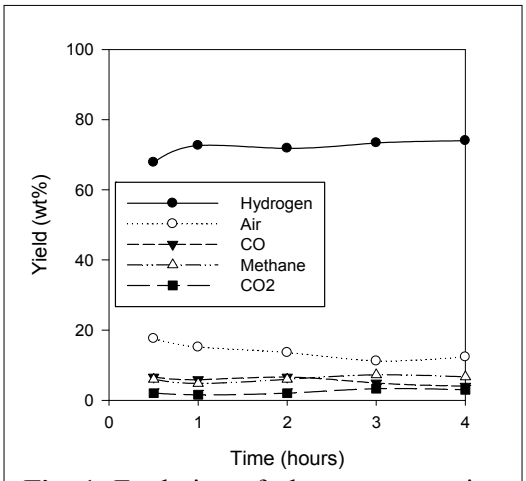

Fig. 1. Evolution of glucose conversion (○), fructose yield (■), HMF yield (◇) in the presence of Beta(OF)-Cal500.

HMF yield was gradually decreased due to its subsequent reactions.

We consider that the calcination temperature would cause the changes in acid properties of catalysts, leading to different catalytic performance. Thus, Beta(OF) catalysts with different B/L ratios were prepared by calcining the NH_4-form zeolite at different temperatures and their catalytic properties were compared (Table 1). As the calcination temperature was increased, Brønsted acid sites were decreased and consequently the B/L ratio was decreased from 3.6 to 1.1. All the catalysts showed similar glucose conversions ranging from 80 to 88 %, but different product distributions. Beta(OF)-Cal450, -Cal500, and -Cal550, which have high B/L ratios (2.9, 3.6 and 2.9, respectively), showed high selectivities to HMF (65, 66 and 67 %). On the other hand, Beta(OF)-Cal600 and -Cal700 with low B/L ratios (1.3 and 1.1, respectively) showed low selectivities to HMF (55 and 45 %) but high selectivities to fructose (12 and 15 %). These differences would be attributed to different reaction rates in the dehydration of fructose to HMF.

Table 1. Acid properties of Beta(OF) zeolites and their catalytic performance in the conversion of glucose to HMF.[a]

Entry	Catalyst	Acidity (mmol/g)[b]			Conversion[c] (%)	Selectivity (%)	
		Brønsted	Lewis	B/L ratio		Fructose	HMF
1	Beta(OF)-Cal450	0.61	0.21	2.9	81	4	65
2	Beta(OF)-Cal500	0.71	0.20	3.6	86	3	66
3	Beta(OF)-Cal550	0.62	0.22	2.9	88	4	67
4	Beta(OF)-Cal600	0.31	0.24	1.3	86	12	55
5	Beta(OF)-Cal700	0.20	0.19	1.1	80	15	45

[a] Reaction conditions: catalyst, 0.1 g; glucose, 0.67mmol; water, 4.5 ml; DMSO, 0.5ml; THF, 15 ml; temperature, 180 ºC; time, 3 h. [b] Acid properties of the samples were measured by IR observation using pyridine as probe molecule. [c] Conversion of glucose.

3 Conclusions

We first demonstrated that the high-aluminum composition of OSDA-free Beta was successfully utilized by taking advantage of the acid properties appropriate for the conversion of glucose to HMF, resulting in the yield over 70 %. The favorable features of the catalyst are proximity of Brønsted and Lewis acid sites and a high B/L ratio. The Beta(OF) zeolite showed stable activity during the consecutive runs.

Keywords: catalytic oxidation, biomass, hydrogen, peroxide, cellulose, oligosaccharide, acids

1 Introduction

The treatment of organic wastes and biomass is very important problem, which coincides with increasing demand for natural products. Therefore, the rapid expansion of the biomass-using industry occurs in recent years the more especially as biomass is a renewable resource. It has been estimated that there is an annual worldwide production of 10–50 billion tons of dry lignocellulose, accounting for about half of the global biomass yield [1]. Lignocellulose is composed of up to 75% carbohydrates, and in the near future it will become an essential source of fermentable carbohydrates for the production of liquid biofuels as well as a large variety of commodity chemicals and biodegradable materials [2]. Lignocellulosic biomass is known to be recalcitrant to biodegradation and processing due to the rigid and compact structure of plant cell wall and catalytic technology is necessary for biomass treatment. Iron oxides are widely used in various chemical processes due to their low toxicity and relatively low cost. A new relatively simple colloid catalytic system based on iron (III) oxides combined with environmentally friendly oxidants - hydrogen peroxide and/or atmospheric oxygen was worked out [3-6] for biomass treatment.

The aim of this study is to investigate the possibilities of the colloid catalyst based on Fe(3+) oxides together with hydrogen peroxide to process lignocellulosic biomass of different origin in reaction vessels of different sizes. The main attention is brought to develop waste-free and environmentally friendly features of catalytic treatment and to reveal the optimal conditions for biomass treatment.

2 Experimental/methodology

Materials: The catalyst was produced by hydrolyzing iron (III) chloride (Merck KGaA, Germany) according to [3-6]; 30% hydrogen peroxide (analytical grade) was used for oxidative treatment of lignocellulosic materials (pine sawdust, olive pomace, oat and rice straw).

Experimental procedure: The colloidal catalyst as thin suspension is prepared in the reaction vessel; after that, biomass is placed into the vessel and in 8-10 hours H_2O_2 is added. The treatment is carried out at 60°C. Liquid micro volumes are taken periodically in the course of reaction to determine H_2O_2 and acid concentration. When all H_2O_2 had been decomposed, the solid and liquid parts of reaction mixture are separated by centrifugation. The solid residue is washed out with clean water and all the water solutions are combined. The washed solid residue is dried under the flow of warm air. We used glass and stainless steel reaction vessels of different sizes: 200 mL, 3 L, and pilot device 50 L. All vessels were equipped with stirrer, a reflux condenser and thermostatic jacket.

Analytical methods: Catalyst samples and solid oxidation products were investigated by transmission electron microscopy (TEM) on an LEO 912 AB Omega microscope (Carl Zeiss) and by micro analyst SX 100 (CAMECA, France) and AFM NT-MDT SOLVER HV.

The products obtained (both a solid product obtained after catalytic treatment and a solid residue obtained from water solution) were analyzed by FT-IR method, using Perkin-Elmer FTIR-1725 spectrometer with auxiliary device Perkin-Elmer PEDR.

3 Results and discussion

The catalytic oxidative treatment of pine sawdust, olive pomace, oat and rice straw biomass results in formation of water solution of organic acids, esters and other low molecular oxidation products derived from lignin, hemicelluloses, cellulose, lipoproteins and sugars; the solid oxidation product constitutes mainly of cellulose and its derivatives. The yield of solid residue is equal to 15-45 % [6]; it depends on biomass nature, reagents concentration ratio (biomass, catalyst, H_2O_2), and oxidation process duration.

Some special features were discovered in the processing of rice straw as compared with other biomass samples. Figure 1b shows that H_2O_2, added to the original straw rapidly decomposes (1b) without acids formation (curve 3b) and the visible destruction of rice straw. It turned out that rice straw catalyses useless H_2O_2 decay in the absence of catalyst. Sawdust and oat straw do not affect the decay of H_2O_2 (Fig.1a, curve 3a). Pre-processing of rice straw by boiling for 2 hours completely disables the straw against the decay of H_2O_2. TEM data show that boiling removes the top glossy layer and uncovers fibrillar structure. We also found that rice straw contains up to 8% of SiO_2, which forms in water phase stable finely dispersed suspension.

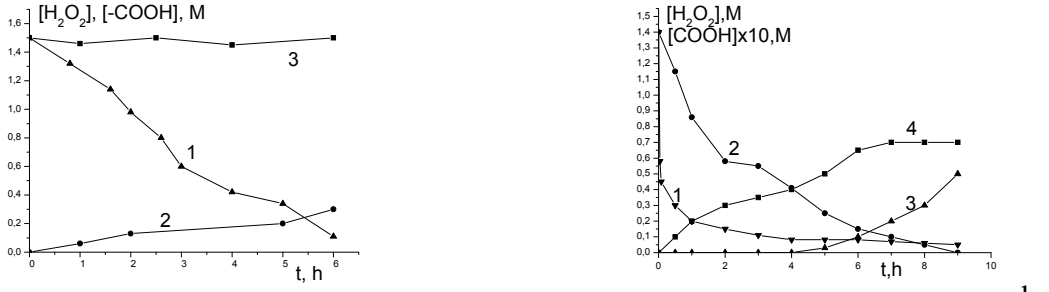

Fig.1 Kinetics of H_2O_2 consumption (1a,1b,2b) and acids accumulation (2a,3b,4b) in the catalytic processing of pine sawdust (a) and rice straw (b) at 60°C; 3a – without catalyst; 1b,3b - original straw; 2b,4b – rice straw pre-treated by boiling.

It must be noted that in a greater volume of the pilot device, the exothermic nature of oxidation reaction displays, therefore the heating is necessary only at the beginning of the treatment.

The results show that the catalytic oxidative processing of vegetable raw materials with the use of H_2O_2 and air as the oxidant and colloidal catalyst based on oxides of iron (3+) is environmentally friendly and waste-free method of recycling of plant biomass into useful products. The solid residue of biomass treatment, as a rule, represents cellulose, which is a food additive E 460 and finds application in pharmaceutical and food industries; it is also used as a component of building materials (putties, cements, composites). Water solution of organic acids and esters can be used in agriculture for fodder processing. Currently, the water phase of oxidation mixture has been successfully used for treatment of seeds and boarding seedling.

Heterogeneous Oligomerization of Ethylene over Highly Active and Stable Ni-Exchanged Mesoporous Materials

Hulea V.[1*], Andrei R.A.[1], Fajula F.[1], Cammarano C.[1], Popa M.I.[2]

1 - Charles Gerhardt Institut, Ecole Nationale Superieure de Chimie, Montpellier, France

Keywords: eyhylene oligomerization, nickel, mesoporous materials

1 Introduction

With annual worldwide capacity of 140 million tons, ethylene is among the most important basic organic chemicals. Currently ethylene is produced from crude oil derivatives (*via* steam thermal cracking), but alternative methods involving natural gas, coal and biomass proved their industrial potential. For example, methanol conversion into ethylene and propylene (*via* zeolite-catalyzed MTO process) or bio-ethanol conversion into ethylene, are very promising technologies [1]. Among the industrial applications involving ethylene, the oligomerization reaction is of considerable interest for producing starting materials for lubricants, surfactants, alcohols, amines, and acids. Ethylene oligomerization can be efficiently catalyzed by homogeneous and heterogeneous catalysts having transition metals (in particular nickel) as active sites. Usually, nickel is contained in complexes with different ligands [2], but it can also be stabilized as highly dispersed ionic species on inorganic supports [1,3,4]. Through exhaustive catalytic studies [3,4] we investigated the activity, the selectivity and the stability to deactivation of Ni-exchanged mesoporous materials for the ethylene oligomerization performed in both batch and flow mode, at low reaction temperatures. Mechanistic aspects were also discussed.

2 Experimental

AlMCM-41 (3.5 or 10 nm pore size) was prepared by direct synthesis [3]. AlSBA-15 (7.9 nm pore size) was prepared by post-synthesis alumination of a pure silica SBA-15 material using sodium aluminate as aluminium sources [4]. Calcined Na^+-mesoporous silica-alumina samples were converted into Ni^{2+}-form by cationic exchange with nickel nitrate. The catalysts were characterized by XRD, TEM, ^{27}Al-MAS NMR, ^{29}Si MAS NMR and N_2 adsorption-desorption. Ethylene oligomerization was performed in both batch and flow mode. The oligomers were analyzed by GC.

3 Results and discussion

As a general rule, under mild conditions, the catalysts were highly active and selective. Table 1 summarizes the average catalytic activity (A), the TOF values and the oligomers distributions (wt%) for representative tests. Activities (estimated by weighting the reaction mixture) were between 150 and 175 $g_{oligomers}\ g_{catalyst}^{-1}\ h^{-1}$. It is important to point that these are the highest yields ever reported in the literature with Ni-based heterogeneous catalysts. Additionally, the high TOF values exhibited by the Ni-exchanged mesoporous materials are comparable to those obtained in the ethylene oligomerization processes catalyzed by Ni^{2+}-based complexes [4]. The oligomers consisted of C4, C6, C8 and C10 olefins. Only traces of alkanes and odd carbon number alkenes were identified, indicating that the hydrogen transfer or the acid catalyzed cracking reactions are not occurring to a significant level.

Table 1. Catalytic behavior of Ni-based catalysts: batch mode, 150 °C, and 3.5 Mpa.

Catalyst	Si/Al	Ni (wt%)	A($gg^{-1}h^{-1}$)	TOF (h^{-1})	C4	C6	C8	C10
Ni-AlSBA-15 (7.9 nm)	7.0	2.6	175	14 200	40.6	37.3	14.8	7.3
Ni-AlMCM-41 (3.5 nm)	9.0	2.0	150	15 720	45.1	33.0	14.9	7.0
Ni-AlMCM-41 (10 nm)	9.0	2.0	158	16 560	40.2	33.2	15.5	11.1

In order to evaluate the deactivation rate of the catalysts, the ethylene oligomerization was carried out in flow mode, in a fixed-bed dynamic reactor, using ethylene without inert carrier gas. Table 2 compares the conversions of ethylene (%) obtained on Ni-AlSBA-15 and Ni-AlMCM-41 (pore size of 3.5 nm) with those previously obtained on representative Ni-based catalysts, such as Ni-silica-alumina (mean pore size of 3.4 nm) [5] and Ni-Y zeolite (pore diameter about 1 nm) [6]. Ni-AlSBA-15 (with shows a deactivation rate (d.r.) of 1.6 10^{-3} h^{-1}) is by far the most stable catalyst compared, for instance, to Ni-MCM-41 (d.r. 6.2 10^{-3} h^{-1}) or Ni-Y (d.r. 8.6 10^{-3} h^{-1}). Note: d.r. = $(a_0-a_t)/(a_0 \times 80)$, where a_0 is the initial conversion and a_t the conversion after 80h. The stability of the activity of the Ni-AlSBA-15 catalyst can be related to the SBA-15 topology where the large interconnected mesopores facilitate the diffusion of the products, particularly the bulkier ones, and results in a lower deactivation rate of these catalysts.

Table 2. Ethylene conversions (%) on various porous Ni-based catalysts (flow mode).

Tme-on-stream (h)	1	20	40	60	80
Ni-AlSBA-15[a]	93	90	87	84	81
Ni-AlMCM-41[a]	95	72	57	49	44
Ni-Slica-alumina[b]	70	53	36	24	15
Ni-Y zeolite[c]	58	36	24	14	7

[a] 150 °C, 3.0 MPa; [b] 0.33 wt% Ni, 300 °C, 1.1 MPa; [c] 1.13 wt% Ni, 130 °C, 3.5 MPa

The experimental results obtained on Ni-based catalysts, confirmed the existence of two types of mechanisms which contribute to the conversion of ethylene into C4-C10 olefins: one mechanism involving metallacyclic intermediates over Ni^+ active sites (to form 1-C4 and 1-C6 olefins from ethylene), and a second one based on acid catalysis (isomerization and co-oligomerization reactions), leading to the formation of octenes or higher olefins [4].

4 Conclusions

Ni-AlSBA-15 and Ni-AlMCM-41 are very active and stable catalysts for ethylene oligomerization. Productivities up to 175 g of oligomers per gram of catalyst per hour were obtained in batch mode. In a fixed-bed flow reactor, the catalysts showed very high stability of the activity with time on stream.

Keywords: UHMWPE, morphology, technology, mechanical properties, solid-state processing

1 Introduction

In the last two decades the problem of production, processing and using of ultra-high molecular weight polyethylene (UHMWPE) - linear unbranched polyethylene with a molecular weight greater than $1\text{-}10 \cdot 10^6$ g/mol, has attracted many researchers. This engineering material, depending on the technology of production and processing, has particular molecular architecture and unprecedented mechanical properties.[1] Due to such properties as high abrasion resistance, mechanical strength and high modular characteristics, chemical resistance, low coefficient of friction, biocompatibility, the relative simplicity of the structure and thus affordability, this material has become popular. That is why it is widely used in various fields of technology and human life.

2 Results and discussion

Over the past two decades in the published literature has appeared new information that can help to revise the basic concepts of optimization technology of UHMWPE, the state of the molecular structure and morphology of the polymerization product, the possibility of management in the polymerization process and the possibility of simplifying processing of UHMWPE into products with ultra-durable and ultra-modular properties. [2 -10]

Analysis of the conditions for the formation of nanostructured components morphology of reactor powders (RP) of UHMWPE in the polymerization process allowed us to formulate the requirements for the polymerization, which would result in forming RP of UHMWPE with improved morphology and improved processability. Similar conditions were expressed in the works of Dutch researchers. [7,9,10]

These requirements are as follows:

1) During the formation of RP of UHMWPE it is appropriate to apply the single-site catalyst systems that provide live (pseudo) mechanism for the polymerization of ethylene.

2) Conditions for obtaining RP of UHMWPE (temperature, ethylene pressure, concentration of catalyst and cocatalyst, polymerization time) must correspond to that the rate of formation of the macromolecules and the rate of growing crystallites from them were comparable.

These conditions should hinder the formation of links between growing polymer chains and improve the morphology of the resulting polymer, thereby facilitating the processing RP of UHMWPE into products.

We have the examples of two types of phenoxy-imine catalyst systems, shown that compliance with these requirements provides the opportunity to get RP of UHMWPE capable of solid-state processing to produce a ultra-durable and ultra-modular threads with 2.5 -3.5 GPa and 110-130GPa,respectively.[8-10]

The processing conditions are described in [7].

The results show that modifying the technology of producing RP of UHMWPE may get UHMWPE with improved morphology, which allows realizing a solid-phase processing of RP of UHMWPE into products with ultra-durable and ultra-modular properties.

3 Conclusions

This technology is a significant step forward compared to currently available processing of UHMWPE involving solutions both in hardware design, as well as on the economy of the process. Similar technology is now also being developed by Teijin Corporation.

Keywords: zirconocenes, carboalumination, cycloalumination, asymmetric, catalysis

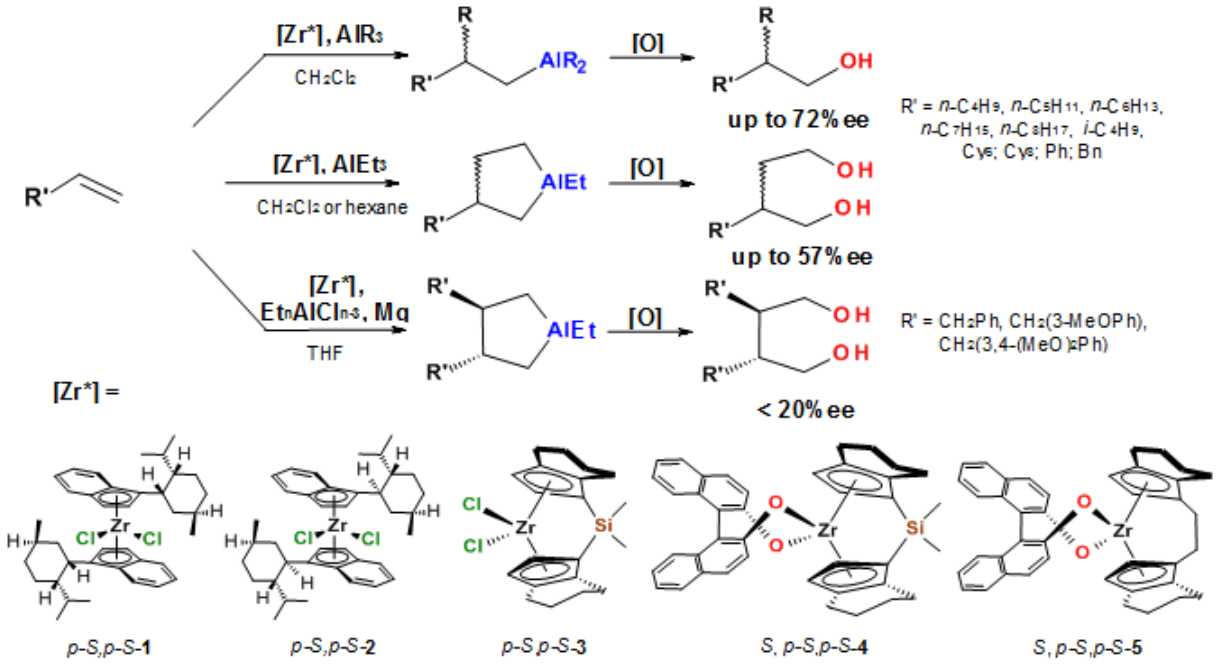
1 Introduction

Chiral η^5-complexes of Zr and Ti have found wide application as components of catalytic systems for highly chemo- and stereoselective construction of C-H, C-C, and metal-C bonds. Among these studies the development of catalytic enantioselective methods for alkene functionalization by organoaluminum compounds (OACs) [1-3] will give effective ways to the synthesis of important enantiomers for organic and organometallic chemistry.

2 Results and discussion

The catalytic action of enantiomerically pure conformationally rigid and non-rigid complexes Zr **1-5** in the reaction of alkenes of various structures with OACs has been studied (Scheme 1).

Scheme 1



It was shown that the reaction chemo- and enantioselectivity depend on the catalyst and alkene structure, as well as solvent nature. Thus, the reaction of $AlEt_3$with linear alkenes in hydrocarbon solvents, catalyzed with complex (-)-bis-(1-neomenthylindenyl)zirconium dichloride (**1**), predominantly gives *S*-enantiomers of 3-alkyl substituted alumolanes with 23-37%*ee*. In contrast, the use of chlorinated solvent (CH_2Cl_2) provides carbometallation products in a 70-80% yield with enantiomeric purity 47-70%*ee*, *S*. In the case of vinylcycloalkanes and styrene, the process runs with the formation of roughly equal amounts of carbometallation products and substituted alumolanes with enantioselectivity of 39-69%*ee* and 40-57%*ee*, respectively.

The catalyst **2**, which contains menthyl-substituted η^5-ligands, showed the less enantioselectivity both in the carboalumination pathway (18%*ee*, *R*) and cycloalumination (24%*ee*, *R*).

The conformationally rigid complexes **3-5** exhibited lower enantioselectivity in the reaction AlR_3 (R = Me, Et) with 1-alkenes then catalyst **1**. The reaction of 1-alkenes with $AlEt_3$ in CH_2Cl_2 at room temperature in the presence of **3-5** proceeds over 24 hours with conversion of 60-90% and gives mainly acyclic OACs with yield of 20-65% and enantiomeric purity of 15-50%*ee*, *S*. Moreover, the formation of alumolanes with yield of 20-30% and 12-26%*ee*,*S* was observed. Interestingly, in these experiments we isolated enantiomerically enriched functionally substituted stereoregular alkene oligomers (up to 34%) with a number of units n=3-6.

It was found that the reaction of substituted allylbenzenes (Ar = phenyl, 4-methoxyphenyl, 3,4-dimethoxyphenyl) with $EtAlCl_2$ (Et_2AlCl) and Mg in THF in the presence of catalytic amounts of neomenthyl-substituted zirconocenes provides *trans*-3,4-dibenzylalumolanes with enantiomeric purity of 11-20%*ee*.

We showed the applicability of *R*-MTRA and (*R*)- 2- phenylselenopropanoic acid (*R*-PSPA) [4] for the estimation of enantiomeric purity and absolute configuration assignment of stereogenic centers in *β*-chiral primary alcohols and 2-substituted 1,4-butanediols resulting from oxidation and hydrolysis of organoaluminum products.

The effect of a solvent nature on the rate of intramolecular exchange between conformers of neomenthyl-substituted zirconocenes, which are formed as a result of the rotation of the indenyl fragments relative to $[ZrCl_2]$, has been shown for the first time by the means of DNMR spectroscopy. Further, we carried out a theoretical study on the possible rotamers of the conformationally non-rigid catalytically active centers. Comparison of the conformer composition and dynamics of the complexes with their activity and stereoselectivity in the reactions of OACs with alkenes led to the conclusion that the enantioselectivity of the reactions is determined by the kinetic factor, namely, by the rate of interaction in a pair: conformer of catalytically active center - substrate. Thus, in order to achieve high enantioselectivity in the studied reactions the catalyst molecule should have a specific conformational mobility for the formation of a suitable rotamer, which lifetime will be sufficient for the alkene insertion.

3 Conclusions

Thus, the rigid structure of the enantiomerically pure Zr catalysts is not the necessary condition for enantioselective transformations of terminal alkenes in the reactions with OACs. The “key-lock” relationship between catalytically active centers and substrates, i.e. the kinetics of their interaction defines the activity, chemo- and enantioselectivity of the studied catalytic systems.

Tuning the Selectivity of Nanocatalysts by Using the Ligand Modification Strategy: Experiment and Theory

Fu G., Chen G.X., Zhao Y., Zheng N.F.*

State Key Laboratory for Physical Chemistry of Solid Surfaces and College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, China

* gfu@xmu.edu.cn

Keywords: selectivity, ligand modification, DFT, steric effect, electronic effect, atom coverage

1 Introduction

Selectivity is of paramount importance in catalysis. To realize the important structural parameters which can be tuned to achieve good selectivity are highly desirable. Recently, ligand modification strategy has been introduced to enhance the catalytic performance in selective hydrogenation reaction [1-3]. In this contribution, we combined experiments and DFT calculations to extend the scope of ligand modifation, and proposed that such a enhancement can be understood in terms of steric effect and/or electronic effect.

2 Results and discussion

The chemoselective hydrogenation of α, β-unsaturated aldehydes to the corresponding unsaturated alcohols is of fundamental interest in heterogeneous catalysis, because the formation of the saturated aldehydes favors over that of the unsaturated alcohol due to their thermodynamic nature. Previously, we have demonstrated that amine-capped Pt_3Co alloyed nanoparticles can be used as efficient catalysts for the selective hydrogenation of α, β-unsaturated aldehydes. DFT calculations showed that when the shorter-chained amines are used as capping agents, the α,β-unsaturated aldehyde still have change to sitting on the surface. On the other hand, the long carbon chains that are capped onto the Pt_3Co nanocatalysts imparted steric hindrance so that CAL molecules did not lie flat on the nanoparticle surface. Our calculations demonstrated that CAL molecules can only enter into the array of OAm molecules edge on with their aldehyde groups while the C=C bonds directed away from the catalytically active surface. This finding indicated that the presence of long-chain amines on the surface of the nanoparticles was essential to the high hydrogenation selectivity towards α, β-unsaturated alcohols [1] .

The second example would show that the coated ligand would shape the selectivity through electronic effects. The hydrogenation of nitroaromatics is a typical consecutive reaction that yields many products including nitrosoaromatics, N-hydroxyanilines, and anilines. Among them, N-hydroxyanilines are of importance in many applications. Experimentally, the high (>95%) selectivity to N-hydroxyaniline was first achieved by ethylenediamine (en) coated ultrathin Pt nanowire. DFT calculations demonstrated that the strong binding of en significantly altered the adsorption behaviors of the Pt catalysts, making the coordinated unsaturated Pt atoms only accessible by the electron deficient species, such as nitrobenzene and the nitroso intermediate. In contrast, the binding of N-hydroxyaniline with en-coated Pt nanowire becomes relative weak, which would be substituted by other stronger adsorbates (such as en, nitrobenzene or nitrosobenzene) easily once it was formed, thus switching off the deeper hydrogenation.

In fact, adsorbed H atom could also be viewed as surface modifier, which significantly affects the nature of the surface and controls the selectivity. Experimentally, we found that Pd nanosheets and Pd tetrahedra exposed by {111} facets had good catalytic activity for styrene hydrogenation but no activity for trans-stilbene hydrogenation; while Pd nanocubes enclosed by

{100} facets exhibit high activity for both of the substrates. For clean Pd{111} and Pd{100}, both substrates strongly adsorbed on the surfaces. Under typical reaction conditions, both Pd{111} and Pd{100} were covered by H atoms, and the adsorption of olefins became very weak. In this case, Rideal type hydrogenation mechanism turned out to be dominant rather than the classical Langmiur-Hinshewood type mechanism [4]. Interestingly, for the first step hydrogenation, Pd{111} was more active than Pd{100} because the Pd-H bond on Pd{111} was liable to be broken. On the other hand, the second step hydrogenation critically depended on the stability of half-hydrogenated intermediates. For trans-stilbene on Pd{111}, the half-hydrogenated intermediate was so unstable that the second step hydrogenation should overcome a barrier as high as 0.92 eV, thus inhibiting the whole hydrogenation.

3 Conclusions

The main conclusions can be summarized as follows:

(1) Ligand modification could precisely shape the selectivity through steric and/or electronic effects.

(2) Adsorbed H atom could also be viewed as a surface modifier, which would alter the stability of adsorbed molecules or intermediates as well as the hydrogenation mechanism.

Keywords: fluoroalkylation, phosphorylation, green chemistry, electrochemical synthesis, catalysis, transition metal complexes

1 Introduction

In recent years, a lot of therapeutic candidates or advanced materials based on of arenes with fluoroalkyl or phosphonate substituents were created, the prominent examples being anticancer, antibacterial, and anti-HIV agents. From a synthetic chemistry point of view, a wide range of methodologies for the incorporation of a phosphonic acid group or perfluoroalkyl group have been discovered and reported. However, the synthesis pathways to these compounds are very complex, often multi-step and involve high temperatures, pressures, expensive reagents and catalysts. Nevertheless, the high value for medical, agrochemical and engineering industries is the impetus that provokes and promotes exploratory research related to the simplification of the processes. That is why the aim of the work is to provide a simplified method for the catalytic fluoroalkylation products through cross-coupling reaction of organic and fluoroorganic halides, as well as phosphorylation of substrates through CH-activation of aromatic precursors excluding the use of chemical oxidants and reductants.

2 Results and discussion

The unsaturated transition metal complexes of Ni, Co with "no-innocent" ligands have been chosen as catalysts, due to several factors : Ni and Co or Pd are more accessible than Pt, wherein the nickel and cobalt compounds have a very favorable combination of properties required for organic reactions by coordination, namely a sufficiently low ionization potential (promotes oxidative addition); the tendency to form square-planar complexes and the ability to achieve pentacoordination to allow the connection; high electron affinity (promotes reductive elimination). Some properties are contradictory, but a compromise should to be reached for the successful implementation of all stages of the catalytic cycle. The successful choice of the catalytic system metal-ligand-solvent- co-catalyst ion (from sacrificial anode) in certain ratios allows to achieve the high yields of the desired products.

To achieve our goals , we tried to solve a number of interrelated tasks, namely, to study and demonstrate the possibility of electrocatalytic aromatic fluoroalkylation under mild conditions, to justify the choice of the most efficient and affordable catalysts - nickel, copper, cobalt complexes with different ligands to improve the implementation of processes in an electrochemical cell with different soluble and insoluble anodes , the process to establish patterns of cross-coupling and CH- functionalization to make assumptions about the key stages of the catalytic cycle.

As a result, a one-step catalytic method for aromatic perfluoroalkylation with metal complexes electrochemical reduction under mild conditions with decisive role of the sacrificial anode metal ion has been developed. This technique was tested with various catalysts and anode

metals. Some laws of this reaction were discovered. Some regularities of this reaction, such as the linear dependence of Ar-R_F yield vs reduction potential of the catalyst, the copper anode fundamental importance for the selective formation of the cross-coupling product, which confirms the important role of transmetallation step in the catalytic cycle, were shown.

A key role of transmetallation during the catalytic cycle has been assumed. Catalyst begins catalytic cycle for the oxidative addition reactions of M(I)L (M = Ni, Co) with R_FX, but the resulting intermediate - sigma-complex R_FMLX then either reacts with the formation R_FCuLX by transmetallation, which further reacts with PhI under conditions of electroreduction of formation of the desired cross-coupling products, or stage of the transmetallation is later, at the stage bi-organyl sigma complex $R_F(Ar)ML$. It is known that nickel complexes of the type $Ni(Ar)CF_3L$ are very stable and do not lead to cross-coupling products Ar-CF_3. Therefore transmetalation of intermediate sigma complexes with copper favors the catalytic reaction and provides a reductive elimination in the formation of cross-coupling product.

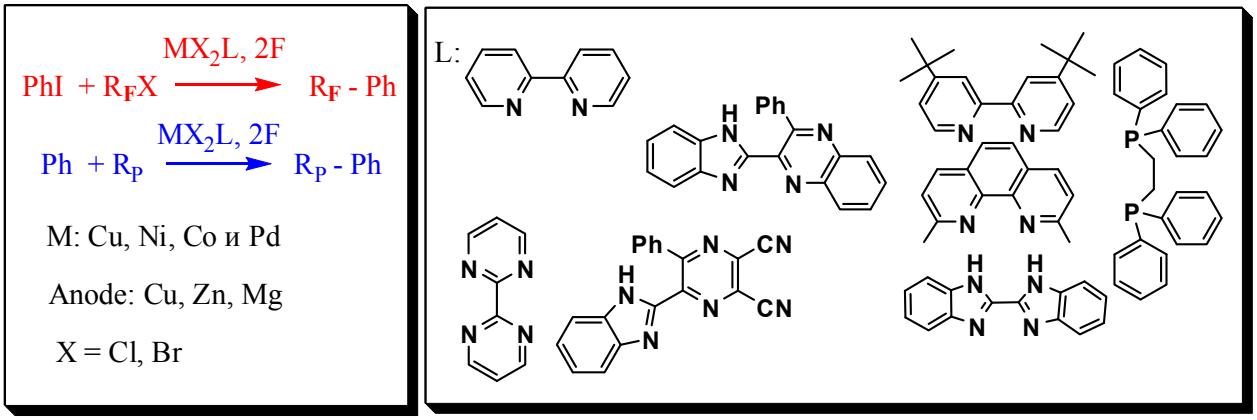

Fig. 1. Schematic representation of studied processes

3 Conclusions

New approach to C-H bonds of aromatic substrates phosphorylation, based on nickel, cobalt or manganese complex in the high oxidation states generation and regeneration on the electrode was proposed. New methods of organofluorine and organophosphorus compounds synthesis can find possible practical application for biologically active, hydrophobic or plasticizing compounds production.

Keywords: rare-earth metals, homogeneous catalysis, olefin, hydrophosphination, hydroamination

1 Introduction

Rare-earth complexes proved to be efficient catalysts for a wide range of transformations of unsaturated substrates (polymerization, hydroamination, hydrosilylation, hydroboration etc).

2 Results and discussion

The synthesis and characterization of heteroleptic alkyl, hydrido, amido rare-earth (+2 and +3) and alkaline-earth complexes supported by various N,N-, N,N,N,N-, N,N,O-, N_2,O_4-, N,N,P(O)-ligands as well as their catalytic activity in intermolecular olefin hydrophosphination and hydroamination will be reported. The new complexes afford highly active, chemoselective and, in the case of monoadditions, 100% *anti*-Markovnikov regiospecific catalysts (down to 0.04 mol-% loading) for the hydrophosphination of styrene with $PhPH_2$ under mild conditions. The highest TOF 330 h^{-1} at 60 °C was observed for Yb(II) amido complex. These complexes also turned out to be efficient precatalysts for the intermolecular hydroamination of styrene and pyrrolidine.

Keywords: CO_2, alcohol, surfaces, FTIR

1 Introduction

The relevant increase of the cost of oil and the rate of consumption of its recourse is stimulating a great efforts toward the disclosure of new routes to produce chemicals. CO_2 is a non-toxic, abundant and cheep carbon resource, so its conversion to valuable chemicals became a topic of high scientific interest. One of the perspective directions is non-reductive transformation of CO_2 to organic carbonates that can be used in the production of polycarbonate and polyurethane resins, electrolytes for lithium ion batteries, alkylating and carbonylating reagents and inert solvents. Zeolites BEA are characterized by three-dimensional 12-membered ring channel system and their large pores allow an easy diffusion of the various reactants into the zeolite structure. Modifying BEA zeolites with both Cs^+ exchanged ions and Cs-oxide like nanospecies it is possible to increase their basic properties [1] and their capacity for CO_2 activation.

2 Experimental/methodology

Cs/BEA catalyst was prepared by ion exchange of acidic BEA zeolite (RIPP, China), followed by impregnation with a solution of CsOH [2] in order to attain a final Cs/Al ratio = 1.6.

Infrared spectra were collected using a Bruker IFS 28 spectrometer (MCT detector; resolution: 4 cm-1). The samples were pressed in self supported pellets and placed in a quartz cell with CaF2 windows that allowed all thermal treatments (100 Torr O2 at 450°C for 1 h with subsequent outgassing at 450°C for 1h) and adsorption/desorption experiments to be carried out in situ.

High-resolution mass spectrometry analyses were performed using an LTQ Orbitrap mass spectrometer (Thermo Scientific).

3 Results and discussion

Introduction of Cs by wet impregnation after ion exchange significantly increase catalyst basicity. At higher Cs contents, Cs-overloading followed by the formation of Cs-oxide-like species with strong basicity dispersed within the zeolite pores takes place. FTIR analysis verifies that after ion exchange the presence of Brønsted acidic framework-bridged OH groups on the zeolite surface were not observed. The following impregnation with CsOH and subsequent Cs2O formation resulted in the almost complete disappearance also of nonacidic terminal silanols. On the surface of the impregnated samples CO2 adsorbtion with the formation of carbonates (interacting with basic centers) was observed. Methanol, ethanol, 1-and 2-propanol, butanol and catechol were adsorbed on Cs/BEA surfaces with the formation of alcolates.

Figure 1 shows methanol/CO2 co-adsorption on the surface of Cs1.6/BEA catalyst. Spectra of pure catechol registered in water (at different pH) indicated that dissociative adsorption of catechol occurred on Cs-oxide-like particles with a formation of C6H4OH- species. A strong band at 1750 cm-1 with two shoulders at 1780 and 1725 cm-1 is due to the formation of the organic carbonate species. The same band was observed after the adsorption of dimethyl carbonate on the surface of Cs1.6/BEA. The reaction is time-favoured – the first traces of the band at 1750 cm-1 can be observed after 1-2 hours of the contact and then the intensity of the band progressively increased. High-resolution mass spectrometry analyses confirmed the presence of corresponding organic carbonates in aqueous washout solutions. We also observed that the activity of the reaction between CO2 and alcohol decrease with the increase of the carbons atoms number in the alcohol chain of linear carbonates (Fig. 2).

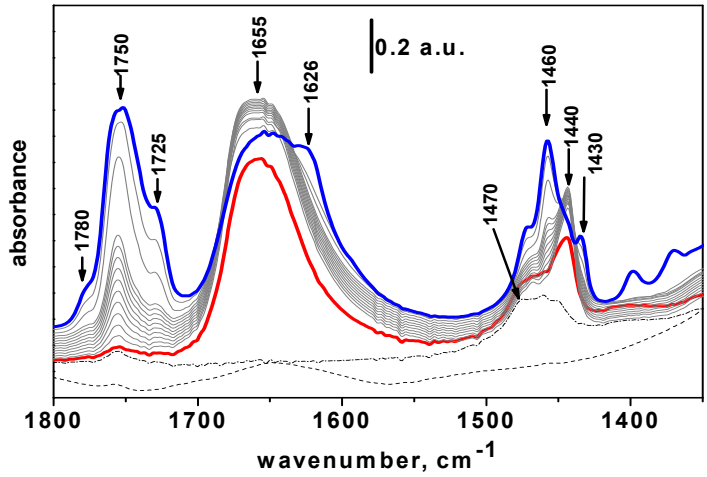

Fig. 1. Methanol/CO_2 co-adsorption on $Cs_{1.6}$/BEA. Dash line - $Cs_{1.6}$/BEAripp, dash dot line – alcohol (10 torr) adsorption, solid lines - CO_2 (100 torr) co-adsorption: red line – right away after CO_2 introduction, blue line – after 100 h of contact.

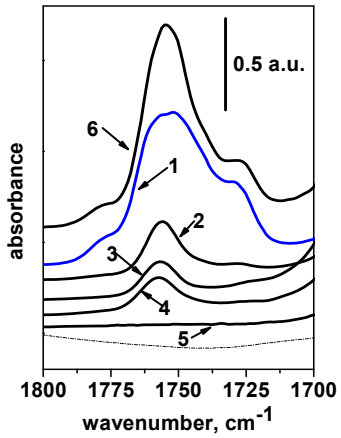

Fig. 2. Formation of organic carbonates after ca. 100 h. of alcohol/CO_2 co-adsorption on $Cs_{1.6}$/BEA: 1 – methanol, 2 – ethanol, 3 – n-propanol, 4 – iso-propanol, 5 - butanol, 6-catechol. Dash line - $Cs_{1.6}$/BEAripp before adsorption.

4 Conclusions

The efficiency of the reaction between alkyl C1-C4 alcohols and CO2 to form the corresponding organic carbonates decreased as the length of the alkyl chains increased. Conversely, an aryl alcohol (catechol) appeared as an active substance in the reaction with CO2 for the production of the carbonate. This features suggest that flexible alkyl moieties of adsorbed alcohol molecules can hinder the interaction with co-adsorbed CO2 (in the form of carbonates), whereas larger but rigid aromatic rings do not interfere with the interaction with neighbour carbonates.

Keywords: addition, isopulegol, verbenol oxide, benzaldehyde, dioxinol, zeolites

1 Introduction

New biologically active substances are synthesized from a variety of compounds isolated from natural sources. It has been published recently that compounds with benzodioxin framework can possess promising analgesic activity [1]. Compounds with the mentioned structure were synthesized by the reaction between *cis*-verbenol oxide and aromatic aldehydes in the presence of an excess of montmorillonite clay [2]. Due to importance of the target compound, low selectivity towards it and a very limited amount of experimental data available, there is a need to investigate synthesis of compounds with promising biological activity.

In the current research, syntheses of compounds with the desired benzodioxin framework were investigated (Fig. 1). Besides verbenol oxide (Fig. 1, compound 1) also substrates with analogous structure, namely isopulegol (Fig. 1, compound 3) and 3-methyl-6-(prop-1-en-2-yl)cyclohex-3-ene-1,2-diol (Fig. 1, compound 2), product of verbenol oxide isomerization, were tested in the reaction with benzaldehyde.

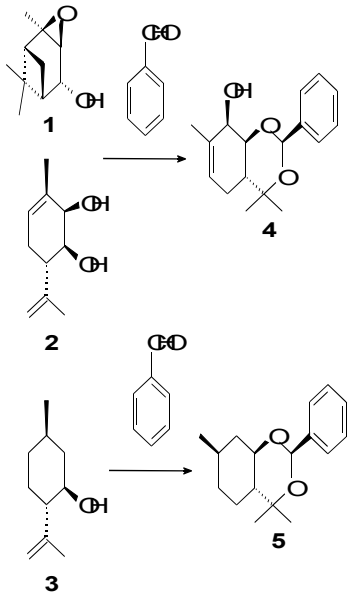

Fig. 1. Reaction schemes of addition reactions of verbenol oxide **1**, 3-methyl-6-(prop-1-en-2-yl)cyclohex-3-ene-1,2-diol **2** and isopulegol **3** with benzaldehyde

2 Experimental/methodology

Metal-modified zeolites beta were prepared, characterized and tested in the present study. As a comparison proton forms of zeolites were also evaluated for addition reactions.

The characterization of catalysts was carried out using XRD, SEM, N_2 adsorption, XPS and

FTIR spectroscopy with pyridine as a probe molecule.

Addition reactions over heterogeneous catalysts were carried out in the liquid phase using a batch-wise glass reactor. In a typical experiment the initial concentration of substrate and the catalyst mass were 0.04 mol/l and 0.3 g, respectively. The kinetic experiments were performed under the following conditions to avoid mass transfer limitation: the catalysts particle size below 90 μm and the stirring speed of 390 rpm. The catalyst was activated in the reactor at 250 °C in an inert atmosphere for 30 min before the reaction. Benzaldehyde was used in excess (V_L=50 ml) and toluene was used as a solvent or reactions were carried out without addition of any solvent. The reaction temperature was 70 °C. The samples were taken at different time intervals and analyzed by GC. The products were confirmed by GC-MS and NMR methods.

3 Results and discussion

In the present work zeolite Beta-150 (150 = SiO_2/Al_2O_3 molar ratio) was modified by iron, characterized and tested per se and in the modified form for syntheses of compounds with the desired benzodioxin framework. Three different substrates were used in addition reactions with benzaldehyde. The results obtained during the study are shown in Table 1.

Table 1. Results of addition reactions using different substrates.

Substrate	Catalyst	Conversion (%) (after 120 min)	Selectivity to desired product (%) at 75 % (* 100 %) conversion level
VO	H-Beta-150	100	* 40
	Fe-Beta-150	100	* 43
IP	H-Beta-150	100	* 16
	Fe-Beta-150	76	15
DIOL	H-Beta-150	98	8
	Fe-Beta-150	79	7

Note: VO = verbenol oxide, IP = isopulegol, DIOL = 3-methyl-6-(prop-1-en-2-yl)cyclohex-3-ene-1,2-diol

Addition reactions were observed to be influenced by the structure of the used substrate as well as by the physico-chemical properties of the catalysts. Verbenol oxide was evaluated as the most promising substrate for preparation of the compound with the desired structure.

4 Conclusions

Metal supported zeolites were prepared, characterized and tested per se and in the modified form in addition reactions of various substrates with similar structure with benzaldehyde. Activity and selectivity of tested catalysts were correlated with their physico-chemical properties. The study was mainly focused on the substrate structure and the influence of Lewis and Brønsted acid sites of catalyst on the selectivity toward desired the dioxinol product with potential analgesic activity. Detailed kinetic analyses and reaction mechanisms will be discussed in the final work.

Fabrication of Efficient and Stable Solid Acids via Encapsulation of PS-SO_3H within Hollow Interiors

Yang Q.*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China

* yangqh@dicp.ac.cn

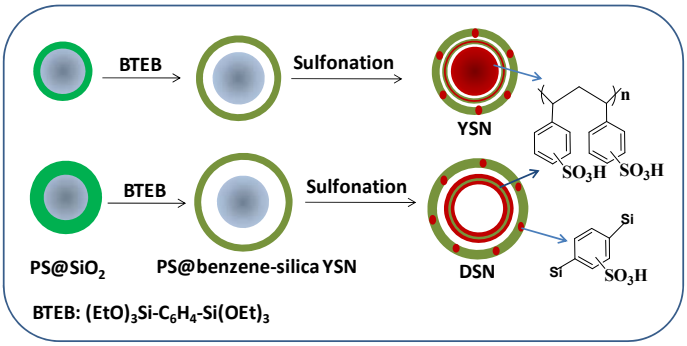
Keywords: solid acids, PS-SO_3H, hollow interior, silica, encapsulation

1 Introduction

Driven by environmental consideration and safety concerns, the replacement of hazardous and corrosive mineral acids by solid acids is one of the important tasks for green and sustainable production of chemicals. Polystyrene sulfonic acid resins are among the very important solid acids in industry and have been widely used in acid catalyzed reactions, such as esterification, olefin hydration, etherification, alkylation of phenols. They generally exhibit high concentration of acid sites but poor thermal stability and very low surface area. A straightforward strategy for improving thermal stability and increasing surface area is to prepare polymer/silica hybrid composites which could take advantages of high surface area, high thermal stability and anti-swelling properties of silica materials via either physically mixing or covalently bonding method. Though polymer/silica hybrid composites exhibit increased thermal stability, higher exposure degree of acid sites and larger BET surface area in comparison with their polymer counterparts[1], the acid strength of PS-SO_3H could not be enhanced and on the contrary it might become lower because of the reduced acid density by this approach. It has been reported that the increment of acid density and spatial proximity may increase the cooperative effect among acid sites, consequently enhancing the acid strength of PS-SO_3H[2]. Herein, we reported the synthesis of efficient and stable solid acids by encapsulation of PS-SO_3H within the hollow interiors of silica hollow nanospheres. The exposure degree of acid sites and the acid strength could be adjusted by controlling the swelling and aggregating properties of PS-SO_3H within silica hollow nanospheres.

2 Experimental/methodology

PS-SO_3H-SiO_2 yolk-shell and double-shell hollow nanospheres were prepared by sulfonation of PS-SiO_2 yolk-shell nanospheres with small and large void space using chlorosulfonic acid in CH_2Cl_2 at 273K, respectively (Scheme 1).



Scheme 1. Schematic illustration for the synthesis of PS-SO_3H-SiO_2 yolk-shell and PS-SO_3H-SiO_2 double-shell hollow nanospheres

3 Results and discussion

Base on the TEM image, the sulfonation of PS-SiO_2 YSNs with large and small void space results in the formation of PS-SO_3H-SiO_2 yolk-double-shell nanostructures (YDSNs) and PS-SO_3H-SiO_2 double-shell nanostructures (DSNs), respectively. Both samples have uniformly dispersed spherical morphology with particle size respectively of 367 and 387 nm, as evidenced by the HR-SEM characterizations. Notably, PS-SO_3H-SiO_2 YDSNs have double shell surrounding the core. The inner and outer shell thickness of PS-SO_3H-SiO_2 YDSNs was of around ~ 30 nm and the particle size of the inner core was about 160 nm. PS-SO_3H-SiO_2 DSNs have particle size of 387 nm with inner and outer shell thickness of 55 and 25 nm, respectively. The element mapping image of the sulfur shows that the PS-SO_3H located mostly in the core and inner shell for PS-SO_3H-SiO_2 YDSNs and mainly in the inner shell for PS-SO_3H-SiO_2 DSNs. The acid strength of PS-SO_3H-SiO_2 DSNs is higher than PS-SO_3H-SiO_2 YDSNs based on ^{31}P NMR characterization.

Table 1. The catalytic performance of solid acids in the esterification[a] of lauric acid and ethanol and Friedel-Crafts alkylation[b] of toluene with 1-hexene.

Catalysts	Esterification[a]		Friedel-Crafts alkylation[b]	
	TOF (h^{-1})	Yield (%)	TOF (h-1)	Conv. (%)
H_2SO_4	40.7	80.4	4 ± 0.1	10 ± 0.8
Amberlyst-15	3.3	42.0	23.7 ± 0.2	98.3 ± 0.5
PS-SO_3H@SiO_2 YDSNs	24.1	84.1	11.5 ± 0.2	94.9 ± 0.5
PS-SO3H@SiO_2 DSNs	20.5	83.8	7.3 ± 0.1	31.3 ± 1.0

In the esterification of lauric acid and ethanol, PS-SO_3H-SiO_2 YDSNs and DSNs with TOF of ・24.1 h^{-1} exhibit comparable activity, probably due to the similar composition and nanostructure of the two materials. In Friedel-Crafts alkylation of toluene with 1-hexene, PS-SO_3H-SiO_2 YDSNs and DSNs with TOF respectively of 11.5 and 7.3 h^{-1} is less active than Amberlyst-15 with TOF of 23.7 h^{-1}. Amberlyst-15 exhibited very fast deactivation rate during four successive cycles. The conversion of 1-hexene decreased from 97.8 % in the first cycle to 45.0 % for the fourth recycle. For PS-SO_3H-SiO_2 YDSNs, the conversion of 1-hexene was quite steady in the following seven cycles. The result suggests that PS-SO_3H-SiO_2 YDSNs is more stable than Amberlyst-15.

4 Conclusions

PS-SO_3H-SiO_2 with DSNs and YDSNs nanostructure was successfully synthesized. It was found that acid strength of solid acids is directly related with the swelling and aggregation of PS-SO_3H in a confined nanospace. PS-SO_3H-SiO_2 YDSNs are more active than PS-SO_3H-SiO_2 DSNs in the Friedel-Crafts alkylation of toluene with 1-hexene. This is due to the fact that the unique YDSNs nanostructure affords superior resistance to the swelling of PS-SO_3H during the catalytic process.

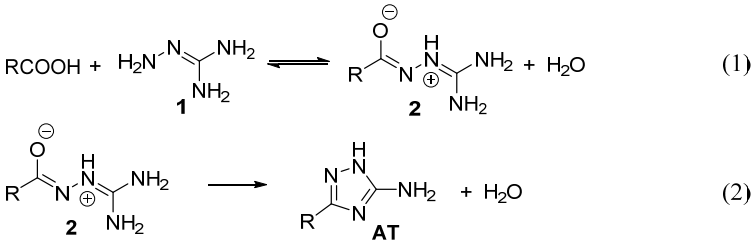
Keywords: amino-1,2,4-triazole, aminoguanidine, carboxylic acids, 2-guanyl hydrazides, catalytic synthesys, reaction mechanism

1 Introduction

C-amino-1,2,4-triazoles (**AT**) are employed as multifunctional reagents for the production of pesticides, medicaments, pigments, corrosion inhibitors, energetic materials, *etc*. One of the promising approaches to the synthesis of **AT** is based on the two-step reaction of aminoguanidine (**1**) with carboxylic acids which proceeds through the formation of intermediate 2-guanyl hydrazides (acylaminoguanidines, **2**):



Although this method has received industrial application for the preparation of some **AT** (R = H, COOH), yields of many **AT** (R = Alkyl-, Aryl-, Heterocyclyl-, *etc*.) in the reactions of **1** with many carboxylic acids are poor, and, therefore, the method needs to be improved. The report describes the results of our studies of the mechanisms, thermodynamic and kinetic parameters of the reactions (1) and (2) under acid and base catalysis as well as new approaches to the catalytic synthesis of 3-substituted 5-amino-1,2,4-triazoles from aminoguanidine and carboxylic acids.

2 Experimental/methodology

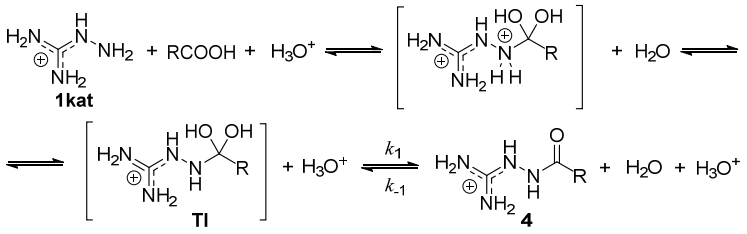
Equilibrium constants (*K*) were determined experimentally by analysis of equilibrium reaction mixtures or calculated from the ratio of rate constants of the direct and reverse reactions, which were determined experimentally. Reaction enthalpies were calculated by the Van't Hoff equation from the temperature dependence of experimentally determined equilibrium constants.

3 Results and discussion

Formation of protonated 2-guanylhydrazides (**4**) from aminoguanidine and carboxylic acids in water solutions is a reversible acid-catalyzed reaction that proceeds with appropriate rate at pH ≤ 2 for the majority of carboxylic acids. Within the limits of experimental error equilibrium constants (*K*) do not depend from acidity of reaction mixture in the pH range 0.6-2.0 and vary from 4 to ~20 l/mol at 25 °C for simple aliphatic carboxylic acids and amino acids ($NH_2(CH_2)_nCOOH$, n = 1÷3). The *K* values for the reactions of formation of 2-guanyl hydrazides of aromatic acids are sufficiently smaller. Thus, $K = 0.23\pm0.03$ and $\sim 2\cdot10^{-2}$ l/mol for the formation of 2-guanyl hydrazides of benzoic and 3-pyridinecarboxylic acids, correspondingly. Reaction enthalpies (ΔH) are 30±2.5 kJ/mol and practically independent from the

structure of carboxylic acid.

On the basis of kinetic studies we established that mechanism of the acid-catalyzed reaction of formation of 2-guanylhydrazides in general is analogous to the mechanism of the acid-catalyzed reactions of amines with carboxylic acids in water solutions [1], however, the monoprotonated molecule of aminoguanidine (**1kat**) plays the role of nucleophile instead of a free base **1**:



The reaction rate is described by the kinetic equation:

$$\frac{dc_{(4)}}{d\tau} = k_1 c_{(1kat)} c_{RCOOH} c_{H_3O^+} - k_{-1} c_{(4)} c_{H_2O} c_{H_3O^+}$$

At 80 °C and pH = 1.0 the apparent rate constants $k_1' = k_1 \cdot c_{H_3O^+}$ varies from 10^{-1} to 10^{-3} l/(mol·min) for simple aliphatic carboxylic acids, k_1' ~ 10^{-4} for PhCOOH and ~ 10^{-5} for pyridine-3-carboxylic acid, and k_1' ~ 10^{-4} ÷ 10^{-5} l/(mol·min) for amino acids $NH_2(CH_2)_nCOOH$ (n = 1÷3). Noteworthy, while for aliphatic carboxylic acids rate constant predictably decreases with increase of hydrocarbon chain length, for amino acids rate constant increases with increase of a number "n" of CH_2 links of $NH_2(CH_2)_nCOOH$. Apparently, it can be explained by a decrease in repulsive interactions between the protonated NH_2 group of the amino acid and aminoguanidine cation (**1kat**) during formation of transition state (**TI**). Activation energies for the reaction of formation of compounds **4** calculated from Arrhenius equation are in the range 21 ÷ 42 kJ/mol, activation energies of the reverse reaction of hydrolysis vary from 52 to 70 kJ/mol.

Kinetics and mechanisms of the thermal and base-catalyzed reactions of cyclization of 2-guanyl hyrazides into aminotriazoles (**AT**) are also considered in the report.

Taking into account kinetic and thermodynamic regularities of the reactions (1) and (2) we elaborated new one-pot methods for the preparation of 3-substituted 5-amino-1,2,4-triazoles (R = Alkyl-, Aryl-, Pyridyl-, $NH_2(CH_2)_n$-, $COOH(CH_2)_n$-, *etc*.).

4 Conclusions

Thermodynamic parameters, kinetics and mechanisms of the reactions (1) and (2) were studied and new effective approaches to the catalytic synthesis of 3-substituted 5-amino-1,2,4-triazoles from aminoguanidine and carboxylic acids were developed.

Keywords: propylene epoxidation, propylene oxide, Fe-silicate

1 Introduction

Propylene oxide (PO) has a production rate by the fine chemical industries of 15 mil. Tons/year. The value of this chemical has increased dramatically over the years due to its importance as an intermediate reactant in the polymer, pharmaceuticals or textile industries [1].

The main production (around 60%) is based on the hydroperoxide process in liquid phase. As well as the liquid phase synthesis (hydroperoxide or chlorohydrin processes), the PO synthesis can be achieved in gas phase by heterogeneous catalysis. The most successful results found in the literature use Au-nanoparticles supported over titano-silicates (Au-$TiSiO_2$) and, usually the use of H_2/O_2 mixtures on the gas stream is mandatory to obtain high selectivity to PO. However, low propylene conversion and water formation are the main drawbacks [1].

On the other hand, metal oxides (Ru and/or Cu) based catalysts usually use molecular O_2 on the gas stream for propylene epoxidation. Some works have studied iron impregnated on silica for the PO synthesis in presence of N_2O as oxidizing agent. In these cases, the PO selectivity is lower than the Au-$TiSiO_2$ systems, but is possible to achieve a higher propylene conversion [2].

In this study, we have developed a one-step synthesis catalyst based on very well dispersed iron single sites on a silica structure. The catalyst has been tested in propylene epoxidation reaction, using two different atmospheres H_2/O_2 and O_2 to evaluate the behavior of the catalyst.

2 Experimental/methodology

Preparation of $Fe_{0.01}SiO_2$. The synthetic procedure has been adapted from the literature [3], using a gel composition with the following molar ratio (8738 H_2O; 410 TMOS, 237.6 Urea; 1.57 HAc; 1 Pluronic® F127), tetramethyl orthosilicate (TMOS) as silica precursor and Pluronic F127 as macroporosity formation agent. To this precursor solution, the necessary amount of $Fe(NO_3)_3 \cdot 9H_2O$ is added to obtain a Fe/Si molar ratio of 0.01. The silica solution is introduced in a Teflon autoclave to submit the sample to a thermal treatment at 40ºC (24 h) and 120ºC (6 h). Finally, the sample is calcined at 550ºC for 6 h. By this synthesis it is possible to generate µ-spheres (3-5 µm) of mesoporous silica interconnected between them with a large amount of macroporous cavities.

Propylene Epoxidation. The catalytic tests are performed in a quartz tube reactor with a feed composition O_2/C_3H_6 (10 % each) and He as carrier gas (GHSV= 10000 ml $h^{-1}g^{-1}$ in all cases). The temperature is raised up to 500ºC at 3ºC/min.

3 Results and discussion

Figure 1 shows a SEM image of the SiO_2 structures generated with and without the incorporation of Fe, where a clear difference in morphology can be observed. For the case of un-doped silica (Fig. 1 left), µ-spheres with well defined size and shape can be observed, due to the spinodal decomposition process occurring during the hydrothermal treatment. However, when Fe is incorporated (Fig. 1 right), the isolated spheres can no longer be observed and an

amorphous structure is obtained. This is due to the iron incorporated on the silica structure, that diminishes the solution/precipitation reaction during the hydrothermal treatment and hinders the formation of the spheres.

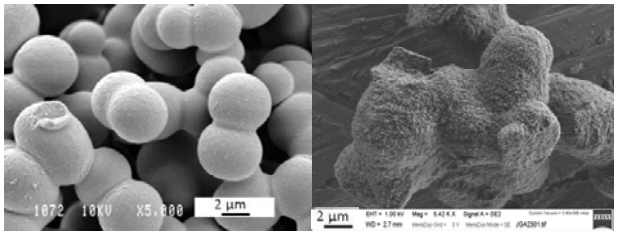

Fig. 1. Pure silica spheres (left) and $Fe_{0.01}SiO_2$ structure (right).

The catalytic tests results (Propylene conversion and propylene oxide generation and selectivity) performed with the sample $Fe_{0.01}SiO_2$ are shown in Figure 2.

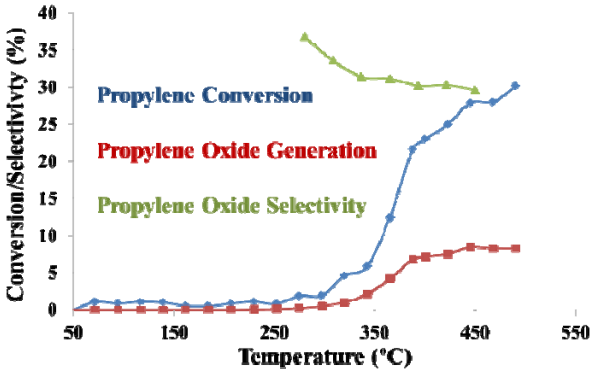

Fig. 2. Catalytic behaviour of $Fe_{0.01}SiO_2$ in O_2/C_3H_6.

The well dispersed $Fe_{0.01}SiO_2$ catalyst shows really interesting properties for the PO production with molecular O_2. The small amount of well incorporated iron (0.01% mol with respect to Si) increases considerably the catalytic properties of the material. In this sense, pure SiO_2 has not any activity in the reaction. After the reaction, carbon deposits were detected, which could be eliminated with a treatment up to 500ºC in synthetic air. Very interesting results have been achieved, with a propylene conversion around 30% with a selectivity towards PO of 30% at 450ºC with molecular O_2 using an iron-silicate based catalyst.

4 Conclusions

A novel catalyst has been synthetized for propylene epoxidation with molecular O_2 and H_2/O_2 mixtures with a good performance, due to the very well dispersed iron single-sites on the silica support. Additional characterization (FTIR and UV-VIS) is mandatory to get insights into the reaction mechanism that is taking place in the presence of the catalyst.

Keywords: guerbet reaction, hydrotalcite, 1-propanol, 1-butanol, acid-base properties

1 Introduction

Nowadays, bio-ethanol is emerging as one of the key building blocks for production of renewable chemicals. This has led to identification of several conventionally produced chemicals for which production from bioethanol is an attractive alternative [1]. One such potentially interesting family of products consists of Guerbet alcohols, which are widely used in the chemical industry for applications in cosmetics, chemical intermediates, lubricants or solvents [1, 2]. For these reasons, the synthesis of Guerbet alcohols is potentially a reaction of great importance for enhancing the potential of biomass-derived chemistry. This reaction consists in the synthesis of higher alcohols from lower alcohols and involves both acidic and basic sites [3]. The reaction mechanism is most generally proposed as a four steps sequence: (1) two alcohol molecules are oxidized/dehydrogenated to aldehydes, which (2) react in an aldol condensation after proton extraction to give the aldol, which is further (3) dehydrated to vinyl aldehyde before (4) hydrogenation to the final Guerbet alcohol [4]. Basic sites are known to promote the dehydrogenation and aldol reaction, while acidic ones usually catalyze the dehydration reaction, which means that bifunctional catalysts are needed.

In this work, hydrotalcite catalysts with various Mg/Al ratios (x=2, 3, 4, 5, 6, 7), were prepared by ultrasound assisted co-precipitation method. The synthesized solids have been characterized in terms of structural, textural, and surface properties, including the acid-base and red-ox features, by a variety of techniques (BET, XRD, Raman spectroscopy, TG, and TPR). The strength, strength distribution, and number of acidic and basic sites were estimated by adsorption microcalorimetry measurements of NH_3 and SO_2, whereas their nature was evaluated by FTIR of adsorbed CO_2 and pyridine. A variation of the 'Guerbet' reaction, using a mixture of methanol and ethanol in order to produce two valuable products for the chemical industry, namely 1-propanol and 1-butanol in gas phase was performed. A special attention was devoted to the relationship between the surface acid-base features and the catalytic activity.

2 Experimental

The hydrotalcite materials were prepared by dropwise addition of $Al(NO_3)_3 \cdot 9H_2O$ and $Mg(NO_3)_2 \cdot 6H_2O$ into a solution of Na_2CO_3 in an ultrasonic bath. The pH of the solution was maintained at 9.5 by NaOH addition. The solution was kept under stirring for 1 h at room temperature and then placed in an oven at 63 °C for 24 h before washing with deionized water. The samples were further calcined at 400 °C for 4 h in an air flow. The adsorption heats were measured in a heat-flow microcalorimeter of the Tian-Calvet type (C80 from Setaram), linked to a volumetric line allowing the introduction of small doses of probe molecule. The nature of the acidic and basic sites on the surface of

the catalysts was determined by the FTIR of adsorbed pyridine and CO_2, respectively. Spectra were recorded at room temperature after desorption was carried out by evacuation for 30 min at 50, 100, 150, 200, 250 and 300 °C. The gas phase catalytic reaction was performed in a fixed bed reactor, under atmospheric pressure and at 200, 250, 300, 350 and 400 °C. The feed composition was He : methanol : ethanol = 80 % : 10 % : 10 % with a total gas flow of 50 ml/min. The tail gas out of the reactor was analyzed by an on-line GC-MS (gas-chomatography mass-spectrometry) technique.

3 Results and discussion

Figure 1 gives the total and irreversible number of acidic and basic sites present on the materials surface. The irreversible amount roughly represents the number of strong sites. The basicity of the samples increased with the Mg/Al ratio to a value of 5, after which the decrease of the number of basic sites is obvious. The acidic properties are also varying with this ratio but to a much lower extent.

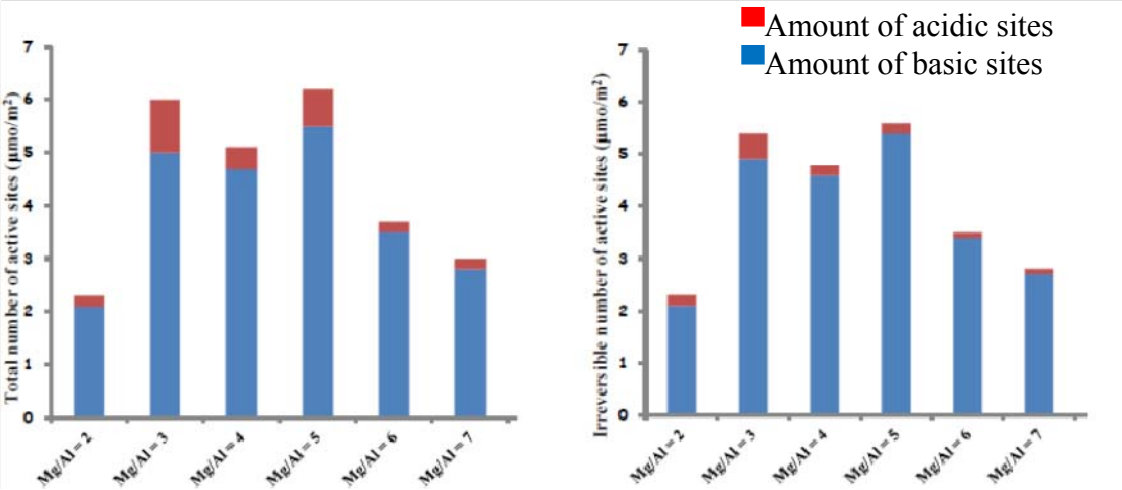

Figure 0. Histograms of amounts of acidic and basic sites for materials investigated in this work.

The results of the catalytic test showed that the conversion of ethanol and methanol is increasing with the temperature on the majority of the catalysts, except for the sample with Mg/Al=2. Furthermore, the highest conversion of both reactants was observed on the samples with Mg/Al ratio of 4 and 5, the samples with the highest amounts of active sites on their surface. Selectivity measured at 400 °C show that the main products are from Guerbet and from intra- or inter molecular dehydration reactions. The targeted products are mainly formed on the catalysts with Mg/Al ratio of 3, 4 and 5, but also the presence of many heavier products, formed by successive reactions between alcohols and reaction products, was observed.

4 Conclusions

The presented results show that it is necessary to control the amount and the strength of both acidic and basic sites in order to produce the desired products. The samples that possess high amounts of basic sites, but do not have very strong basic sites (Mg/Al= 2 and 3) are those which show the highest yields of 1-propanol and 1-butanol, without the production of heavier compounds.

Keywords: aminomethylphosphines, nickel(II) complex, hydrogen production

1 Introduction

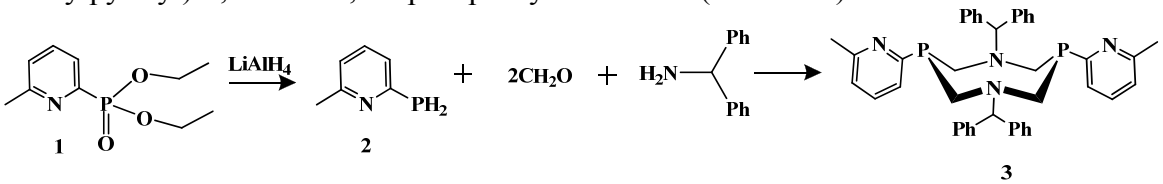
Cyclic aminomethylphosphine ligands cause growing interest because of their structure – combination of two donor atoms types - nitrogen and phosphorus - in sufficient proximity to each other to enhance catalytic activity of transition metal phosphine complexes.

Recently the ability of these ligands complexes to catalyze Suzuki-Miyaura reaction [1] and reactions of electrochemical oxidation and/or hydrogen production [2-4] was demonstrated. The ability of the ligands to the proton-transfer is one of the determining factors for the catalytic activity of the aminomethylphosphine nickel(II) complexes for the electrochemical hydrogen conversion [4]. The electronic and steric properties of the substituents on both nitrogen and phosphorus atoms can be used to tune the catalysts [5]. Complexes of pyridyl containing 8-membered cyclic aminomethylphosphines are examples of functionalized systems, which combined the both aminomethylphosphine and pyridylphoshpine properties [4]. Moreover the nickel (II) complexes with these ligands showed the perfect results as a catalyst for the electrochemical oxidation or production of hydrogen in the fuel cell.

Herein we report the synthesis of novel aminomethylphosphines and nickel(II) complexes with the methylpyridyl substituents on the phosphorus and the bulky α-phenylbenzyl substituents on the nitrogen atoms.

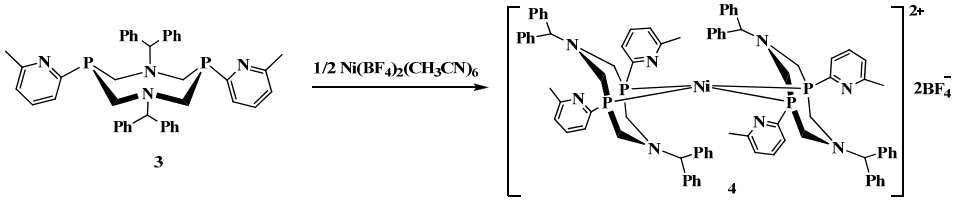
2 Results and discussion

Initial phosphine **2** was synthesized by the reduction of the corresponding phosphonate **1** [7] (Scheme 1). The condensation reaction of 6-methyl-2-phosphinopyridine **2**, formaldehyde and α-aminodiphenylmethane leads to the formation of novel 1,5-bis(α-phenylbenzyl)-3,7-bis(6-methylpyridyl)-1,5-diaza-3,7-diphosphacyclooctane **3** (Scheme 1).



Scheme 1. Synthesis of **3**

Interaction between the ligand **3** and $Ni(BF_4)_2(CH_3CN)_6$ in a ratio of 2:1 resulted in the formation of a new bis-P,P-chelate complex **4** (Scheme 2).



Scheme 2. Synthesis of complex **4**

Complex **4** shows catalytic activity (TOF ~13000 s^{-1}) in the electrochemical hydrogen production comparable to the most active electrocatalysts based on analogous Ni(II) complexes with unsubstituted pyridyl fragments on phosphorus atoms [4]. This fact makes it one of the most perspective catalysts for the design of the non-platinum fuel cell.

3 Conclusions

The novel 1,5-diaza-3,7-diphosphacyclooctane with methylpyridyl substituent on the phosphorus and the α-phenylbenzyl substituent on the nitrogen atom and its bis-P,P-chelate nickel(II) complex were obtained. Nickel(II) complex demonstrates high activity in the electrochemical proton reduction.

Methane to Methanol – Influencing Factors for the Direct Catalytic Low Temperature Oxidation with Copper Zeolite Catalysts

Schaller B.[1,2*], Curtin T.[1], Leahy J.J.[1,2]

1 - Materials and Surface Science Institute, Department of Chemical and Environmental Sciences, University of Limerick, Limerick, Ireland

2 - Carbolea Research Group, Department of Chemical and Environmental Sciences, University of Limerick, Limerick, Ireland

* Barbara.Schaller@ul.ie

Keywords: methane oxidation, methanol, zeolite, catalyst copper

1 Introduction

A "dream" reaction of modern heterogeneous catalysis is the quantitative direct partial oxidation of methane to methanol [1]. Methanol is a flexible key component for several alternative fuels and can be obtained from renewable sources through anaerobic digestion of organic matter. Methane is very symmetric which results in extremely high C-H bond stabilities. Activating these bonds requires high activation energies. Stopping the oxidation and releasing the formed methanol from the catalyst surface are challenging problems.

Currently, methanol is synthesized via an indirect selective two-step process using syngas, which is costly and energy consuming. In nature, the C-H bond in methane can be oxidized in mild conditions using methane mono-oxygenase enzymes. One of these enzyme families contains a di-copper complex. The aim of this work is to develop a new catalytic method for this reaction and mimic this highly active di-copper complex. Indeed, from current reported literature, copper catalysts supported by zeolites seem to be relatively promising for this partial catalytic oxidation reaction [2,3].

2 Experimental/methodology

Catalyst preparation

The catalysts were prepared using two different aqueous ion exchange techniques: single exchange with pH-change and multi exchange. Copper acetate was used as a precursor salt and different zeolites as support. For the preparation of bimetallic catalysts wet impregnation using the exchanged copper-zeolites was used.

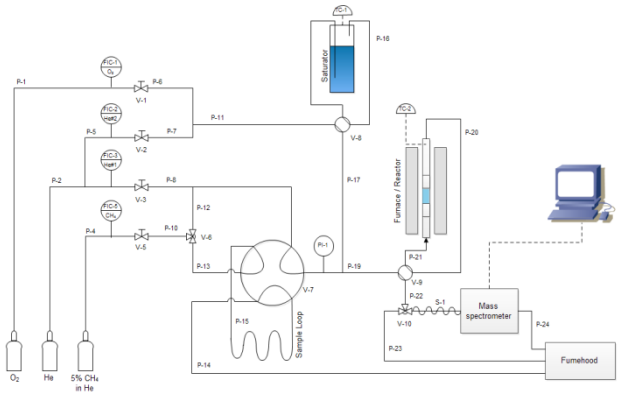

Fig. 1. Flowchart of test rig with Mass Spectrometer (MS) device for the reaction of CH_4 with O_2 to CH_3OH

Catalyst characterisation

Metal loadings were measured by Atomic Absorption Spectroscopy (AAS) using a VARIAN Spectra AA 220 instrument. For determining the oxidation state of copper and structure identification, X-ray Photoelectron Spectroscopy (XPS) was used.

Catalyst testing

The experiments were carried out on the test rig shown in Fig. 1. The catalyst was calcined and pre-treated in a high-purity oxygen stream. In order to stabilize the reactive di-copper oxygen intermediate the

catalyst was cooled to 50 °C and heated to reaction temperature [4]. Then O_2 was removed and after its disappearance, CH_4 (5 % balanced with He) was introduced at the reaction temperature. Post reaction, either dry or wet desorption was performed and the desorbing gases were continuously monitored via an online mass spectrometer (MS). Dry desorption was carried out using a dry helium stream while the catalyst bed was heated to 400 °C to desorb the total oxidised product CO_2. For the wet desorption, a wet helium stream was introduced under isothermal conditions to desorb methanol.

3 Results and discussion

As influencing factors for the direct oxidation of methane to methanol several factors were investigated: catalyst preparation, calcination and behaviour of bi-metallic catalysts.
For the aqueous ion exchange two different procedures are compared: the single exchange with pH change and multi exchange. For the single exchange with pH change an exact amount of copper salt was dissolved in water and mixed with the zeolite for 24 h. Ammonia hydroxide was used to change the pH from ~5 to 7. For the multi exchange a 0.1 molar copper acetate solution was prepared and mixed with the zeolite. After 24 h hours the catalyst was filtered and transferred into a fresh copper acetate solution. This step was repeated 3 times. A copper loading of around 4 wt.% was achieved with both techniques. From testing, the multi exchanged catalyst was found to be more active. Fig. 2. presents the Cu(I):Cu(II) ratio of the multi exchanged and pH modified catalyst before and after reaction. The most active catalyst has higher levels of Cu(I) indicating that this may be important for high activity.

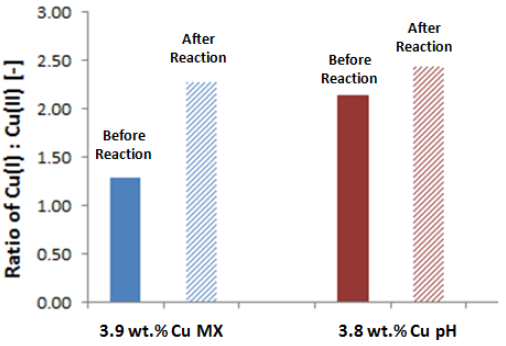

Fig. 2. Ratio of Cu(I) : Cu(II) in the multi-exchanged (MX) Cu-ZSM-5 and the exchanged pH-change (pH) Cu-ZSM-5 before and after reaction using XPS.

After preparation catalysts are calcined either in ex-situ in air or in-situ in 15 % oxygen balanced with helium or high purity oxygen. Results show that in-situ calcined catalysts show higher product amounts compared to ex-situ calcined catalyst.

Some bimetallic catalysts were prepared using the wet impregnation technique of previously prepared uncalcined copper zeolite catalysts. Some experiments show that higher methanol desorption is possible with bimetallic catalyst.

4 Conclusions

The catalytic performance of the methane to methanol oxidation is influenced by factors such as catalyst preparation and diverse pre-treatment steps.

IV-OP50

Heterogeneously Catalyzed Aqueous Phase Amination and Isomerization of Biogenic Isohexides

Rose M.*, Pfützenreuter R.

Institut für Technische und Makromolekulare Chemie, RWTH Aachen University, Aachen, Germany

* rose@itmc.rwth-aachen.de

Keywords: amination, isomerization, liquid aqueous phase, heterogeneous catalysis, platform chemical, biogenic isohexide, isosorbide

1 Introduction

The replacement of conventional monomers by novel biomass-derived building blocks is of major importance for the utilization of renewable resources in polymers and plastics production. Numerous multifunctional alcohols are readily available from oxygen-rich plant biomass. Prominent examples are isohexides, a group of three rigid C6 diol isomers [1]. Isosorbide is industrially produced from starch. Recent research proved the feasibility of cellulose as raw material, thus, avoiding a competition with food production. The isomers isomannide and isoidide are accessible by isomerization via a dehydrogenation and a subsequent rehydrogenation reaction yielding an equilibrium isomer mixture [2].

2 Experimental/methodology

Further functionalization of the hydroxyl groups enables these monomers also to be used in various other polymer types. In this context the amination of alcohols is of great interest especially regarding the production of polyamides. The amination of alcohols with ammonia to primary amines is typically carried out in gas phase processes at temperatures >300°C catalyzed by Lewis acids. Due to low vapor pressures and insufficient thermal stability of biogenic substrates gas phase amination is often not possible. In recent years the homogeneously catalyzed liquid phase amination of alcohols including the isohexides has been reported [3]. It is based on the hydrogen autotransfer mechanism in analogy to the isomerization reaction but comprising three reaction steps: 1) an initial dehydrogenation of the alcohol to the ketone, 2) the formation of the imine with ammonia, and 3) the subsequent rehydrogenation to yield the primary amine (Figure 1).

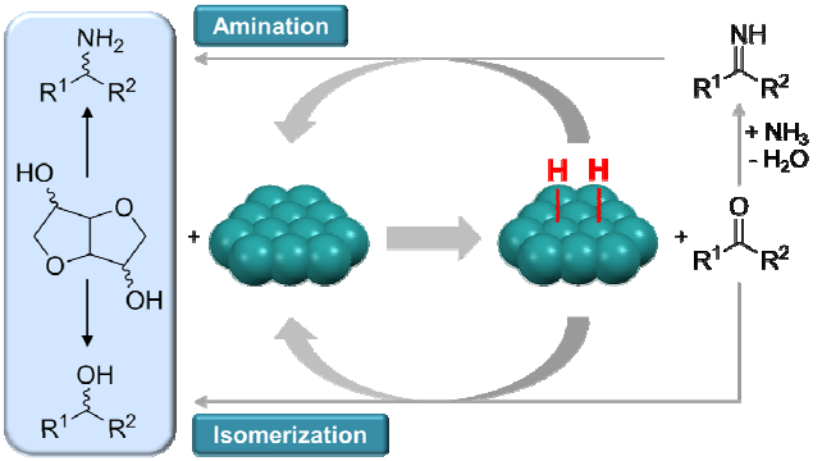

Figure 1. Reaction route for the isomerization and the amination via a dehydrogenation/rehydrogenation mechanism without overall hydrogen consumption.

3 Results and discussion

Hence, we developed a heterogeneously catalyzed process for the amination of isohexides with ammonia [4]. The reaction can be carried out in organic solvents or, much more of interest for an industrial process, even in aqueous solutions and solvent free systems of molten substrate. Catalysts were screened and reaction conditions optimized. Suitable catalysts such as Ru/C were identified that enable the reaction at temperatures of 160-200°C. By investigating the reaction conditions of the amination as well as of the isomerization in the absence of ammonia we found that a certain partial pressure of hydrogen is necessary for the reaction to occur using conventional solid catalysts. Thus, despite following the same reaction route without overall hydrogen consumption the hydrogen autotransfer mechanism can be excluded since a certain coverage of the catalysts surface with hydrogen seems to be necessary to shift the reaction towards the products.

An unusual effect of stereoselectivity of the bifunctional isohexides was observed (Figure 2). In dependence on the initial configuration of the hydroxyl groups the different mono- and diamines are obtained indicating the endo-configured hydroxyl groups to be more reactive while the exo-configured groups are the thermodynamically favored ones. Additionally, reaction kinetics of both reactions the isomerization and the amination were determined to gain insights into the reaction path and mechanism.

4 Conclusions

Overall, with this work a foundation is established for the future development of commercial processes for the production of isohexide-based amine monomers as well as of aqueous phase amination processes of biogenic alcohols in general.

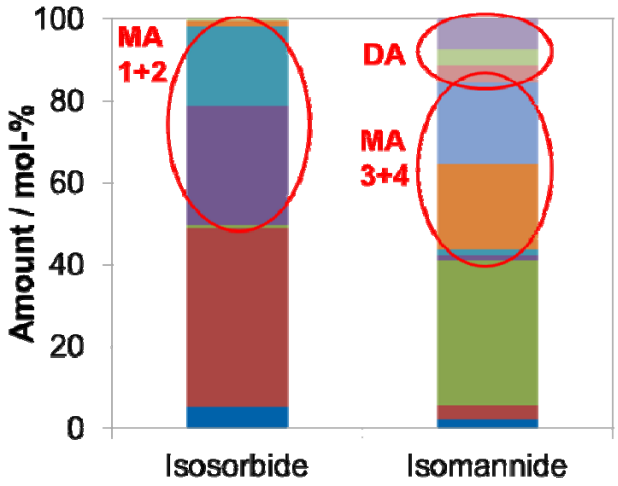

Figure 2. Varying product distribution of the differently configured monoamines (MA) and diamines (DA) upon using isosorbide and isomannide as substrate, respectively.

Keywords: syngas, co-catalyst, rare earth metal, Fischer-Tropsch synthesis, liquid hydrocarbons

1 Introduction

Fischer–Tropsch (FT) synthesis is an effective technology to indirectly upgrade coal, natural gas, and biomass resources to hydrocarbons that can be further upgraded to fine chemicals and fuels [1,2]. Recently, because of increased focus on energy security and the implementation of more stringent environmental legislations on liquid fuels, FT synthesis has received considerable worldwide attention in both industrial and academic domains [1-4]. Among the reported FTS catalysts, only iron and cobalt catalysts appear economically feasible on an industrial scale [5]. Cobalt-based catalysts have been widely investigated for FT synthesis due to high activity at low temperature (below 513 K), high resistance to deactivation, low water-gas shift activity and high selectivity to C_{5+} linear hydrocarbons [6]. The catalytic performance of cobalt FT catalysts can be enhanced by promotion with noble metals [7]. Two of the most important factors in determining the active cobalt surface site density that are relevant to the FTS reaction are reducibility and surface dispersion [6].

In this work the catalyst based on Co with adding noble and rare earth metals supported on alumina were synthesized and tested.

2 Experimental/methodology

The Co-containing catalyst with additives of a noble metal (M_1) and a rare earth element (M_6) and supported on alumina were prepared. The content of Co and noble metals in the catalysts was constant and equal to 5 wt.%. The amount of rare earth metal was varied within 0.5-5 wt.%.

The 5%(Co-M_1)-M_6/Al_2O_3 catalysts were tested in the Fischer-Tropsh synthesis. For hydrogenation of carbon monoxide the syngas with a ratio of $H_2/CO=2$ was used. The process was carried out in a stainless steel reactor under pressure varied from 0.5 to 1.0 MPa, temperature region of 190-235^oC, and gas hourly space velocity (GHSV) of 1000-3000 h^{-1} with using 6 mL of the catalyst.

The physico-chemical properties of the catalyst were studied by BET, TEM, X-Ray and TPR-methods.

3 Results and discussion

The effect of pressure, temperature, and space velocity on the 5%(Co-M_1)-M_6/Al_2O_3 catalysts performance in syngas conversion have been studied. The typical effect of temperature on CO conversion and selectivity over the 5%(Co-M_1)-0.5%M_6/Al_2O_3 is presented on Fig.1. It is shown that increasing temperature from 190 to 235 ^oC is accompanied with rising carbon monoxide conversion from 12.3 to 93.6%, increasing methane formation from 1.4 to 4.4%, and increasing carbon dioxide selectivity from 0.5 to 6.1% respectively. Dependence of selectivity to

formation of liquefied hydrocarbons on temperature has the extremum character. The highest yield of C_{5+} hydrocarbons is observed at 230°C. With increasing temperature from 230 to 235 °C selectivity on C_{5+} fraction is decreased from 79.7 to 62.1%.

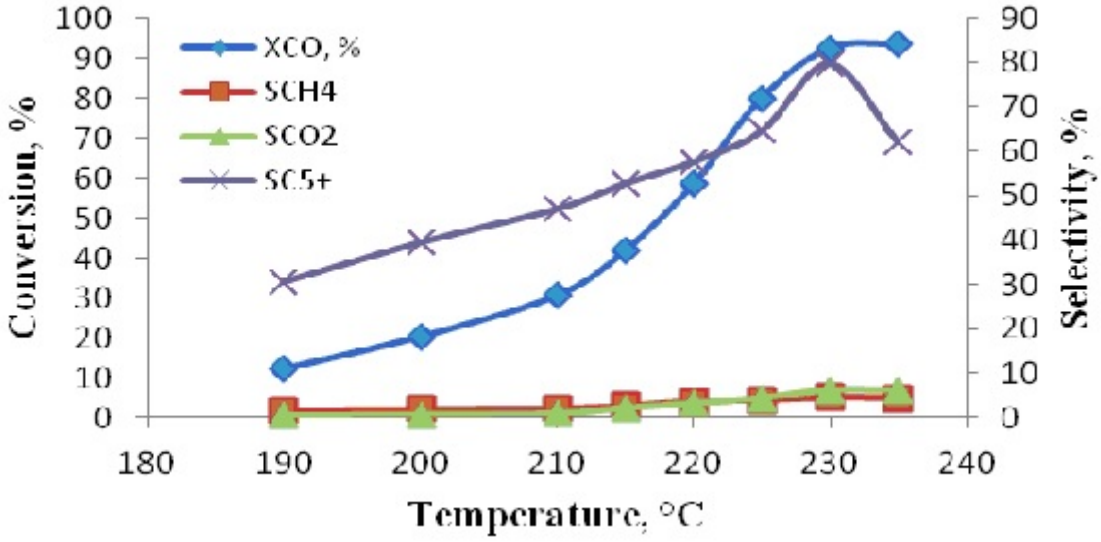

Fig. 1. Effect of temperature on hydrogenation process of CO over the 5%(Co-M_1)-0.5%M_6/Al_2O_3 at H_2/CO=2, P=1.0 MPa and GHSV=1500 h^{-1}

The 5%(Co-M_1)-0.5%M_6/Al_2O_3 catalyst was continuously tested more than 50 hours and showed no decrease in activity and selectivity in the production of gasoline-kerosene fraction of hydrocarbons. By TEM it has been observed that the addition of a noble metal leads to increase in dispersion of metal particles size. TPR analysis has shown that the noble metal also facilitates the Co reproducibility. The role of rare earth metal is in stabilisation of high dispersed state of the catalysts.

4 Conclusions

Thus, results obtained indicate that the developed multicomponent Co-containing catalysts promoted by addition of a noble metal and rare earth element are active and stable in the Fischer-Tropsch process as well as selective in producing the narrow hydrocarbon fraction.

Metalcomplex Catalysis on Oil Metalloporphyrins

Agahuseynova M.M.*, Quluyeva Z.E., Adigezalova M.B., Abdullayeva G.N.

Azerbaijan State Oil Academy, Baku, Azerbaijan Republic

* minira_baku@yahoo.com

Keywords: porphyrin, supramolecular, chemistry, oil metalporphyrine, complex, petrochemical, synthesis

1 Introduction

Metalloporphyrins connections are biocatalists that imitate properties of natural enzymes. This applies particularly to porphyrin complexes of iron (II), copper (II) and cobalt (II). The remarkable feature of these connections is absorption of molecular oxygen that in their cavity easily passes to the supraoksidny anion of Or^{2-}.

Last, because of high activity to oxidize hydrocarbons at relatively low temperatures to give the corresponding alcohols, ketones and others. Because of this, the use of metalloporphyrins as catalysts for petrochemical processes become relevant scientific and technical value. In addition, when the use of metalloporphyrins as catalysts for transformations of hydrocarbons implemented various mechanisms of enzymatic catalysis.

Over the past 25 years were obtained and studied various properties of synthetic metalloporphyrins. It is established that synthetic metalloporphyrins in catalytic properties are not inferior to natural metalloporphyrins. However, synthetic metalloporphyrins are practically insoluble in hydrocarbons. In this connection there are serious technical difficulties at using of them as catalysts or other aims.

2 Experimental/methodology

Synthesis methods of obtaining individual transition metal complexes with porphyrine consentrate have been developed. Porphyrine consentrate has been received by extraction of heavy oil and asphaltenes with asetone and ethanol. The method is based on demetalization and further metallization processes. As result of metallation reaction of porphyrine concentrate with phenylsodium it has been prepared disodium substituted derivatives, which by interaction with transition metal salts gives transition metalporphyrine complexes. Totally 16 new compaunds have been sythesized.

3 Results and discussion

The compozition and the structure of synthesized porphyrine complexes has been studies using infra-red-and electron spectroscopy methods.

It is necessary to note that synthesized transition metal-porphyrine complexes gives adducts with molecular oxygen. Transition metal-porphyrine-molecular oxygen complexes oxidize unsaturated organic compounds and alkenes. It has been shown that molecular oxygen-transition metal-porphyrine adducts oxidize alkenes giving corresponding oxiranes.

Nickel-porphyrine complex has interesting catalytic properties. This complex has been tested in hydrogenation of aromatic hydrocarbons: naphthalene and other arenes. Besides, nickel-porphyrine, prepared on the base of oil porphyrine consentrate, can be used as catalyst in hydrogenation of heavy oil resudue.

In comparison of oil metal-porphyrine complexes with corresponding complexes synthetic porphyrines it has been found that oil metal-porphyrines have good solubility in hydrocarbon condition. Thanks to this property metal-porphyrines, prepared from oil porphyrine consentrate

can be used as additives. Many of prepared transition metal-porphyrine comp- lexes have great interest as molecular oxygen carriers. On the base of expe-rimental datas it has been calculated equilibrium constants of reactions of formation of transition metal-porphyrine-molecular oxygen adducts. It has next sequence:

$$K_{Mn} >> K_{Fe} > K_{Co} > K_{Ni}$$

4 Conclusions

Thus, our studies revealed that catalytic properties of oil metalporphyrins have been studied and found that synthesized complexes fasilitate the selective reaction of olefins oxyqeneting at low temperatures. The study of complexformation influence on ligand reactionability it has been ditermined that redistribution of electron density causes the changes by reaction ability when oxygen molecules transform from free state info coordinated.

Synthesized oxygen adducts of metalporphyrine complexes are oxygen carriers and provide oxygenizating reactions in mild condition with high output.

Metal-Free Polymer Catalyst for Selective Semihydrogenation of Alkynes

Akhmedov V.*, Ahmadov I., Nurullayev H., Ahmadov V.

M.F.Nagiyev Institute of Catalysis and Inorganic Chemistry of the National Academy of Sciences of Azerbaijan, Baku, Azerbaijan Republic

* advesv@gmail.com

Keywords: polymeric, carbon, nitrides, metal-free catalyst, alkynes, hydrogenation

1 Introduction

Heterogeneous catalysis has a rich history of facilitating energy in the efficient selective molecular transformations and contributes to most of industrial chemical processes. Prevailing at the present time catalytic processes utilized in chemical industries use metals or metal oxides as catalysts. These systems are often high energy-consuming and not selective, wasting resources and producing greenhouse gases. Metal-free heterogeneous catalysis using carbon compounds is a potentially interesting alternative to some current industrialized chemical processes. Owing to their structural and electronic properties, polymeric nanocarbons and their nitrogen containing structural analogs provide the prerequisites required for heterogeneous catalysts. They have the correct electronic and microstructure. Their surfaces remain clean in contrast to conventional catalysts and they can provide a stable performance over a long period of time demonstrating a remarkable thermal stability. Due to the special semiconductor properties polymeric carbon nitrides (PCN) can act as a metal-free heterogeneous catalyst. PCN possessing high thermal stability can be made by condensation of different nitrogen-containing liquid precursors such as cyanamide, dicyandiamide, melamine or cyanuric acid. Depending on reaction conditions, a variety of materials such as nanoparticles or mesoporous powders can be obtained.

We have demonstrated for the first time that PCN can be successfully used as solid catalysts for the selective hydrogenation of phenylacetylene in the absence of any metal and metal oxides.

2 Experimental

High purity hydrogen (99.5%) was used. PCN was synthesized from melamine and dicyanodiamide [1]. The prepared PCN was characterized by X-ray diffraction (Bruker-D2 Phaser, Germany) and Fourier transform infrared spectroscopy (Nicolet-iS10, USA). The X-ray diffraction pattern of this compound reveals a partly crystallized (about 40%) bidimensional single phase with an interplanar distance equal to 3.24 Å, which is consistent to the theoretical values predicted by Teter and Hemley for the graphitic form of carbon nitride [2]. The infrared spectrum performed on this phase exhibits features very similar to those of carbon nitride reported in literature [3]. The group of multiple bands in the 1700–1000 cm^{-1} spectral region is characteristic of *s*-triazine ring vibrations (C=N and C–N stretching modes).

Catalyst testing was conducted at atmospheric pressure in a flow type microreactor. The following experimental conditions were used for a typical run: 0.5 g of polymeric carbon nitride was loaded into the reactor tube (inner diameter 8 mm) and a thermocouple was placed at center of the catalyst bed to monitor the reaction temperature. The temperatures used were typically between 50–250^{0}C. The catalyst was treated at room temperature for 30 min in flowing hydrogen (60 cm^3/min) and then heated to the reaction temperature. A typical experimental run consisted of passing the alkyne solutions in different solvents (acetone, cyclohexane and heptane) over the catalyst in a stream of hydrogen. All the reaction products were analyzed by chromatography equipped with FID (Agilent – 7820A) on a HP-5 capillary column 30 m long.

3 Results and discussion

Hydrogenation of carbon–carbon multiple bonds is one of the most important processes widely used in chemical industry. Currently, this type of reaction is carried out on a very large scale, using noble metals such as platinum, palladium and the first row transition metals such as nickel. We have established that PCN can replace metals for partial hydrogenation of triple bonds in acetylene compounds [4]. In the present study a highly efficient catalyst on the base of synthesized polymeric carbon nitride has been developed for partial hydrogenation of phenylacetylene providing good to excellent conversion with remarkable selectivity (up to 95-97%) without additives. Compared with known metal-containing catalysts for partial hydrogenation of multiple C-C bonds, the developed method is more advantageous: 1) this method provides a selective hydrogenation of phenylacetylene to styrene with effective catalyst recyclability and prevents the consumption of precious metals; 2) they can provide a stable performance over a long period of time demonstrating a remarkable thermal stability.

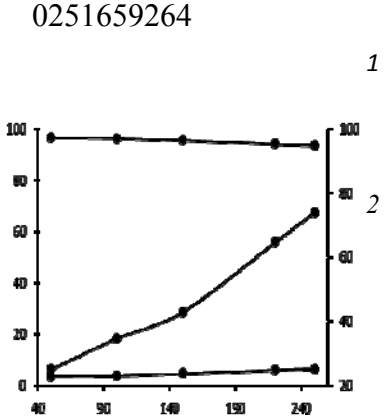

Fig. Partial hydrogenation of phenyl-acetylene in n-heptane (10-12%) vs. temperature on free-metal polymeric carbon nitride: *1*– styrene selectivity, *2*– conversion of phenylacetylene, *3* – ethylbenzene selectivity; hydrogen flow rate) = 60 cm^3/min, reactant flow rate = 0.05 cm^3/min.

Figure demonstrates the activity and selectivity of PCN in the partial hydrogenation vs. temperature for phenylacetylene molecule. PCN is so reactive that noticeable conversion of triple bonds takes place even below 50^0C. This catalyst shows significant differences in product distributions depending on the temperature: there was observed slight decreasing selectivity for the styrene by increasing the process temperature.

4 Conclusions

Since PCN possesses high thermal and chemical stability, it is a valuable and useful material for some other practical applications as well. These findings also provide potential opportunities for the advanced design of metal-free heterogeneous nanostructured catalysts.

Keywords: hydrogen production, Fe catalyst, methane decomposition, carbon nanofibers

1 Introduction

Hydrogen production has received great industrial importance and interest from the recent decade, since it is considered to be a perfect fuel for fuel cell applications [1]. In comparison to fossil fuel based energy sources, hydrogen not only have quite high heating value (141.86 MJ/kg), but also inherently cleaner fuel, since water is the only combustion product. On the other hand, the environmental study related, scientist, community has reported several serious concerns about CO_x emission and its subsequent effects on the environment [2]. Consequently, according to environmental protection view point, the quest of environment friendly energy production processes has become one of the most challenging and demanding task. Recently, catalytic decomposition/cracking of methane (CDM) has attracted massive research interest, since it offers the most promising alternative path owing to the ability of CO_x free hydrogen production [3]. In the present work, the performance of Fe based catalyst for hydrogen and nano-structured carbon production from CDM was investigated. Particularly, the effect of different supports, i.e., γ-Al_2O_3, MgO, SiO_2, La_2O_3 and TiO_2-P25 on hydrogen and carbon yield was studied, at moderate temperature of 700 °C.

2 Experimental/methodology

Supported Fe catalysts used in this study were prepared by an incipient wet-impregnation method. In all catalysts 20 wt% Fe loading was fixed. The impregnation of active metal over support was carried out under constant stirring at 80 °C for 3 h. After impregnation the catalysts were dried overnight at 120 °C and followed by calcination at a temperature of 500 °C for 3 h. CMD experiments over Fe based catalysts were performed at atmospheric pressure in a fixed-bed tubular (9.1 mm i.d. and 13 cm long) micro-reactor (PID Eng & Tech micro activity reference) at 700 ºC. Prior to activity test the catalyst was reduced under continuous flow of H_2 (40 ml/min) at 500 °C for 90 min. The In a typical test, the volume ratio of the feed gas mixture, i.e., methane/nitrogen was 10/1, whereas the total flow rate was 33 ml/min. The composition of the outlet gas was analyzed by online gas chromatography (Alpha Mos PR2100) equipped with a thermal conductivity detector.

3 Results and discussion

Figure 1(a-b) show the hydrogen yield verses time on stream (TOS) and carbon yield for Fe based catalysts supported on different carriers respectively. It is notable from results that the type of support material has a significant effect on catalytic performance. Among all catalysts the Fe-Si catalyst exhibited the least, whereas the Fe-Al catalyst presented the best performance both in terms of hydrogen and carbon yield. For instance, Fe-Al catalyst presented 52.1% initial hydrogen yield and 10.5 (gC/gFe) carbon yield as compared to initial hydrogen yield of 1.4% and carbon yield of 0.21 (gC/gFe) for Fe-Si catalyst. Since, Fe-Al catalyst performed better than

all others so this catalyst was selected to study the morphology of deposited carbon after CDM reaction. Figure 2(a-b) display the FESEM and TEM micrographs of Fe-Al spent catalysts at respectively. It is apparent from results that the Fe-Al catalyst ensured the formation of carbon nanofibers, with the typical outer diameter of 30–70 nm. Due to the interweaving of carbon nanofilaments, it remains very tough to estimate the exact length of these nanofibers form FESEM images. Nevertheless, their length varies up to micrometer range.

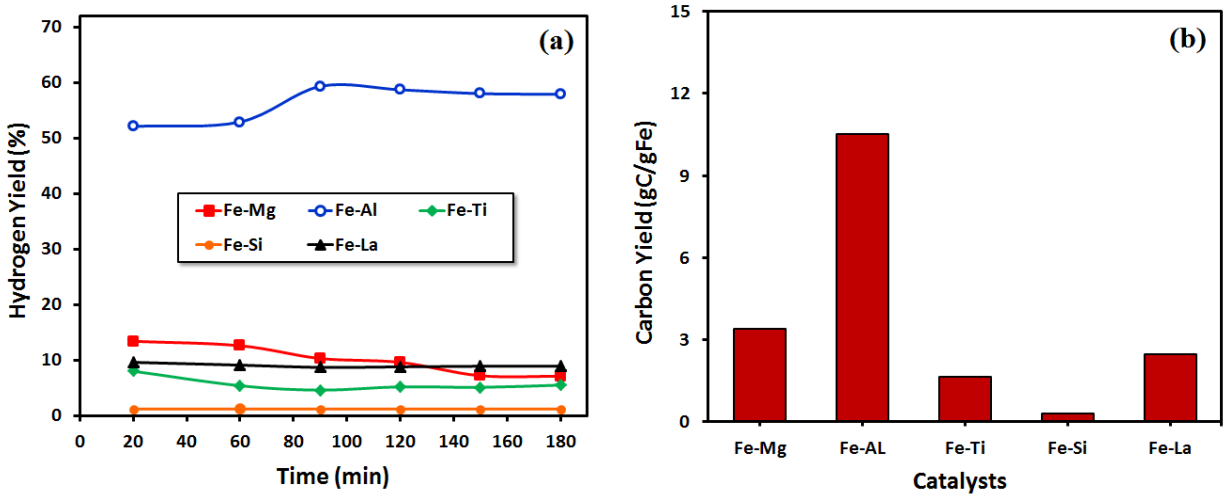

Fig. 1. Variations of H_2 and carbon yield over Fe based catalysts supported on different carriers.

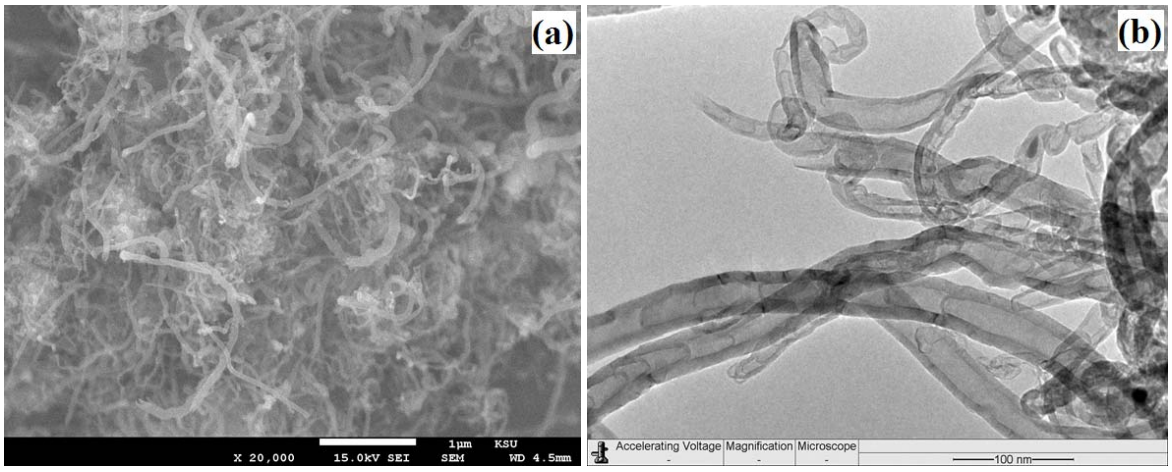

Fig. 2. FESEM (a) and TEM (b) images for Fe-Al spent catalyst.

4 Conclusions

Effect of different supports on Fe based catalysts for CDM showed that Fe-Al presented better hydrogen yield and formation of carbon nanofibers as evidenced by SEM and TEM.

Novel Class of Natural Zeolite for the Catalytic Acetalization of Carbonyl Compounds and Diols

Alotaibi R.[1*], Alotaibi F.[1], Kosslick H.[2], Schulz A.[2]

1 - King Abdulaziz City for Science and Technology 1, National Center for Petrochemical Technology, Riyadh, Kingdom of Saudi Arabia

2 - Universität Rostock, Institut für Chemie Abteilung Anorganische Chemie, Rostock, Germany

* raletabi@kacst.edu.sa

Keywords: novel natural zeolites, acetalization catalysts, sustainability, green, catalysts

1 Introduction

Zeolites are an important class of catalysts expected to manage the demand of sustainability, which requires more efficient use energy and chemical resources [1]. More effective use of feedstock for production of chemicals and transportation fuels require use of heavy oil less valuable low-quality resources like oil sands or biomas decomposition products by cracking and hydrocracking in liquid phases. Under these conditions, zeolite catalyst undergo rapid deactivation and catalyst recycling is cost and process intensive. Furthermore, used synthetic zeolite catalyst are expensive. They are prepare by hydrothermal reaction from reaction gel containing expensive organic templates and cause wastewater pollution. Application of natural zeolites is very attractive. They are cheap, environmental benign and non-hazardous and can be used as spent catalyst without recycling. However, despite several thousands of literature paper consider industrial applied synthetic zeolites, only a few paper consider natural zeolite based catalysts [2]. Although a high catalytic potential of natural zeolites is expected and principally confirmed. This subject is still a "undiscovered white research landscape" of high interest and, therefore, new regarding sustainable catalysts for sustainability demands. These reasons encourage us as to start a new research topic dealing with new heterogeneous natural zeolite based catalysts. This project deals with the preliminary evaluation and improvement of Clinoptilolite and Mordenite for use as catalytic material in petrochemical process. Catalyst design will be achieved by tailoring properties taking into account key factors as structural origin, composition, stability, porosity and acidity as key parameter determining catalytic performance.

2 Experimental/methodology

Three different natural materials, probably containing natural zeolites have been obtained. Additionally, one natural zeolite sample, containing mainly clinoptilolite, called "Clinofit", has been supplied by the German partner. The materials have been worked up for further use, structural investigated by XRD and FTIR. The water capacity has been determined. Proton-exchanged samples have been catalytically tested. The aim of the preliminary investigation with provided natural materials was to determine the nature (structure) and crystallinity of provided the materials to proof that thee these materials can act as acid catalysts in order to establish a proof-of-principle that these materials can the used for the development of nature based new green catalysts .g. for cracking of heavy feedstock, and to check the usefulness of the used catalytic test reaction, namely the acetalization of benzaldehyde with 1,3-butanediol. Obtained samples will be characterized with highly sophisticated methods like solid state NMR, which have been only scarcely applied to natural zeolites. The acid property tuning will be investigated using acid catalysed model reaction. The goal is to develop the basis for the preparation of a natural zeolite based catalyst for petrochemical and petroleum refining applicationThis

acetalization has been chosen as test reaction, because it is catalyzed by acid and basic sites occurring in minerals, e.g. natural zeolites (NZ). It can be carried out in easier to handle liquid phase and it is expected to be sensitive also for the detection acid sites of lower acidic strength as well as to the number of sites (specific acid site concentration). Furthermore, the use of the diol is more space demanding because it is connected with the formation of a 6-ring beside of the phenyl ring of the benzaldehyde. It provides better information of the accessibility of site even for larger molecules as is required for the conversion of heavy feedstock. For catalytic testing the reaction solution was prepared by mixing 10g of benzaldehyde with ca.9g of 1,3-butanediol and addition of 100 mL t of toluene as solvent.. The benzaldehyde and toluene was re-distilled prior to use. The reaction was carried out in 3-necked flask connected with a condenser on the top. An oil bath was use as heating source the mixture was magnetically stirred. After heating to reflux temperature (ca. 116°C), the calcined catalyst has been added immediately. µL sized samples were used liquid ^{1}H-NMR for quantitative determination of the reaction progress. 2-dimensional ^{1}H-NMR spectra were used to confirm the assignment of NMR signals.

3 Results and discussion

The results of the catalytic tests are summarized in Table 1. All samples are catalytic active in the acetalisation of benzaldehyde with 1,3-butanediol, however, the conversions differ significantly.

Table 1: Catalytic activity (conversion) of natural zeolite sample in the acetalisation of benzaldehyde with 1.3-butanediol

Sample	Name	Catalyst amount	Conversion / %	IR /cm^{-1}
NZ 01/14	Natural Zeolite(j54)	100mg	49	988
NZ 03/14	Natural Zeolite(JNE5)	100mg	18	980
NZ 05/14	Clinofit^{R}Si materials	200mg	88	1015

These results show that the acetalisation reaction is a proper test for the evaluation of the catalytic activity of nature based green catalysts. The differences between the samples are well expressed. 100-200 mg of the material are sufficient to carry out the catalytic performance test.

4 Conclusions

The results show that the nature based zeolitic materials are catalytically active and a proper base for the development of new green catalyst for sustainable use of chemical feedstock.

Keywords: 2-iminopyridine, nickel, ethylene polymerization, oligomerization, methylalumoxane

1 Introduction

During the last two decades nickel(II) complexes with bidentate *N,N*-donor ligands have been attracting considerable attention as catalysts for polymerization of ethylene and linear α-olefins yielding polymeric products with various types of branching [1]. Up to date, the post-metallocene catalysts based on nickel complexes providing branched and hyperbranched polyethylene [2] are of great importance due to the unprecedented chain architectures and unique physical properties of these polymers [3].

Nickel(II) complexes with 2-[(arylimino)alkyl]pyridine ligands are of special interest due to the simplicity of ligands syntheses, rich opportunities for fine tuning of their steric and electronic properties by the introduction of different substituents into the phenyl rings, and the ability to give low-molecular-weight polyethylene with different content of branches. However, only ethylene polymerizations over 2-iminopyridine catalysts with electron-donating (alkyl) substituents at the aryl rings have been reported previously [4]. It is challenging to probe the effect of electron acceptors on the performance of nickel catalysts. Previously, introduction of electron-withdrawing groups was reported to increase the activity of analogous iron, cobalt and nickel tridentate bis(imino)pyridine catalysts for ethylene and norbornene polymerization [5].

2 Experimental/methodology

All manipulations with air- or moisture-sensitive compounds were performed under an atmosphere of argon using a glovebox, break-sealed or standard Schlenk techniques.

Syntheses of 2-iminopyridine ligands were performed in toluene by Schiff condensation of 2-formylpyridine, 2-acetylpyridine or 2-benzoylpyridine with appropriate aniline using either strong Brønsted or Lewis acids as catalysts. The ligands obtained were characterized by ^{1}H, ^{13}C and ^{19}F NMR spectroscopy.

The corresponding nickel complexes were readily prepared by the reaction of the ligand with $NiCl_2$ or $NiBr_2$*(1,2-dimethoxyethane) in dry acetonitrile, tetrahydrofuran or dichloromethane with good yields. The structure of the complexes obtained was proved by elemental analysis, X-ray diffraction studies and ^{1}H NMR spectroscopy of paramagnetic molecules.

Ethylene polymerization was performed in a 1 L steel autoclave. During the polymerization ethylene pressure, stirring speed and temperature were maintained constant. The experimental unit was equipped with an automatic computer-controlled system for ethylene feed and recording the ethylene consumption.

^{1}H and ^{13}C NMR spectra of branched polyethylenes and oligomer mixtures were recorded either on a Bruker Avance-400 MHz NMR spectrometer (at 400.130 MHz and 100.613 MHz, respectively) or on a Bruker DPX-250 MHz NMR spectrometer (at 250.130 MHz and 62.903 MHz, respectively).

3 Results and discussion

In the present work a series of 2-iminopyridine nickel(II) dichloride (or dibromide) complexes containing electron-withdrawing substituents (R_2-R_5 = F, Cl, Br, CF_3) in aryl moieties have been examined in ethylene polymerization and oligomerization using methylalumoxane as a co-catalyst.

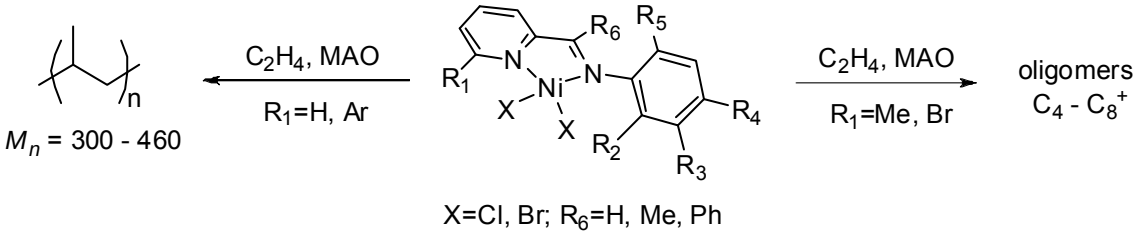

Fig. 1. 2-iminopyridine nickel(II) complexes

All complexes containing substituted 6-position of pyridine ring (R_1 = Me, Br) and fluoro-substituted phenyl ring (R_2, R_4, R_5 = F, CF_3) displayed high activities (up to $9.6 \cdot 10^6$ g·(mol Ni)$^{-1}$·h^{-1}·bar^{-1}) towards ethylene oligomerization yielding a wide variety of ethylene oligomers (1-butene, (*Z*)-2-butene, (*E*)-2-butene, 2-ethylbutene-1, 1-hexene, (*Z*)-2-hexene, (*E*)-2-hexene, (*E*)-3-hexene etc.).

Catalysts with unsubstituted or aryl-substituted 6-position of pyridine ring (R_1 = H, Ar) and *o*-trifluoromethyl group in phenyl ring turned out to be highly active towards ethylene polymerization (up to $6.6 \cdot 10^6$ g·(mol·Ni)$^{-1}$·h^{-1}·bar^{-1}) yielding low-molecular-weight branched polyethylenes (20-85 branches per 1000 determined by ^{1}H and ^{13}C NMR spectroscopy), with *sec*-butyl branches being identified. To the best of our knowledge, this is the highest reported activity for ethylene polymerizations and oligomerizations over 2-iminopyridine nickel catalysts.

4 Conclusion

New 2-iminopyridine nickel complexes have been found to be highly active catalysts of ethylene polymerization and oligomerization upon the activation with methylalumoxane. The catalytic activity as well as the product morphology has been found to correlate with the number and position of electron-withdrawing substituents.

Keywords: organocatalysis, heterogeneous catalysis, synthetic methods

1 Introduction

Carbon-oxygen bond forming reaction is one of the most important transformations in organic synthesis and industrial processes. Ethers are largely employed as biologically active compounds, drugs, fragrances and diesel blends.[1] Several methods are reported for the preparations of ethers from alcohols, but not without limitations. A variety of Lewis acids are employed as catalysts for etherification reaction, also in presence of organosilanes. Elegant catalytic methods for etherification reactions are represented by the use of transition metals.[2] In most of the cases, the methods based on transition metal catalysts display good performances, however the homogeneous conditions used represent a major drawback for industrial applications. Ionic liquids recently emerged as a novel class of compounds with multiple possible uses from alternative "green" reaction media to active molecules in catalytic reactions. Supported ionic liquid-like phase (SILLP) are a class of materials that have interesting applications.[3]

In this work a novel class of thiazolium based supported ionic liquid phase (SBA-15-Thia, fig. 1 left) is reported.[4] The solids were tested as catalysts for the etherification of benzyl alcohols. The catalytic activity was also compared with the analogous materials based on imidazolium salts (SBA-15-Imi, fig. 1 left). The heterogeneous organocatalysts display excellent performances in the etherification of alcohols. To the best of our knowledge, this is the first time that a multilayered covalently supported imidazolium or thiazolium-based material has been reported as catalyst for the synthesis of ethers.

2 Experimental/methodology

The synthesis of the heterogeneous organocatalysts bearing either imidazolium[5] or thiazolium[4] active sites (SBA-15-Imi and SBA-15-Thia respectively) were successfully accomplished by grafting the corresponding bis-vinyl salts (bis-Imi or bis-Thia) on a thiol-functionalized SBA-15 mesoporous silica. The two materials were extensively characterized by N_2 physisorption, transmission electron microscopy, X-ray diffraction, ^{29}Si and ^{13}C MAS-NMR and elemental analysis. In order to explore their activity, 1-phenylethanol was selected as model compound. The catalytic tests were performed under solvent-free conditions at 160 °C and in different gas phase (oxygen, air, nitrogen). The etherification reaction was performed using more than 5 g of 1-phenylethanol and only 10 mg of catalysts.

3 Results and discussion

The two solids, SBA-15-Thia and SBA-15-Imi, display good specific surface area and high percentage of active sites, which are promising features for catalytic applications. It is worth to

mention that challenging conditions in terms of substrate to catalyst weight ratio (mg alcohol/ mg catalyst = 540) were employed. Both materials displayed good catalytic performances. However the SBA-15-Thia shows a better conversion and selectivity compared to the analogous imidazolium based material. This evidence highlighted that the nature of the *N*-heterocyclic ring has an important role in the reaction. In addition, the SBA-15-Thia was employed for reaction in shorter reaction time (7 h) in oxygen, air or nitrogen phase, and we observed that the selectivity increases by decreasing the percentage of oxygen in the reaction mixture. Some kinetics studies clearly evidenced an oxygen dependent behavior of the SBA-15-Thia catalyzed reaction (fig. 1 right).

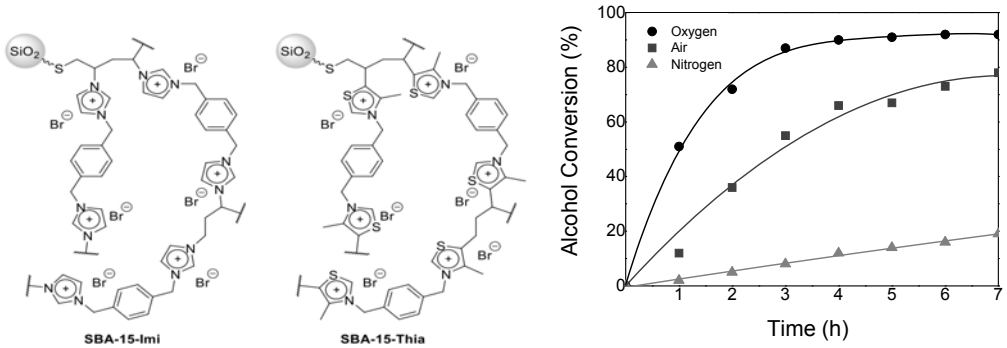

Fig. 1. SBA-15-Imi and SBA-15-Thia (left); Conversion of 1-phenylethanol with SBA-15-Thia as function of the time under oxygen, air or nitrogen atmosphere (right).

The supported thiazolium-based material was successfully used in the etherification reaction of other two benzylic alcohols and used in seven consecutive cycles without lose of catalytic activity. Further studies were carried out using unsupported thiazolium salts, with or without a methyl group at C-2 position of the thiazolium moiety (Homo-Thia-H and Homo-Thia-Me). The results of these tests show a reduced performance for the catalyst Homo-Thia-Me. This could be attributed to a negative combination of steric and electronic effects. Finally, we performed the etherification reaction of (*S*)-1-phenylethanol and the ether products indicate that the reaction follows mainly a S_N1 pathway. A mechanistic pathway was proposed.

4 Conclusions

Thiazolium and imidazolium hybrid materials were prepared and tested as catalysts for the etherification of 1-phenylethanol. The SBA-15-Thia displayed an excellent catalytic performance, also with others benzyl alcohols. These results allow proving that oxygen play an active role in the reaction probably regenerating the catalysts. This study represents the first use of thiazolium-based compounds as catalysts for the etherification reaction of alcohols.

Keywords: mesoporous-zeolites, propene, oligomerization, chromium zeolite, beta

1 Introduction

The main advantages of synthetic zeolites are that they can be engineered with a wide variety of chemical properties and pore sizes. Although the use of zeolites as catalysts are well established and there are a large increase of zeolite types and applications of theoretical approaches for prospective zeolite structures, the synthesis and modification of the commercial zeolites to avoid drawbacks associated with steric and diffusion limitations of zeolite is one of the main approaches in catalysis for zeolites [1]. Now the development of mesoporous zeolites or hierarchical zeolites has turn in the new direction to take in synthesis of zeolites [2,3,4]. Herein we evaluated the effects on the catalytic activity after incorporate mesoporosity by templating method in the conventional HBETA and loading this with Cr (loading of 1 and 3%).

2 Experimental/methodology

Meso/microporous zeolites were prepared by hydrothermal synthesis and templating method with multiwall carbon nanotubes for producing hierarchical zeolite crystals with intracrystalline mesoporosity. The composition of molar gel was 12.36 $(TEA)_2O$: 0.98 K_2O: 1.98 Na_2O: Al_2O_3: 49.71 SiO_2: 891 H_2O. The metal was incorporated through isomorphous substitution (3 and 5 wt-%). The characterization of these materials by X-ray diffraction (XRD) was used to identifying phases in a Panalytical Empyiria 2012. Surface areas were obtained in TriStar 3000 V6.08 equipment, using the BET method from the nitrogen adsorption. Additionally the materials were characterized by SEM, atomic absorption, NH_3-TPD and thermal analysis. Finally the catalytic reation were performed at 270 ºC and 26 bar in a fixed bed reactor charged with 1g of the catalyst and exposed to a feed of 5% of propylene/nitrogen with a total flow of 44 ml/min.

3 Results and discussion

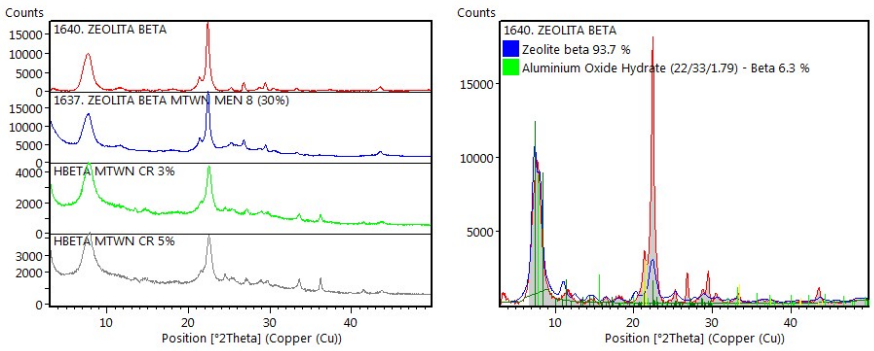

Figure 1 XRD patterns (right: as-synthesis zeolites, left: quantitative refinement of HBETA)

All samples were characterized by X-ray (figure 1) powder diffraction to identify the structure phase and determine the effect of the post-synthesis treatments on the zeolite structure. Its comparison of peak positions of XRD spectra with reference from PDF4 DATABASE indicating the presence of BEA phase. Chemical compositions of catalyst show an appreciable incorporation of Cr regarding expected. BET surface areas for hierarchical zeolite resulted in an increase of the external surface of 100 m^2/g and pore diameter of 0.58 nm.

Analysis of activity in the propylene oligomerization (figure 2), revealed that differing morphology within the zeolites has a significantly impact in the conversion. The conversion of propylene were better for the hierarchical zeolites than the parent zeolite, which agrees with the increase of pore diameter that facilitates the absorption of propylene on Bronsted acid sites and its transformations through aromatization and oligomerization reactions. The differences in the catalytic activity of Cr zeolites arises because the heteroatoms isomorphous substituted help in fine-tuning the strength of the acid sites and in introducing bifunctional features to zeolite. The selectivity to higher hydrocarbons obtained were low in all cases indicating that some hydrogen transfer may still occur. Nevertheless, the differences related to parent zeolite beta indicates the important role played by the size channel system when the reactants can diffuse into this type of pores. It is demostrated that the creation of mesopores in the zeolite has a possitive effect because improve the catalytic activity in the modified catalysts.

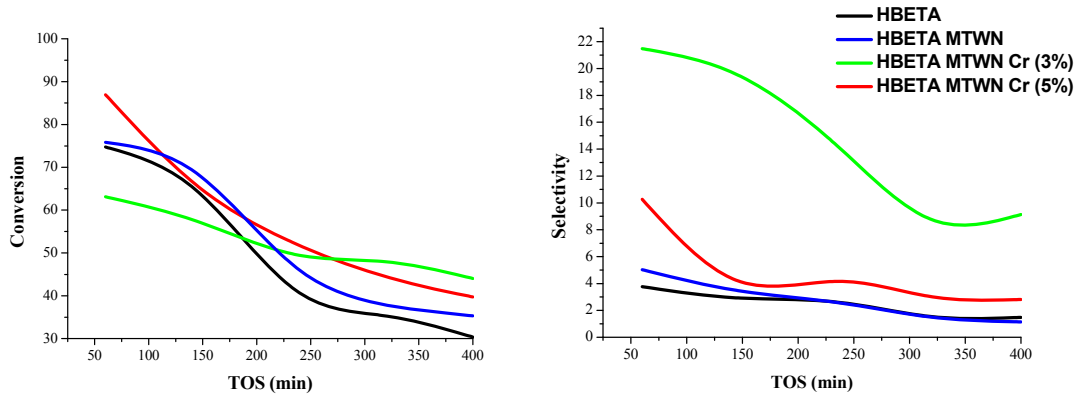

Figure 2 Conversion and selectivity meso/microporous H-BETA

4 Conclusions

An increased in accessibility of the pores of the zeolite improved the diffusional limitation of the HBETA; and the incorporation of metal created a coordinative center for propylene oligomerization.

Keywords: green chemistry, heterogeneous catalysis, amidation, organic chemistry, oxides

1 Introduction

Amidic group synthesis is a fundamental step for the manufacture of a variety of biological compounds and innovative materials, currently deserving a high scientific concern [1,2]. Indeed, the main current industrial processes rely on reaction between amines and activated carboxylic acids precursors or on the direct condensation between carboxylic acids and amines at high temperature [2]. All these processes suffer from serious economic and environmental drawbacks due to the use of unsafe and harmful reagents like thionyl or oxalyl chloride including *poor atom economy* and high *E-factors*, while the latter are also unfeasible for many functionalized substrates [3]. Then, the direct catalytic synthesis of amides from ammines and acids has been recently indicated as a major Green Chemistry issue [1,2].

Therefore, this work provides a comparative view of the reactivity pattern of various commercial and lab-made oxide catalysts (γ-Al_2O_3, CeO_2, ZrO_2, TiO_2) in the synthesis of N-phenylpropionamide (T, 383K) from aniline and propanoic acid, shedding lights onto the physico-chemical properties determining their catalytic functionality.

Table 1. List of catalysts used in the N-phenyl-propionamide synthesis and their catalytic performances.

Sample	Supplier	SA ($m^2 \cdot g^{-1}$)	NH_3 uptake (μmol/g)	$X_{Aniline}$	$X_{P.\ Acid}$	Amide yield[a]
γ-A_2O_3 (1.5E)	AKZO NOBEL	261	433±30	0.22	0.25	0.24
TiO_2_Merck	MERCK	10	8±1	0.05	0.04	0.04
TiO_2_P25	EVONIK	55	260±20	0.47	0.49	0.47
CeO_2_LM	Lab-made	90	65±5	0.28	0.27	0.27
ZrO_2_LM	Lab-made	21	100±10	0.08	0.10	0.09

[a] N-phenyl-propionamide yield by gravimetric analysis.

2 Experimental/methodology

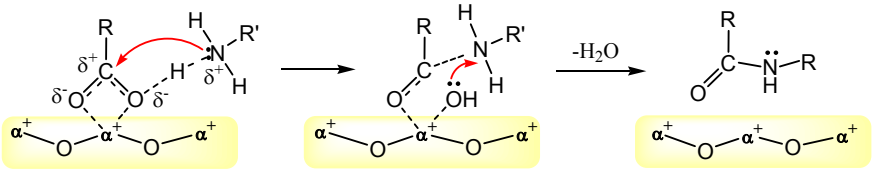
The list of commercial and lab-made oxide catalysts along with their code, the main physico-chemical properties and activity data in the amidation reaction [3] are given in Table 1.

Surface Area (SA) values were determined from N_2-adsorption isotherms, elaborated by the standard B.E.T. method, while concentration and strength distribution of the surface acid sites were probed by NH_3-TPD analysis and modelling of TPD profiles according to the procedure elsewhere described [4]. IR measurements were carried out at r.t. after adsorption of propanoic acid on pre-activated samples and, subsequently, after admission of 1-pentanamine on acid saturated sample [3].

Catalyst testing in the synthesis of N-phenylpropionamide from propanoic acid and aniline was performed at 383K in a Pyrex-glass batch reactor equipped with a Dean-Stark device for azeotropic distillation operations [3]. Reagents conversion has been obtained by GC analysis, while final (24h) amide yield values (Table 1) were obtained by gravimetric analyses [3].

3 Results and discussion

Results of catalytic tests indicate that TiO_2_Merck and P25 present the lowest and highest yield, while other systems show intermediate values (Table 1). Tests at various (stoichiometric) reagents concentration show that the reaction is 0th-order, likely indicating the occurrence of a typical Langmuir-Hinshelwood (L-H) pathway kinetically controlled by adsorption-desorption phenomena, as sketched in the below reaction scheme [3,5]. In fact, in presence of (apolar) toluene as solvent, an acid-base interaction between reagents drives the formation of an adduct that, further to the adsorption on catalyst surface, undergoes an intra-molecular rearrangement with the formation of the "C-N" bond and water elimination [3].



Scheme 1. *Proposed mechanism of the amidation reaction on oxide catalysts.*

IR spectroscopic measurements of adsorbed propanoic acid show the formation of *bidentate*, *bridging* and *unidentate* carboxylate species on surface Lewis acid sites, the (decreasing) reactivity roughly parallels the surface specific activity in the amidation reaction (TiO_2_P25 > ZrO_2 ≈ TiO_2_Merck ≈ CeO_2 > γ-Al_2O_3) [3]. In addition, surface acidity characterization data by NH_3-TPD analysis (Table 1) allows to obtain the TOF values of the studied systems, depicting an exponential decreasing trend on total acidity (Fig. 1), supporting the inhibiting role of the acid sites on product(s) desorption rate.

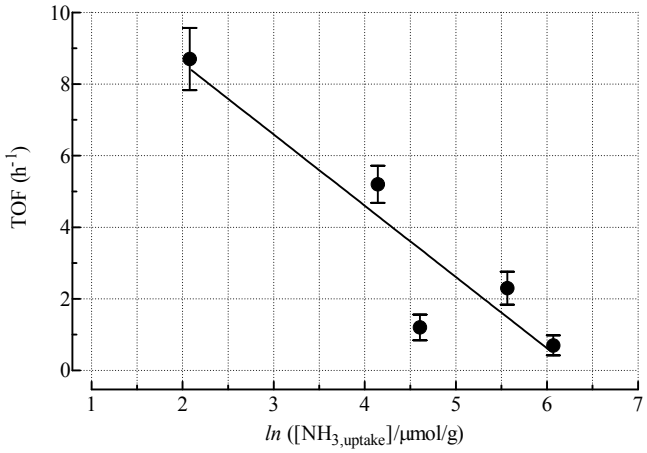


Fig 1. *Relationship between TOF and NH_3 uptake data.*

4 Conclusions

A 0th- order kinetic dependence on reagents concentration suggests that the amidation reaction proceeds via a *L-H* path kinetically controlled by desorption steps (*r.d.s.*).

The formation of *bidentate*, *bridging* and *unidentate* carboxylate intermediates account for the different amidation functionality of the studied materials.

* dementyeva@ips.ac.ru

Keywords: Fischer-Tropsch synthesis, Fe catalysts, polymers, slurry reactor

1 Introduction

Currently Fischer-Tropsch process is becoming increasingly important as the method of obtaining synthetic liquid fuels. Slurry phase synthesis technology is one of the most interesting trends in the development of this process. Addition of the polymer to nanosized metal-containing suspensions allows to prevent sedimentation and also leads to the formation of a completely new active catalyst system with unique properties. The selectivity of this catalysts can be controlled by varying the structure of polymer and its concentration.

The effect of using different polymers as active component of catalytic system was carried out and the correlation between the structure of the polymer molecules and properties of formed contacts in Fischer-Tropsch synthesis was found.

2 Experimental/methodology

Samples of catalysts were prepared by thermal decomposition of metal precursor solution in a dispersion medium of wax and polymer in an inert gas. Polyacrylonitrile (PAN), polyamide (PA), polystyrene crosslinked with divinylbenzene (PS-dVB), polyvinyl alcohol (PVA), bisphenol polyester (PE-bPh), polypropylene (PP) have been used as an additive. Fischer-Tropsch synthesis was carried out in a three-phase slurry reactor in syngas flow with CO: H_2 ratio 1: 1 (temperature range 220-300°C, P = 2 MPa). In both cases, catalysts were activated before reaction by a treatment with CO for 24 h at 300°C. The particle size of catalytic suspensions were characterized by dynamic light scattering method (DLS). The polymers flexibility was analyzed by estimating of projection orientation persistence length and orientation persistence length. The 3D-models of repeat units for analyzed polymers were built by using SYBYL 8.0. Modeling of the polymers folding into coils was carried out in implicit solvent and topological approach with application of Gasteiger–Hückel method was used to calculate partial atomic charges. The molecular dynamics (MD) simulations were performed by using a suite of programs AMBER 14. The use of implicit solvent was realized with application of the Hawkins–Cramer–Truhlar model within GB/SA formalism. The GAFF was utilized for calculating interatomic interaction energy between the polymer atoms.

3 Results and discussion

The influence of polymer structure on the catalysts properties in the Fischer-Tropsch synthesis has been fixed. It was shown that the addition of polymer into the catalyst composition generally resulted in an increase in selectivity toward target products - liquid hydrocarbons (fig. 1). At the same time reducing the formation of carbon dioxide was observed. The sample prepared with polyacrylonitrile addition (PAN) demonstrated the highest productivity on C_{5+} hydrocarbons: the yield of these products was 30% higher compared to the sample without polymer additives (WAX).

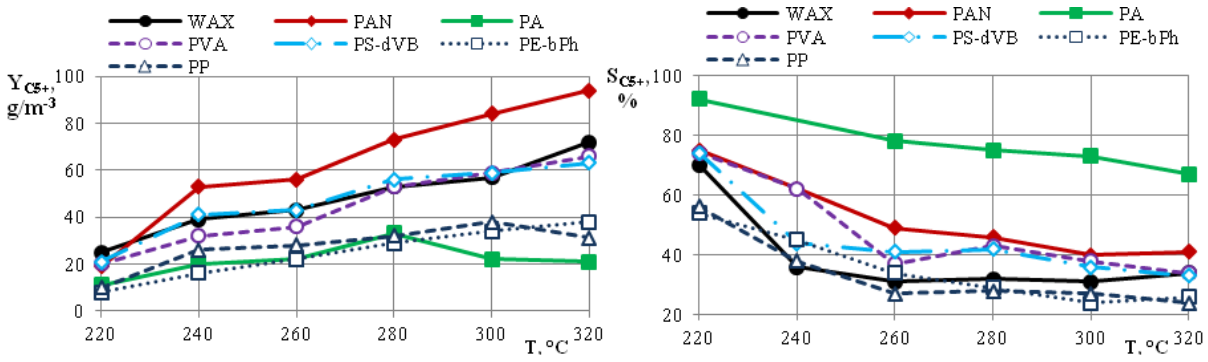

Fig. 1. Fischer-Tropsch reaction results for different temperatures (P=2 MPa, CO:H2=1:1):
a) yield of liquid hydrocarbons, g/m_{syngas}^3; б) selectivity toward liquid hydrocarbons, %.

Dispersed particles size distribution changing was fixed with dynamic light scattering measurements. Particle diameter of the formed suspensions decreased in the presence of different polymers in catalytic suspension from 450 for wax-sample to 170-220 nm, as seen by DLS-spectra.

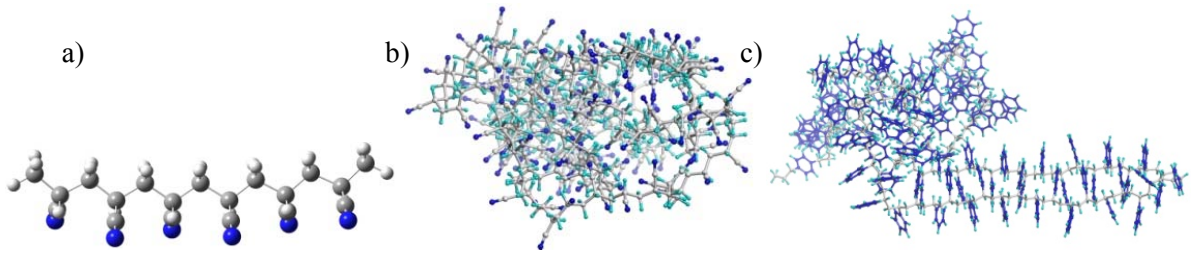

Fig. 2. Modeling of the polymers folding date. a) fragment of the original PAN-polymer chain; b) PAN-coil; c) PS-dVB -coil.

The polymers flexibility and its effect on coils formation was determined by molecular modeling method (fig. 2). Analyzing of the polymers folding into coils and comparative study of their geometry revealed significant differences of the final structure of the polymer molecules forming a complex metal-containing particle - polymer structure. View of PAN-coil allows to predict the most favorable conformation of the polymer around the metal phase particles which leads to formation the most active system for synthesis of hydrocarbons from CO and H_2.

4 Conclusions

The influence of polymer structure on the activity of catalytic system in the Fischer-Tropsch synthesis was found. Modeling techniques revealed the differences in structure conformations and flexibility of different polymers. This factor affects the properties of the resulting metal-containing particle-polymer composite structure.

Keywords: dimethoxymethane, carbonylation, methylmethoxyacetate, cesium, salts of $H_3PW_{12}O_{40}$

1 Introduction

In recent papers [1,2] the gas-phase carbonylation of dimethoxymethane (DMM) to methylmethoxyacetate (MMAc) over Brønsted acid sites (BAS) of zeolites was demonstrated for the first time. It was shown that under the conditions of DMM gas-phase carbonylation to MMAc, reaction (1) is accompanied by side-reaction (2) - DMM disproportionation to dimethyl ether (DME) and methyl formate (MF):

$CH_3OCH_2OCH_3 + CO = CH_3OCH_2COOCH_3$ (1)

$2CH_3OCH_2OCH_3 = 2CH_3OCH_3 + CHOOCH_3$ (2)

The mechanisms of reactions (1) and (2) were suggested, which are sililar to classic mechanisms of the Koch carbonylation reactions and Cannizzaro aldehyde disproportional reactions, respectively.

Results reported in [1-4], as well as fundamental and practical interest to carbonylation of oxygenated compounds of C_1 chemistry encouraged our studies of DMM carbonylation to MMAc over acidic cesium salts of 12-tungstophosphoric acid. The results obtained are presented in this report.
