The book of abstracts includes the plenary lectures, keynote lectures, oral and poster presentations on the following topics:

- Novel catalytic materials and processes for securing supplies of raw materials
- Catalyst preparation and characterization
- Energy-related catalysis
- Catalysis and chemicals
- Catalysis and environmental protection
- XI European Workshop on Innovation in Selective Oxidation (ISO ‘15) "Selectivity in Oxidation: Key to new resources valorization"

Plenary lectures

PL-1

Catalysis in Organic Chemistry: from Butlerov to these Days

Ananikov V.P.*

Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Moscow, Russia

* val@ioc.ac.ru

Keywords: organic synthesis, catalysis, atomic precision

Mechanistic studies have revealed fascinating nature of catalytic reactions that are now ubiquitously employed in modern organic chemistry. A variety of metal species are generated during well-known catalytic reactions [1-4]. In fact, mononuclear metal complexes, metal clusters and nanoparticles are easily accessible on catalyst activation stage or during the course of the catalytic reaction. Formation of "cocktail" of metal species in solution is not uncommon starting with wide variety of different metal precursors (pre-catalysts) [3]. Recent studies provided important evidence on unusual reactivity of small metal clusters, especially the properties connected with "superatomic" structural units [2].

Another important point is evolution of the metal catalyst during catalytic reaction. Evolution of metal complexes in homogeneous catalysis as well as evolution of supported metal catalysts under heterogeneous conditions are the processes of paramount importance. Understanding the nature of these processes is required to achieve selective transforamtions and to develop stable and recyclable catalysts.

Design of new generation of adaptive catalytic systems to facilitate transformations in organic synthesis will be presented and discussed with a focus on development of organic synthesis procedures performed with "atomic precision" [5].

Enhancing Catalytic Rates in Constraints – from Acid-base to Metal Catalyzed Reactions

Lercher J.A.[1,2*]

1 - TU München, Department of Chemistry, Garching, Germany
2 - Institute for Integrated Catalysis, Pacific Northwest National Laboratory, Richland, WA, USA

* johannes.lercher@tum.de

Understanding the elementary steps in acid-base and metal catalyzed organic transformations is a key for improving existing and developing new catalysts and process routes for nearly all energy related chemical conversions. Solid acids and bases with nano-pores such as zeolites act as solid Brønsted and Lewis acids being excellent model as well as industrial catalysts with well-defined acid-base sites and a well-defined reaction space around the sites. Within the pores of molecular sieves reacting molecules are constrained in a reaction space, which can be subtly adjusted via direct synthesis, as well as via the addition of cations, oxidic clusters or organic fragments. The impact of such changes on mono- and bimolecular reactions such as elimination reactions of alcohols, cracking and alkylation of hydrocarbons are discussed for gas and liquid phase reactions.

Experimental methods to define the state of the reacting molecules combined with detailed kinetic analysis and theory will be used to explain the principal contributions of the interactions and the confinement to determine reaction rates. The chemical environment in these pores also influences metal catalyzed hydrogenation and hydrogenolysis via new pathways enabled by the proximity of metals and Brønsted acid sites. Using examples for catalyzed reactions in gas and liquid phase, it will be shown that the reactivity can be drastically increased by tailoring the space around the active site.

Fossil and Renewable Energy: the Turning Point of the Liquid Fuels Production

Bellussi G.*

Eni S.p.A, SVP Downstream R&D, San Donato Milanese – I, Italy

* giuseppe.bellussi@eni.com

Keywords: bio-fuels, renewable, heavy oil conversion, slurry hydroprocessing

Energy, as well as food and water is a basic need for survival. Over the past 150 years, the energy availability guaranteed first by coal and then by oil and gas, has supported the growth of the world population to the current level of 7 billion people. The increase of population prompted the demand of basic needs and therefore the exploitation of planetary resources, impacting on their availability and increasing the environmental pressure.

Today the availability of energy sources and the effects on the environment generated by their use, are among the main critical issues that humanity faces. The production and trade of energy resources are often linked to events with important socio-economical impact, just remember the effects generated by the discovery and exploitation of shale-gas and shale-oil and then by the fall in oil prices. The strong concern on climate change and environmental effects of entropic activity is pushing the majority of nations to react through shared actions, but the conflicting requirements of developed countries and those under development are slowing down the effectiveness of these processes. At the recent UN climate conference held in Lima last December (COP-20), weak progress have been made. It was reconfirmed the principle of common but differentiated responsibility, already introduced in the first United Nations Framework Convention on Climate Change in 1992, which states that every nation must take action to mitigate the climate change according to its own financial and infrastructural capability. It was also introduced a tool (Lost & Damage) through which developing countries particularly vulnerable to the consequences of climate change will be able to receive financial compensation for natural disasters now inevitable, but the main differences between the parties were not reconciled and the most important decisions have been postponed to the next conference in Paris in December 2015. The European Union countries are facing the consequences of these changes with the addition of local problems. The production of liquid fuels in Europe has suffered from an economical point of view from 2008 until the second half of 2014, when the drop in oil prices has given breath for the refinery industry. The problems of this sector are generated by the progressive reduction in fuel demand, by the entry of not negligible amount of bio-fuels, by the obsolescence of the European refining system, characterized by a relatively large number of medium/small refineries and by the high cost of energy. Although since 2007, 14 plants have been closed, persists in Europe overcapacity of refining that endangers other production sites. This crisis is structural in its nature and therefore major interventions targeted to balance supply and demand are required as well as new technological solutions. A reduction of refining capacity appears unavoidable, but at the same time the production of bio-fuels matching the technical and environmental needs, the efficiency improvement of refining technologies to pursue the reduction of energy consumption and the total conversion of crude oil in good quality middle distillates must be strongly pursued. The disciplines most involved by these needs are catalysis, materials science and process engineering. In this presentation some recent results related to the production of bio-fuels and to the total conversion of the oil barrel to middle distillates will be presented and discussed trying to highlight the prospects and the opportunities that science and technology can offer for the mitigation of the problems exposed.

PL-4

Catalysis Using Supported Gold and Gold Palladium Nanoparticles

Hutchings G.J.*

Cardiff Catalysis Institute, School of Chemistry, Cardiff University, Cardiff, UK

* hutch@cf.ac.uk

Gold catalysis has become a well-established field of endeavour. Much still remains to be discovered in this interesting research field, but to date much progress has been made. In this lecture recent preparation strategies to make supported nanoparticles will be described and discussed. These will involve the use of colloidal and impregnation methods. Monometallic gold catalysts will be discussed together with bimetallic gold palladium and trimetallic gold palladium platinum catalysts.

The first part of the talk will discuss the use of carbon-supported gold nanoparticles for the hydrochlorination of acetylene.[1] This is one of the original reactions where the high activity of gold catalysts was first observed.[2] Details of the catalyst characterisation will be described showing the evolution of the catalyst structure as it is exposed to the reaction conditions. Using detailed aberration-corrected STEM together with X-ray photoelectron spectroscopy the important features of this catalyst will be explored.

In the second part the preparation of bimetallic gold palladium and gold platinum catalysts will be described for the oxidation of alcohols, the activation of C-H bonds[3] and the direct synthesis of hydrogen peroxide.[4] In the final part the preparation and use of the more complex trimetallic nanoparticles will be discussed.[5] One particular example concerns the oxidation of benzyl alcohol as when using supported gold palladium nanoparticles toluene can be observed as a by-product. This by-product can be switched off in two ways. First the design of the bimetallic catalyst support is crucial and the interfacial sites are considered to be important for the selective oxidation to benzaldehyde. Oxides that maximise the interfacial contact give lower toluene formation and with MgO and ZnO in particular no toluene formation is observed although high activities for selective oxidation are observed. Secondly, addition of platinum to the gold palladium bimetallic also swiches off toluene formation. The origins of these effects will be discussed.

PL-5

Mesoporous Metal-Organic Frameworks as Platforms for Single-site Heterogeneous Catalysts

Hupp J.T.*

Northwestern University, Evanston, IL, U.S.A.

* j-hupp@northwestern.edu

AIM (ALD In MOFs) is an emerging synthesis technique that provides access to well-defined arrays of non-aggregating, monodisperse, and organic-capping-ligand-free clusters of metal atoms, metal-oxides/hydroxides, and metal-sulfides. The technique entails adapting atomic-layer-deposition (ALD) chemistry to mesoporous metal-organic framework materials that present suitable node- or linker-based reaction sites. By using multiple, individually self-limiting, ALD growth cycles, clusters of varying, predetermined size, and clusters comprising mixed compositions can be synthesized. In some cases the obtained clusters lack stable analogues in conventional heterogeneous catalyst synthesis chemistry, in part due to a propensity for conventionally synthesized clusters to aggregate under typical conditions for catalysis of gas-phase reactions. As one might guess, the properties of AIM-synthesized clusters and the associated porous-MOF scaffolds render the clusters readily accessible to candidate molecular reactants. The clusters, in many cases, display high catalytic activity for both gas-phase and condensed-phase reactions reactions. Notably, excellent steam stability and moderate thermal stability (temperatures to ca. 350 ^{o}C) can be obtained with appropriately designed MOFs This presentation will center on one or two case studies, including AIM-MOF synthesis, structural characterization, catalytic activity, and computationally informed analysis of mechanisms of catalysis.

Because the catalytic clusters comprising nodes and subsequently installed metal atoms are monodisperse, both coordinatively and in terms of cluster size, the resulting ensembles are amenable to structural and functional characterization with a level of precision previously associated mainly with single crystal metal or metal-oxide surfaces. The porosity of the MOF scaffold, however, makes the catalyst arrays three-dimensional and greatly increases the number of active sites relative to two-dimensional arrays. In addition to boosting overall catalytic activity, the presentation of monodisperse catalysts in 3D rather than 2D arrays greatly facilitates structural and functional characterization.

This presentation will touch on catalyst characterization, including *in operando* characterization. The characterization methods include DRIFTS, EXAFS, total X-ray scattering and pair-distribution-function analysis, single-crystal X-ray diffraction, and energy-dispersive microscopy. Both structural characterization and functional characterization are facilitated by comparative computational modeling and simulations.

PL-6

Dynamics in Heterogeneous Catalysis

Schlögl R.[1,2*]

1 - Fritz-Haber-Institut der MPG, Berlin, Germany
2 - MPI Chemical Energy Conversion, Mühlheim, Germany

* acsek@fhi-berlin.mpg.de

Heterogeneous catalysis carries its name from the concept of a well-defined heterogeneous interface between the catalyst surface and the reactant environment. The processes of adsorption, desorption and reaction between adsorbates describes the overall reaction. Under conditions where adsorption dominates the overall reaction such an interface can be clearly identified and studied by many techniques.

Under conditions of high performance catalysis with significant turnover this definition becomes increasingly difficult. Strong structural modifications of the solid surface are involved in such reactive states. We identify the transformation of a sharp interface into a termination layer with substantially different structural and chemical properties than the bulk. In certain cases even the bulk underneath a sub-surface region of the solid undergoes reaction-induced transformations.

These phenomena are at the center of the so-called gaps in catalysis science. They describe catalysts as chemically dynamical systems interacting with the molecular dynamics of the reactants. Under such conditions the definition of active sites as elements of the bulk structure of a catalyst material becomes questionable as well as the concept of a surface where all constituents are active. Consequently the metrics of “activity” becomes a challenge. The often-practiced structural analysis of a catalyst outside its reaction environment describe a state of the system as far apart from the reacting state as “models” constructed from a-priori assumptions about the nature of the active state.

The contribution illustrates the role of in-situ techniques in discovering and analyzing such active states of catalysts. In consequence we may realize that the distinct difference between homogeneous and heterogeneous catalysis gradually vanishes under the unified concept of a dynamical active site resulting from catalyst-reactant interactions.

PL-7

Models for Heterogeneous Catalysts: Complex Materials at the Atomic Level

Freund H.-J.*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Faradayweg, Berlin, Germany

* freund@fhi-berlin.mpg.de

Our understanding of catalysis, and in particular heterogeneous catalysis, is to a large extend based on the investigation of model systems. The enormous success of metal single crystal model surface chemistry, pioneered by physical chemists, is an outstanding example. Increasing the complexity of the models towards supported nanoparticles, resembling a real disperse metal catalyst, allows one to catch in the model some of the important aspects that cannot be covered by single crystals alone. One of the more important aspects is the support particle interface. We have developed strategies to prepare such model systems based on single crystalline oxide films, which are used as supports for metal, and oxide nanoparticles, which may be studied at the atomic level using the tools developed in surface science.

However, those oxide films may also serve as reaction partners themselves, as they are models for SMSI states of metal catalyst. Using such model systems, we are able to study a number of fundamental questions of potential interest, such as reactivity as a function of particle size and structure, influence of support modification, as well as of the environment, i.e. ultra-vacuum or ambient conditions, onto reactivity.

The thin oxide film approach allows us to prepare and study amorphous silica as well as 2D-zeolites. Those systems, in spite of their complexity, do lend themselves to theoretical modelling as has been demonstrated.

PL-8

Fundamental Studies of Metal-Exchanged Zeolites for Selective Catalyticreduction of Nitrogen Oxides in Oxygen Excess

Skoglundh M.*

Competence Centre for Catalysis, KCK, Chalmers University of Technology, Göteborg, Sweden

* skoglund@chalmers.se

Selective catalytic reduction with ammonia (NH_3-SCR) is a well-established and effective method to eliminate nitrogen oxides (NO_x) in oxygen excess for stationary and mobile applications. For the latter case vanadia supported on titania was the first NH_3-SCR catalyst that was commercialized. This catalyst is highly effective around 350-450°C, however at lower or higher temperatures, the efficiency of the catalyst to reduce NO_x decreases. Furthermore, problems like toxicity of volatile vanadium compounds and high activity to oxidize sulfur dioxide have promoted the development of alternative catalysts. Zeolite systems are in this connection interesting candidates. Presently, iron- and copper-exchanged zeolite structures are the most attractive alternatives to the traditional vanadia-based SCR catalyst. However, several challenges arise when using metal-exchanged zeolites in exhaust gas after-treatment systems for vehicles. Two of the more important issues are the hydrothermal stability and the tolerance against chemical poisoning. Furthermore, the possibility to control the distribution of the metal species in the zeolite by thermal treatment during the preparation or after deactivation is another important aspect of metal-exchanged zeolite structures.

The first part of this lecture will focus on iron-exchanged zeolite beta, Fe-BEA, as NH_3-SCR catalyst. The deactivation of Fe-BEA after hydrothermal treatment, and phosphorous and potassium exposure has been studied experimentally and by kinetic modeling as well as activation and regeneration of the catalyst using hydrogen treatment. The fundamental mechanisms for thermal and chemical degradation of Fe-BEA will be presented and discussed. Furthermore, the activation and regeneration of the catalyst by hydrogen exposure will be discussed. The second part of the lecture will focus on copper-exchanged zeolite structures. The solid-state ion-exchange of different types of zeolite structures from copper oxides has been studied experimentally in different atmospheres. It is shown that the copperexchange is possible at unprecedented low temperatures, as low as 250°C, when facilitated by ammonia. The influence of the treatment conditions on the copper-exchange and the mechanism of the ion-exchange process will be presented and discussed. Such copperexchanged zeolite structures with high copper loading are potentially interesting catalysts for a number of technical applications.

Keynote lectures

V-KN1

Catalytic Wastewater Treatment

Descorme C.*

Institut de recherches sur la catalyse et l'environnement de Lyon (IRCELYON), UMR5256 CNRS – University of Lyon, Villeurbanne, France

* claude.descorme@ircelyon.univ-lyon1.fr

Although the water resource is not exhaustible, the water quality must be preserved, which does represent a major challenge for the coming decades. Water is extremely useful on a daily basis for many different industrial, agricultural and domestic applications. As a result of all these different uses, a wide variety of waste effluents is being produced everyday all over the world. The lecture will concentrate on such wastewater but not on the treatments involved upon the production of drinking water.

While conventional wastewater treatment plants, mainly based on biological processes, are quite efficient for the purification of low concentrated, non-toxic and biodegradable wastewater, new solutions had to be imagined for the treatment of toxic and/or non-biodegradable and/or highly concentrated effluents.

Many different approaches have been investigated, numerous combinations have been tested but none of the alternatives developed up to now might be considered as universal. None of them is really better than the other: the more tools in the toolbox, the better.

Before selecting one technology over another, many different parameters have to be considered including the composition of the effluent, the concentration of the pollutants, the physical and chemical characteristics of the wastewater (pH, ionic force, turbidity, etc.), the volumes to be treated, as well as some engineering and economical aspects, etc. The final objective of the treatment is also to be taken into account, i.e. whether the pollutants should be totally mineralized or the treated effluents should only be made biodegradable or the organic content should be recovered to produce new chemicals and/or materials.

Among the possibilities, catalytic processes may play a crucial role, especially when the reaction conditions need to be made milder and/or when the process has to be ran faster and/or whenever selectivity issues are of major concern. Again, different options have been evaluated, including both reduction and oxidation processes.

Key examples taken from the recent literature will be presented all along the lecture, trying to combine different aspects and approaches, going from the development of innovative catalytic materials till the mechanistic information. Looking at the reduction processes, both the hydrodehalogenation and the catalytic reduction reactions will be briefly reviewed and the major challenges to be overcome will be highlighted both in terms of material science or catalytic efficiency (activity and selectivity). Finally, most catalytic oxidation processes will be listed, especially the advanced oxidation processes (AOPs), involving the hydroxyl radicals as the active oxygenated species; and the catalytic wet air oxidation for the most complex type of effluents. The main achievements and the key issues in the different fields will be identified.

II-KN2

Lewis Acid-base Catalysts for the Synthesis of Fine Chemicals

Pârvulescu V.I.*

University of Bucharest, Faculty of Chemistry, Department of Organic Chemistry, Biochemistry and Catalysis, Bucharest, Romania

* vasile.parvulescu@g.unibuc.ro

Keywords: metal nano-particles, Lewis acidity and basicity, preparation method, selective and stereoselective hydrogenation

Particle size is one of the key parameters determining the electronic properties, and as a direct consequence, the catalytic behavior of the supported metals. Sub-nanometric particles were already reported to exhibit beneficial Lewis acid properties for the control of both the activity and selectivity in reactions of importance [1]. However, specific Lewis properties can also be induced in nano-supported metal catalysts.

Based on this importance, the synthesis of metal and alloy nanoparticles of controlled size and shape become a hot topic. Unique properties at the interface between molecular structures and bulk materials can be thus induced following a rational design [2]. Typically, this occurs under strong reduction conditions and requires the presence of a stabilizer able to preserve the above properties.

The aim of this lecture is to present the synthesis of different Lewis acid-base catalysts for the synthesis of fine chemicals. First part will discuss metal- (Pd, Ru, Au, Pt, Ir) and alloy- (Pd-Au) nanoparticles and their catalytic behavior, focusing on the selectivity effects induced after their immobilization onto inorganic carriers. The preparation of the catalysts exhibiting metal Lewis acidity was carried out using several routes: i) the reduction of inorganic metal salts with $Na[AlEt_3H]$ or $Na[BH_4]$ [3-8] followed by the embedding of the resulted colloids in inorganic matrix supports using the sol-gel techniques (SiO_2, ZrO_2, SiO_2-Ta_2O_5]; ii) reduction of the organometallic complexes under supercritical CO_2 conditions followed by the ionic liquid stabilization of the resulted nano-particles [9]; iii) ionic exchange and deposition/precipitation of the noble metals onto zeolites and metal oxides [10-11]; and iV) impregnation of noble metals onto oxifluoride supports [12].

Second part will consider Lewis nano-base catalysts prepared *via* hydrolysis of $Mg(OCH_3)_2$ in a methanol–toluene mixture.

The characterization of these catalysts evidenced in all the cases the presence of the Lewis acid or basic centers. The concentration of these centers was correlated with other properties as particle size and shape, dispersion, etc that were determined using an ensemble of techniques: adsorption-desortption of N_2 at 77K, *in situ* FTIR measurements, DR-UV-Vis, SAXS, XRD, XPS, SEM, TEM, Mossbauer spectroscopy, etc. [2-6].

Finally, the talk will try to associate all these characteristics with the selectivity effects. The effect of the *Lewis acidity* in nano-particles was checked in various reactions like hydrogenation of C=C bonds in simple molecules like styrene or different cycloalkenes, hydrogenolysis of complex molecules like 1,1a,6,10b-tetrahydro-1,6-methanodibenzo[a,e]cyclopropa[c] cycloheptenes, diastereoselective hydrogenation of C=O versus C=C in un-saturated aldehydes and ketones like cinnamaldehyde or prostaglandin derivatives, or reduction of nitric oxides with hydrocarbons. The modification of the supported metal nano-particles by asymmetric ligands like Synphos and cinchonidine will be also discussed comparatively with the homogeneous systems in the selective hydrogenolysis of bicyclo[2.2.2]oct-7-enes and hydrogenation of ethyl pyruvate. The effect of *Lewis basicity* was checked in transesterification reactions.

Conclusions

A correct electron density in metal nanoparticles may lead to very high selectivities, and even activities, in complex reactions. Since there are still many reactions for which the selectivity levels are un-satisfactory future developments in the preparation control of such catalysts are necessary.

IV-KN3

Design of Supported Molecular Catalysts for Organic Synthesis

Jones C.W.*

Georgia Institute of Technology, Atlanta, USA

* cjones@chbe.gatech.edu

Keywords: rhodium, carbene, cyclopropanation, Rh2(DOSP)4, flow reactor, asymmetric, catalysis

1 Introduction

Molecular rhodium metal-ligand complex catalysts are a highly versatile class of catalysts used in both bulk chemical production (e.g. hydroformylation) and in the synthesis (e.g. asymmetric hydrogenation) of high value complex organic molecules, such as pharmaceuticals. In all cases, due to the cost of rhodium and in the latter case the ligands, achievement of high turnover numbers (TONs) is critical. This has led to the exploration of methodologies to increase the TONs of these catalysts by catalyst recovery and recycle. This presentation will describe our development of supported asymmetric dirhodium complex catalysts for cyclopropanations and C-H activation mediated catalytic coupling reactions [1,2]. The catalyst behavior, including reaction and substrate scope, will be initially described in batch reactions. Subsequently, a new design of a flow reactor for deployment of solid catalysts based on polymer/oxide hollow fibers will be described [3].

2 Experimental/methodology

A silica-grafted analogue of the well-known $Rh_2(DOSP)_4$ catalyst that reacts donor-acceptor diazonium compounds with various coupling partners via carbene-mediated reactions was prepared as described in the literature [2]. The obtained catalysts were used in an array of asymmetric cyclopropenation and cyclopropanation reactions, as well as coupling reactions that proceed via catalytic C-H activation, including (i) tandem ylide formation/[2,3] sigmatropic rearrangements with allylic and propargylic alcohols and (ii) combined C–H functionalization/Cope rearrangements in a batch reactor.

Cellulose acetate / oxide composite hollow fibers were also prepared as microfluidic flow reactors [3]. The oxide particles included porous silica particles as well as zeolites. To the silica particles, well-defined molecular catalysts could be grafted, and both an organocatalyst (primary aminopropyl fragments) and organometallic catalyst ($Rh_2(DOSP)_4$ analogue described above) were grafted to the silica particles within the fibers. The fibers were then used as flow reactors for an array of reaction types important in organic synthesis, including a deprotection reaction (Brønsted acid zeolite), a coupling reaction (aminopropyl catalyst), and a series of asymmetric coupling reactions (dirhodium carneoid catalysts).

3 Results and discussion

A wide array of asymmetric coupling reactions were conducted using both the silica-supported dirhodium carbenoid catalyst in batch, with product yields and ee's being comparable in most cases (Fig 1).

Three catalysts were also incorporated into composite polymer/oxide hollow fibers. The fibers containing acidic ZSM-5 zeolite are demonstrated to effect the deprotection of benzaldehyde dimethyl acetal in flow. In addition, fibers containing silica-grafted aminopropyl organocatalysts are shown to efficiently catalyse the Kneovenagel condensation of benzalde-

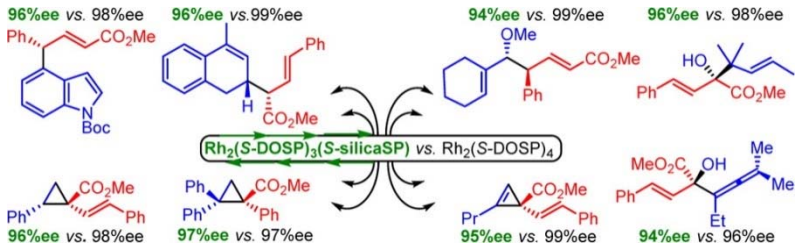

Fig 1. Array of products obtained in asymmetric cyclopropanations, cyclopropenations, as well as C-H coupling reactions catalysed by dirhodium carbenoid catalysts.

hyde and malononitrile in flow. Finally, the dirhodium carbenoid catalyst is demonstrated to catalyse some of the same reactions studied in batch in flow. Fig. 2, below, shows that excellent performance was obtained in flow even after 1000 turnovers were achieved.

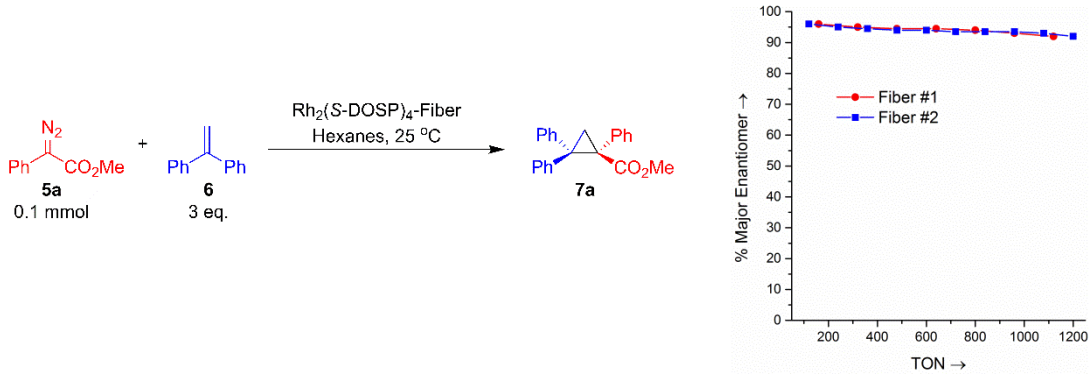

Fig 2. Asymmetric cyclopropanation in flow using dirhodium carbenoid catalyst over 1000 turnovers.

4 Conclusions

A new supported dirhodium carbenoid catalyst supported on porous silica is reported for a variety of asymmetric coupling reactions. This catalyst shows good activity and selectivity, closely paralleling the performance of the parent homogeneous catalyst, $Rh_2(DOSP)_4$. The catalyst is exploited in both batch reactions and in a novel, polymer/oxide hollow fiber microfluidic reactor. The hollow fiber reactor is demonstrated to be a new mode of facilitating catalyst-reagent contacting while carrying out organic synthesis in flow.

Catalysis to Produce Solar Fuels. Status and Challenges

Centi G.*, Perathoner S.

Dept. DIECII, Section Industrial Chemistry, University of Messina, ERIC aisbl and CASPE/INSTM, Messina, Italy

Keywords: solar fuels, CO_2, utilization, artificial leaves, renewable energy, low-carbon economy, sustainable, energy, production

1 Introduction

Realize a sustainable, resource-efficient and low-carbon economy is a major current challenge for society [1,2], but there are main issues to couple the renewable energy sources with the actual energy infrastructure, even considering smart grids. All renewable energy sources except biomass still suffering of major problems of storage and transport at long distance, as well as integration in the industrial production chain. CO_2 conversion to (liquid) fuels using renewable energy sources, e.g. the production of solar fuels, appears as the preferable and more sustainable solution to above problems and to avoid very large investments. The chemical (re)use of CO_2 using renewable energy thus become a key aspect towards the more general goal of resource and energy efficiency, because combines the reuse of a waste and of a relevant carbon sources to the reduction of fossil fuel use as well as GHG and pollutants emissions [3,4]. At the same time, catalysis to produce solar fuels has a major impact in reshaping the future of chemical production and low-carbon bioeconomy. We limit discussion here to the concept of solar fuels as those deriving from the conversion of CO_2 using renewable source of energy to synthetize the products of reaction [5].

2 The impact on scenario for sustainable energy/chemical production

There are many major changes in the chemical production, necessary to respond to the request of a resource and energy efficient sustainable future and to move to a low carbon economy. The use of alternative raw materials is between these driving forces. Biomass as chemical feedstock, (re)use of CO_2, waste valorisation, use of renewable energy, use of fossil fuels alternative to oil (actually accounting for majority of petrochemistry production), from shale gas to coal, are between these driving elements [2,3]. There is a change from the current (oil-centred) petrochemistry to the future of chemical production based on a larger use of alternative raw materials and of renewable energy sources. The lecture will shortly introduce this changing scenario and the impact on moving to solar fuels in this general panorama [3,4].

Solar fuels are a key element to move to a low-carbon bioeconomy [6]. Depending on the model for biorefineries, different options may be possible to integrate bio- and solar-refineries. In the energy biorefinery, where biofuels are the characterizing element, the utilization of CO_2 and renewable energy has the main scope to decrease the carbon footprint and at the same time increase the productivity in energy products. In biorefineries where chemicals are the main product (biofactories) the scope is instead different and the target is the optimal integration of CO_2 utilization within the value chain. However, a range of different other cases are also possible. The lecture will shortly discuss some of the possibilities for new sustainable biorefineries and the opportunities to integrate renewable energy sources in the biorefinery production (solar biorefineries).

There is a changing panorama for bio-based production, with new opportunities offered by the integrated utilization of CO_2 and renewable energy to move to a sustainable and low-carbon bioeconomy.

3 Options and opportunities for solar fuels

There are four main options to implement solar fuels and realize energy efficiency:

- A resource & energy efficiency chemical production, with the objective to reduce the use of fossil fuels as raw material and energy vectors, and to introduce renewable energy in the chemical production chain [2-4].
- Import unexploited renewable energy (RE) resources, via renewable H_2 (water electrolysis) using remote RE sources and CO_2 conversion to methanol or other CO_2-derived energy vectors, and production of solar fuels and chemicals [7].
- Local storage on RE in smart grids, with the main example being power-to-gas (CO_2 to CH_4) [8].
- Develop artificial leaves, in a long-term, for distributed production [9,10].

The lecture will comment these options, their status and opportunities.

4 Moving to artificial leaves

After analysing the motivations why chemical energy storage is the key for a sustainable use of solar energy, and some of the recent progresses in producing solar fuels and related devices, the discussion will be focused on the analysis of the critical elements of artificial leaves to consider for the development of next-generation solar photoelectrocatalytic (PEC) devices [9,10]. There are many challenges to be addressed to realize with good efficiency this process, from the challenges in the electrocatalysts to the understanding of the coupling of the fast processes of charge separation with the slower (at least three order of magnitude) processes of catalytic reduction and charge transfer [11,12]. There is the need to understand this chemistry and to analyse the role of advanced design in nanomaterial to control these processes. Transport processes and reactions at the interface are often dominating the overall performances. Thus, the development of the single components should proceed in parallel with the device development, and not separate as currently. Integrated nano-engineering of materials and devices is the challenge to address properly above problem and to enable the practical implementation of artificial leaf-type devices [13-15]

Carbon Dioxide as Carbon Source for the Energetic and Chemical Value Chain: Challenges and Opportunities for Catalysis

Leitner W.*

Institut für Technische und Makromolekulare Chemie, RWTH Aachen University, Aachen, Germany

* leitner@itmc.rwth-aachen.de

The finite resources of fossil feedstock together with the increase in anthropogenic emission of carbon dioxide (CO_2) are a major concern of global importance. The use of CO_2 as carbon source offers the possibility to contribute to sustainable processes at the interface of the energy and chemical supply chains.

This presentation highlights some of the key scientific challenges associated with these concepts and demonstrates how catalysis research combining molecular and engineering sciences provides key contributions to this area. The general aspects and current trends in academia and industry [1] are illustrated with examples concerning the development, application, and mechanistic understanding of catalysts and catalytic systems for the selective conversions of CO_2 to formic acid [2] and higher carboxylic acids [3], to methanol [4] and for methylation [5], and for polyurethane synthesis [6]. Possible applications include the use of CO_2 as C1-building block for fuels and polymers, as well as for chemicals and pharmaceuticals.

Electron Microscopy Advances in Catalysis

Helveg S.*

Haldor Topsoe A/S, Nymøllevej 55, Kgs. Lyngby, Denmark

* sth@topsoe.dk

Keywords: electron microscopy, atomic-resolution, *in situ*, dynamics, reactivity

In recent years, electron microscopy has made significant progress for the study of solid materials at the atomic-scale. Advancements in electron optics and data acquisition methods have made electron microscopy capable of delivering images with sub-Ångström resolution and single-atom sensitivity [1-3]. Parallel developments of gas cells, sample stages and micro-electro-mechanical system devices have made high-resolution electron microscopy available for *in situ* observations of solid materials during exposure to reactive gas environments at pressures up to atmospheric levels and temperatures of up to several hundred centigrade [4-6]. It is desirable to take advantage of these emerging technologies in the study of heterogeneous catalysts because they provide unique information about surface structures and dynamics.

In this contribution, I will outline advances in electron microscopy that enable observations of catalysts at atomic-resolution and in catalytically meaningful environments. Their application will be illustrated with studies within e.g. hydrotreating, methanol synthesis and diesel automotive exhaust abatement catalysis [1-11]. Moreover, it will be discussed how the atomic-scale observations can beneficially be combined with reactivity data, calculated or measured, from simpler model systems. Hereby, the description of the dynamic functions and properties of catalysts can be extended with information that is specific to the exposed surface sites, which, in general, should contribute to the continued development of new and better catalysts.

Chemical Photocatalysis Using Visible Light

Koenig B.

Faculty of Chemistry and Pharmacy, University of Regensburg, Regensburg, Germany

* burkhard.koenig@ur.de

Keywords: photocatalysis, visible light, conPET, arylation reactions, photoredox catalysis, green, chemistry

The use of visible light for organic synthesis is a very old idea: More than 100 years ago the Italian chemist Giacomo Ciamician discovered and promoted the field. Recently, photoredox chemistry mediated by metal complexes, such as ruthenium-trisbipyridine, or organic dyes, such as eosin or perylenediimides, gained enormous interest for applications in organic synthesis.

We present some of the recent results using photoredox catalysis with visible light from our laboratory including photooxidations, oxidative C-C bond formation and arylation reactions utilizing one or two photons for activation.

Exploiting Acid-base Cooperativity in Metalloenzyme-like Lewis Acid Zeolites for Biomass Conversion

Van De Vyver S., Lewis J.D., Román-Leshkov Yu.*

Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

* yroman@mit.edu

Keywords: biomass conversion, Lewis acids zeolites, C-C coupling, transfer, hydrogenation

1 Introduction

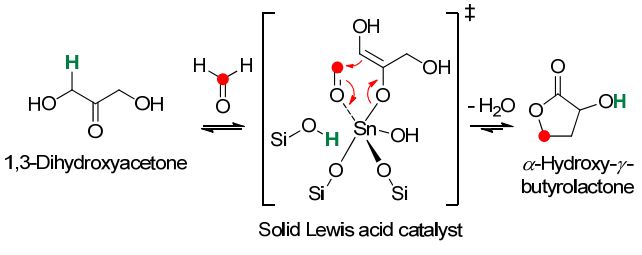
In our efforts to shift away from traditional petroleum-based raw materials to supply fuels and chemicals, biomass has emerged as an attractive renewable carbon-containing feedstock. Its complex chemical diversity has created daunting challenges that require the implementation of robust, active, and selective catalysts to effectively transform it into useful products. In this lecture, new developments in the use of Lewis acid zeolites will be presented in the context of converting biomass-derived oxygenates into value-added products. Specific examples will be presented highlighting the role that catalytic pairs play in enhancing the activation of targeted functional groups, achieving cooperative catalysis, or promoting one-pot cascade reaction sequences. Lewis/Brønsted acid pairs will be discussed in the context of hydrolysis/transfer hydrogenation cascades for the conversion of furfural into gamma-valerolactone, while Lewis acid/base pairs will be discussed in the context of cooperative C-C coupling of oxygenates, including coupling of hydroxyacetone with formaldehyde to form α-hydroxy-γ-butyrolactone (HBL), i.e. a chemical intermediate used for production of pharmaceuticals.[2]

2 Experimental/methodology

Reactivity studies were performed in batch and flow reactors at between 80 and 160 °C using 1,4-dioxane, toluene, water or acetone as solvents, and a metal:oxygenate ratio of 1:100 and a oxygenate:formaldehyde ratio of 1:3 [1]. Sn-Beta was synthesized based on a procedure reported by Corma et al. [3]. Details on the characterization of the catalysts can be found in publication [4].

3 Results and discussion

As a representative example of C-C coupling, the production of HBL will be discussed in more detail. Sn-Beta zeolites effectively catalyze the C–C coupling reaction between DHA and formaldehyde, yielding up to 60 % HBL at 98% conversion after 3 h [1]. Byproducts observed were lactic acid and (1,3-dioxolan-4-yl)methanol. The conversion pathway of DHA into HBL involves consecutive aldol condensation, 1,2-hydride shift, dehydration, intramolecular hemiacetal and keto–enol tautomerization reactions. Of particular importance in this pathway is the aldol condensation step, as our reactivity studies, coupled with spectroscopic and computational analyses, corroborate a mechanism involving soft enolization of DHA followed by an aldol addition of formaldehyde to the Sn-enolate intermediate, generating erythrulose as an intermediate species. More specifically, in our proposed mechanism, the framework Sn atom polarizes the carbonyl group of DHA, resulting in a substantial increase in the acidity of the α-proton. This proton can be removed by the basic oxygen atom connected to Sn, generating a Sn-enolate



Scheme 1. Proposed soft enolization pathway for the catalytic C–C coupling between DHA and formaldehyde using Sn-Beta zeolites.

intermediate and a silanol group (Scheme 1). Coordination of the oxygen atom of formaldehyde to the Sn center induces polarization in the molecule, further enhancing its reactivity by increasing the electrophilicity of the aldehyde carbon.

Formation of the aldol addition product erythrulose as a reaction intermediate in the production of HBL was substantiated by using it as a reactant in place of DHA. A reaction of erythrulose with Sn-Beta under identical conditions as those used for DHA generated a 24% HBL yield, thus confirming that erythrulose can undergo the suggested transformation. To further support our hypothesis, isotopically labeled formaldehyde was reacted with DHA in the presence of Sn-Beta and investigated using GC-MS and 13C NMR. The mass spectrum of the product mixture agrees with that obtained from the reaction with unlabeled formaldehyde, but is shifted by m/z = 1 to higher m/z ratios. Specifically, the main fragment ion at m/z 58, corresponding to the resonantly stabilized species 13CH2=CH–CH+–OH, indicates that HBL contains the 13C label at the C4 position. This was corroborated by 13C NMR, which showed a main resonance at δ = 65.2 ppm corresponding to the C4 atom. The highly selective incorporation of 13C atoms can indeed be rationalized by considering the proposed C–C bond formation mechanism. Formation of erythrulose is calculated to proceed exothermically with a ΔG0 value of 0.4 kJ mol−1, which, although slightly positive, compares favorably to 16.8 kJ mol−1 for the previously proposed aldol condensation of pyruvic aldehyde with formaldehyde into 4-hydroxy-2-oxobutanal [4]. The estimated ΔG0 values of the ring closure and 1,2-hydride shift are -49.1 and -57.0 kJ mol−1, respectively, strengthening the feasibility of the reaction mechanism shown in Scheme 1. Although this abstract is not meant to divulge detailed spectral data, we note that we were also able to observe formation of C5 sugars, indicating the occurrence of two consecutive aldol condensation reactions

4 Conclusions

Catalytic pairs represent a powerful, yet relatively unexplored, strategy for the selective activation of oxygenates. Akin to metalloenzymes, Lewis acid zeolites can be engineered to feature catalytic pairs and catalyze reactions with high activity under mild conditions. In particular, the development of catalytic C–C bond formation schemes based on renewable substrates is of importance to define sustainable paradigms for chemical manufacture. With a few exceptions, aldol condensation reactions between biomass-derived platform chemicals using heterogeneous Lewis acid zeolites have received little attention so far.

Real-time Analysis of Catalytic Reactions Using Simultaneous Orthogonal Methods

Mcindoe J.S.*

Department of Chemistry, University of Victoria, P.O. Box 3065, Victoria, Canada

* mcindoe@uvic.ca

Powerful insights into catalytic mechanisms can be acquired through direct observation of intermediates while the reaction is being carried out. Numerous spectroscopic and kinetic tools have been utilized for this purpose, and our focus has been on developing real-time methodologies to allow electrospray ionization mass spectrometry (ESI-MS) to reliably perform this task in real time. Fast and sensitive and with a high dynamic range, ESI-MS is capable of handling the complex soup of components that is an evolving catalytic reaction. With the use of charged tagged substrates and continuous infusion of sample, the reactants, products, byproducts, catalyst resting state, decomposition products and abundant intermediates can be measured simultaneously and reproducibly at a sampling rate of 1 s^{-1}. However, by offloading the task of assessing reaction progress to an orthogonal method, the overall dynamic range can be increased to over 5 orders of magnitude, i.e. real time analysis of species present at part-per-million levels during reactions performed at typical concentrations (0.1 M). Examples of our approach will be presented in the context of a variety of transition-metal catalyzed reactions, including various palladium-catalyzed cross-coupling reactions and rhodium-catalyzed hydrogenation and hydroacylation reactions.

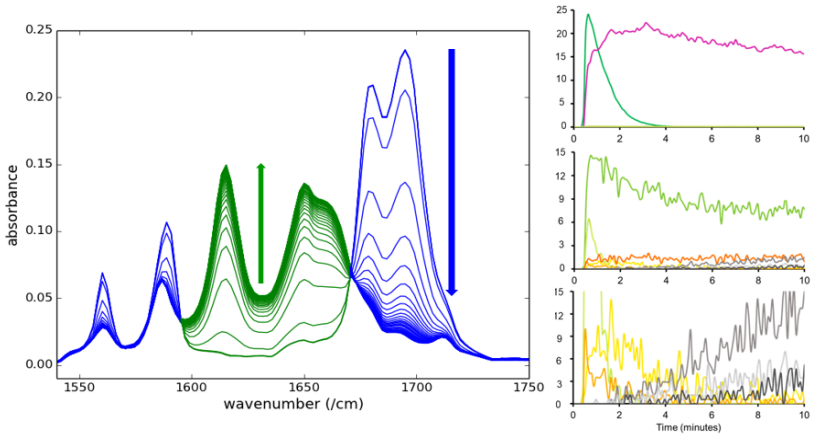

Fig. 1. Complementary real-time spectroscopic and spectrometric data from a catalytic reaction.

Base Metal Catalysis for Cross Coupling and Addition Reactions

Hu X.L.*

Laboratory of Inorganic Synthesis and Catalysis, Institute of Chemical Sciences and Engineering, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

* xile.hu@epfl.ch

Keywords: iron catalysis, nickel catalysis, cross coupling, alkyl, radical, alkynes, alkenes

1 Introduction

The advancement of catalysis has had a significant impact on society. As chemists strive to improve the efficiency of chemical synthesis and to enable green and renewable energy conversion and storage technologies, fundamental research in catalysis is as important today as at any time in the past. Base metal catalysis, where the catalysts contain only elements abundant in the earth's crust, offers potential advantages in cost, availability, scalability, and sometimes compatibility with health and the environment. In this talk, I will present our recent work in base metal catalyzed cross coupling reactions and functionalization of alkenes and alkynes.

2 Experimental/methodology

Cross coupling of alkyl halides is challenging because metal alkyl intermediate species are prone to unproductive beta-H elimination. We have applied Ni, Cu, and Fe-based catalysts for these reactions. We also employ well-defined metal complexes as mechanistic probes.

Alkynes and alkynes are readily available and inexpensive feedstock chemicals. We have developed Fe and Cu catalysis to transform these unsaturated molecules into higher-valued compounds through addition reactions.

3 Results and discussion

We developed a well-defined Ni catalyst, Nickamine, that catalyzes the alkyl-alkyl, alkyl-aryl, and alkyl-alkynyl Kumada coupling of activated alkyl halides, as well as direct alkylation of alkynes and heterocycles (Figure 1).[1-5] The mechanism of these reactions was thoroughly studied using radical probes, kinetics and DFT computations.[6,7] We also studied the mechanism of analogous Fe-catalyzed alkyl-aryl Kumada coupling using defined Fe pincer complexes.[8] A common bimetallic oxidative addition reaction pathway involving alkyl radical intermediates was found for these coupling reactions.

We discovered that Fe catalysts could be used to promote the 1,2-addition of perfluoroalkyl iodides to alkynes and alkenes.[9] The resulting perfluoroalkylated alkyl and alkenyl iodides could be further functionalized by cross coupling reactions. Further investigation showed that copper catalysis can be used to promote the 1,2-addition of alpha-carbonyl iodides to alkynes,[10] resulting beta,gamma-unsaturated ketones which are an important class of organic molecules.

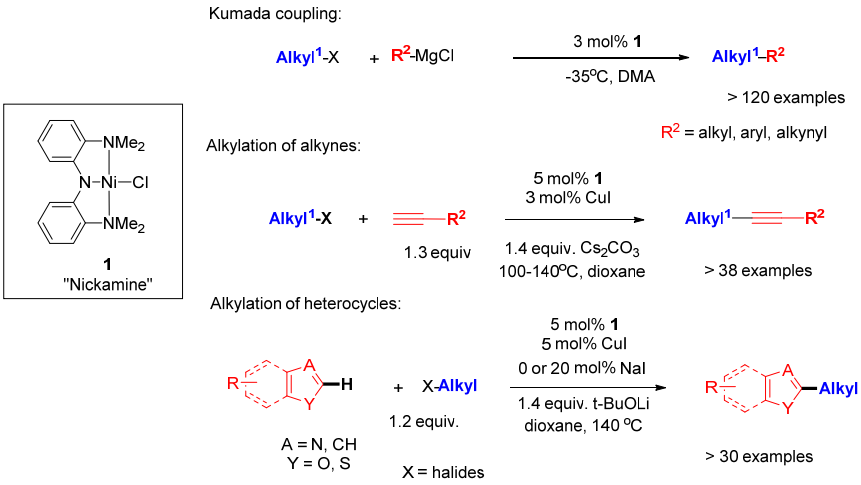

Fig. 1. Cross coupling-type reactions catalyzed by Nickamine.

4 Conclusions

We have developed efficient base metal catalysis for some important organic reactions such as cross coupling and alkene and alkyne functionalization. The complex mechanism of these reactions is started to be elucidated, showing unique features compared with precious metal catalysis.

Catalysis in Confined Space – from Zeolites and Zeotypes to Functionalized Metal-Organic Frameworks

Olsbye U.*, Lillerud K.P.

Department of Chemistry, University of Oslo, Oslo, Norway

* unni.olsbye@kjemi.uio.no

More than a decade of systematic studies of zeolite- and zeotype-catalysed reactions have revealed how confinement effects may alter the rates of individual reactions, as well as the selectivity of complex reaction networks (see e.g. [1-2]).

A parallel, large research effort is targeting another class of nanoporous solids, metal-organic frameworks (MOFs), as a next generation sorbents and catalysts. Ideally, MOFs offer a wide variety of functionalities and pore sizes. However, synthesis as well as chemical, thermal and mechanical stability issues may restrict their applicability. In this lecture, focus will be set on the Zr-MOF series developed at UiO [3-5]. Studies of chemical stability and mechanical strength, catalyst formulation and catalyst performance (ethene oligomerisation, CO_2 reduction) will be presented.

Development of New Catalytic Materials for Sustainable Production of Chemicals

Tatsumi T.*

Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo, Japan

* ttatsumi@cat.res.titech.ac.jp

Our comfortable modern life is supported by numerous chemical, in particular petrochemical, products. At present, petrochemical industry is based on lower olefins that are produced by thermal cracking of petroleum naphtha in Southeast Asia and Europe. We need to develop the methods for manufacturing chemical products from more substantial fossil resources if possible, and for the long term, preferably from renewable resources.

To develop new technologies of efficient and sustainable production of lower olefins that could replace the conventional thermal cracking process**,** we have tried to improve the catalytic performance of zeolites in catalytic naphtha cracking that occurs at much lower temperature and gives higher selectivity for propylene than thermal naphtha cracking. The critical matter is the elongation of catalyst duration time. There are two main causes for the activity loss, coke deposition and dealumination. Several methods for mitigating the deactivation have been developed.

Because of the shale gas revolution, the use of methane as chemical feedstock as well as fuels is attracting widespread attention. At this time methanol is considered as getting more available chemical feedstock. While methanol production through direct oxidation of methane is extremely difficult, it is worth challenging. In any case, methanol to olefins (MTO) reaction is a promising route to the lower olefins. In this reaction, the deactivation as a result of coke deposition is a critical problem. For the MTO reaction a large number of zeolites were screened and we have found CIT-1 (**CON**) zeolite is promising for selectively converting methanol to propylene and butenes without serious loss of activity.

While fossil fuels will be the dominant factor in the future energy and chemicals scenario for a couple of decades to come, we need to develop methods of alternative chemicals production. Compared to petroleum and natural gas, biomass has low H/C and high O/C ratios and low calorific value. Thus biomass could be useful for the production of chemical products that are not manufactured on a massive scale in the current petrochemical industry. It has long been recognized that 5-hydroxymethylfurfural (HMF) is a bio-based "platform" material for producing useful chemicals. Increasing research interest has been paid to the synthesis of HMF from sugars, particularly from glucose. We have found an effective transformation of glucose to HMF over Beta zeolite by finely tuning acid properties. The high Brønsted/Lewis acid ratio is a key factor for selective production of HMF from glucose. Meanwhile, a great deal of effort has been devoted to the production of sorbitol, as bio-based feedstock, from cellulose. For example, sorbitol can be converted to isosorbide (1,4:3,6-dianhydrosorbitol) through double intramolecular dehydration. Isosorbide can be used to produce polymers such as polyester and polycarbonate; Poly-(ethylene-co-isosorbide)- terephthalate is a bio-based alternative to polyethylene terephthalate (PET). Isosorbide can also replace bisphenol A in the production of polycarbonate and epoxy resins. We have developed highly active zeolite catalysts for the dehydration of sorbitol to isosorbide in water.

For a future sustainable chemicals scenario, it may be desirable to develop efficient methods for utilizing CO_2 by using renewable energy, which could be the ultimate goal. Photocatalytic decomposition of water by visible light, which accounts for a great majority of sunlight, is an enormous challenge and it is absolutely necessary to activate the research in this field. In Japan a 10-year METI (Ministry of Economy, Trade and Industry)-sponsored national project that

targets the recycling CO_2 by using solar H_2 started in 2012. This project is named ARPChem (Artficial Photosynthesis of Chemicals). At this moment this project focuses on the production of light olefins as chemical feedstock. We are developing the process consisting of methanol synthesis from CO_2 and H_2, followed by the MTO reaction catalyzed by zeolites.

Progress and Challenges in Urea/SCR Technology for Removing NOx from Diesel Engine

Nam I.-S.*

Department of Chemical Engineering/School of Environmental Science and Engineering, Pohang University of Science and Techlogy (POSTECH), Pohang, Republic of Korea

* isnam@postech.ac.kr

Keywords: NOx, reduction, Urea/SCR, Mn-Fe, bimetallic, catalyst, CuSSZ13, ESR

The advent of energy-efficient automotive diesel engine has significantly reduced its fuel consumption and CO_2 emission to atmosphere in recent decades [1]. From an environmental point of view, however, the emissions of atmospheric pollutants including nitrogen oxides (NOx) from the diesel engine become a primary concern, while CO and HCs can be readily oxidized by a diesel oxidation catalyst (DOC) commonly installed into diesel after-treatment system under lean operating condition. The abatement of NOx from the diesel engine exhaust is thus one of the critical issues for the commercial implementation of the modern energy-efficient diesel engine technology.

Among promising NOx reduction technologies currently available, the LNT and the SCR technologies are the two leading ones despite their inherent shortcomings still remaining as important technical issues to be resolved [2-3]. A practical advantage of the urea/SCR technology over the LNT rests on the fact that it does not require the use of a large amount of noble metals and complex engine controls which is the essential requirement for the LNT technology [4]. The HC/SCR technology lags behind due primarily to its insufficient low-temperature activity and narrow temperature window on top of its poor tolerance toward H_2O and SO_2 [5].

The urea/SCR technology is undoubtedly one of the commercially proven, reliable and available technologies to meet the stringent worldwide environmental regulations including EURO VI and SULEV for reducing NOx emissions from diesel engine [1,6-7]. The V_2O_5/TiO_2 catalyst has been employed as the conventional SCR catalyst especially for the removal of NOx from stationary sources [8,9]. However, V_2O_5/TiO_2 may not be active in the diesel exhaust temperature ranging from 150~250 ^oC for light duty diesel engine to 200~350 ^oC for heavy duty one, and zeolite based-catalysts including ZSM5 and SSZ13 have then been regarded as the promising urea/SCR catalyst to be directly applied to the diesel after-treatment system [10-12]. In recent years, a number of efforts for further improving the low-temperature activity as well as the stability of the urea/SCR catalysts have been underway for their implementation to the next generation vehicles equipped with the advanced diesel engines.

In this presentation, the progress and challenges in the urea/SCR technology to remove NOx from diesel engine will be reviewed in the topics ranging from the underlying catalysis to the recent research trend and commercial applications. Included in the discussion will be the promoted V_2O_5/TiO_2 catalyst by the modification of catalyst support [13,14] as well as the bimetallic catalyst systems aimed at improving the low temperature activity of the current urea/SCR catalysts and their catalytic characteristics [15,16]. In addition, the local environment of active sites in CuSSZ13, currently regarded as the most promising low-temperature SCR catalyst, will be discussed by ESR and XANES studies in order to understand its strong thermal stability [17]. Also presented will be the tolerance of CuSSZ13 toward CO_2, recently reported as a new deactivating precursor for the urea/SCR catalyst [18].

Keywords: nanostructures, coverage effects, subsurface species, transition metal particles, ceria

1 Introduction

Key elements of nanomaterials for current and prospective applications often consist of many thousands of different atoms and thus remain inaccessible for the first-principles (based on Density Functional Theory, DFT) computations due to their size and complexity. However, such systems could be quite realistically represented by computationally tractable smaller model nanoparticles and their aggregates, whose surface structure and reactivity reveal only weak or monotonic size dependence.

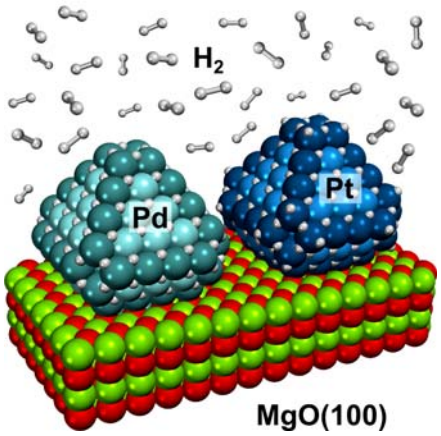

Fig. 1. Models for studies of hydrogen absorption in MgO(100)-supported 1.6 nm large Pd_{127} and Pt_{127} particles with surfaces saturated by hydrogen [8].

2 Results and discussion

We address various problems related to approaching complexity of multicomponent nanomaterials for heterogeneous catalysis and energy technologies in the frameworks of DFT electronic structure modelling.

Among the discussed questions are:
(*i*) To what extent commonly used slab models represent surface properties of metal and metal-oxide nanostructures?
(*ii*) How to design and handle more realistic models?
(*iii*) How significant are interactions at the interface of metal nanoparticles with supporting oxide materials of different kinds and degrees of ordering?
(*iv*) How important are surface coverage effects?
(*v*) Are there reliable ways to computationally optimize chemical ordering of metal components in sufficiently large bimetallic nanoparticles?

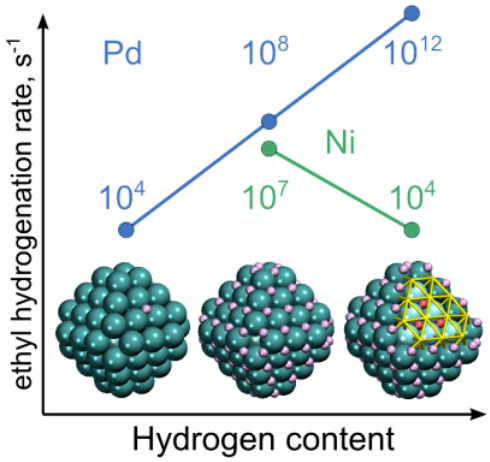

Fig. 2. Subsurface hydrogen can modify the stability and the reactivity of the adsorbed hydrogen in two different ways: in the presence of subsurface H a representative reaction of ethyl hydrogenation is calculated to be strongly accelerated on Pd (Pt), but slowed down on Ni (Rh) [7].

3 Conclusions

The presented results illustrate the current state of advanced theoretical models in heterogeneous catalysis. A general conclusion is that to provide realistic enough description of complex experimentally relevant catalytic systems and processes at affordable computing cost, the models need to be *as simple as possible, but not simpler*.

Operando Studies on PdZn-ZnO, (Pd-)Co_3O_4 and Ni-ZrO_2: Synergies between Surface Science Based Model Systems and Technological Catalysts

Rupprechter G.*, Rameshan C., Föttinger K., Suchorski Y., Bukhtiyarov A., Li H., Anic K., Wolfbeisser A., Lukashuk L.

Institute of Materials Chemistry, Vienna University of Technology, 1060 Vienna, Austria

* guenther.rupprechter@tuwien.ac.at

Our group´s philosophy is to study catalytic surface reactions on heterogeneous catalysts *via a two-fold approach,* employing both *surface science based planar model catalysts* as well as *industrial-grade catalysts* [1-3]. For both, the focus is on examining *active functioning catalysts* under *operando* conditions, at (near) ambient pressure and at elevated temperature (Figure 1).

In particular for ultrahigh vacuum (UHV) based model catalysts that has been a challenge, requiring application of *in situ surface spectroscopy*, such as sum frequency generation (SFG) laser spectroscopy, polarization-modulation infrared reflection absorption spectroscopy (PM-IRAS) and near ambient pressure x-ray photoelectron spectroscopy (NAP-XPS) [1]. To image ("see") ongoing surface reactions by *in situ surface microscopy*, photoemission electron microscopy (PEEM) was applied to polycrystalline samples [2]. For technological catalysts, analogous *operando* studies were performed by Fourier transform infrared spectroscopy (FTIR), x-ray absorption spectroscopy (XAS), near ambient pressure x-ray photoelectron spectroscopy (NAP-XPS), and x-ray diffraction (XRD) [3]. Most of the operando studies were performed at synchrotron sources (BESSY (DE), MaxLab (SE), SLS (CH)), and in lock-step with theory.

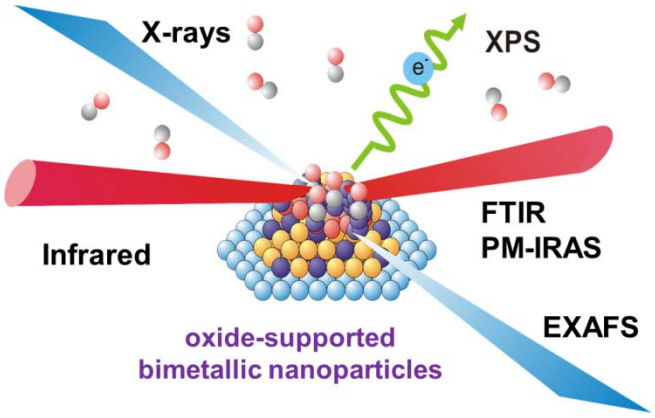

Fig. 1. Schematics of spectroscopic studies of functioning catalysts; from [3].

This two-fold approach yields a better "*holistic*" view of the catalytically relevant atomic and electronic surface structures of catalysts, as well as of molecular details that steer reaction activity and, even more important, reaction selectivity. Comparing surface science based single crystals with nanoparticle model catalysts elucidates the *materials gap*, and comparing UHV to ambient pressure studies reveals the *pressure gap*. In particular, synergisms between studies on model and technological catalysts often provide access to atomistic details.

Among the systems studied are
i) hydrogen generation by methanol steam reforming on alloy (intermetallic) catalysts, i.e. PdZn

surface alloys on Pd(111) single crystals [4] and PdZn nanoparticles supported on ZnO [3], ii) CO oxidation on noble metals [2], thin films and commercial cobalt oxides (Co_3O_4 and CoO), iii) CO and water adsorption, and methane reforming on Ni-ZrO_2, employing an ultrathin ZrO_2 trilayer (O-Zr-O) film on Pt_3Zr(0001) [5] as well as commercial ZrO_2 as support [6].

The combined studies provide detailed mechanistic insight, e.g. on i) the effect of PdZn thickness, surface corrugation and valence band structure on selectivity, ii) locally-resolved catalytic ignition, surface oxide formation/reduction, oxygen vacancy formation as well as carbon balance, iii) electronic structure of ultrathin oxides, and gas-induced oxide and nanoparticle reconstructions. Very recently, we have applied the operando NAP-XPS approach to examine electrochemical water splitting on perovskite-type electrodes under potential control, elucidating polarization-driven changes of surface composition and their effect on reaction kinetics [7].

Photocatalytic Overall Water Splitting: Present and Future

Li C.*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian National Laboratory for Clean Energy, Dalian, China

* canli@dicp.ac.cn

This lecture presents the research progress on solar fuel productions from photocatalytic and photoelectrocatalytic (PEC) processes with the emphasis on the fundamental understanding of the semiconductor-based photocatalytic and photoelectrocatalytic water splitting for solar fuel production.

The great challenge of energy conversion photocatalysis lies in its complicated processes including light absorption (harvesting), charge separation and migration, and redox reactions. In order to gain high photon energy conversion efficiency, a photocatalyst or photocatalytic system must harmonically guarantee high efficiencies of all these three processes instead one of them. Semiconductors with appropriate phase junctions have been demonstrated to be an efficient approach for achieving efficient charge separation [1]. Cocatalysts play important roles in the assembly of efficient semiconductor photocatalyst. It has been conceptually demonstrated Pt-PdS/CdS dual cocatalyst system can achieve 93% H_2 evolution activity in the presence of sacrificial reagents under visible light irradiation (l>420 nm) [2,3]. Recently, it has been also demonstrated that electrons and holes can be spatially separated on the {010} and {110} facets of $BiVO_4$ crystal [4]. It has been demonstrated that the intrinsic nature of charge separation between different facets of $BiVO_4$ together with the synergetic effect of dual-cocatalysts plays key role in photocatalytic activity enhancement [5]. This work opens up a new avenue for the assembly of semiconductor crystal based artificial photosynthesis system by selectively loading of dual cocatalysts on the different facets.

Alternative approaches other than powdered semiconductor system should be also highly considered, such as photoelectrochemical (PEC) and solar cell coupled with water electrolysis catalyst systems. A Ta_3N_5 photoanode coated with ferrihydrite (Fh) layer on which Co_3O_4 water oxidation cocatalyst (Co_3O_4/Fh/Ta_3N_5) was deposited, could yield a photocurrent of 5.2 $mAcm^{-2}$ at a potential of 1.23 V vs. RHE under AM 1.5G simulated sunlight irradiation. And remarkably, about 94% of the initial activity could be maintained even after 6 h irradiation, which is due to the avoidance of the corrosion of Ta_3N_5 via. efficient hole storage and transfer by the Fh layer [6]. A self-biased photoelectrochemical–photovoltaic coupled system consisting of FeOOH/Mo:$BiVO_4$ photoanode and a Pt/p-Si solar-cell-based photocathode showed h_{STH} of 2.5% under parallel irradiation [7].

Novel Catalytic Methods for Synthesis of Organic Building Blocks and Biologically Important Heterocycles

Gevorgyan V.*

Department of Chemistry, University of Illinois at Chicago, Chicago, Illinois, USA

* vlad@uic.edu

We have developed a set of novel efficient transition metal-catalyzed annulation and cycloisomerization methodologies for synthesis of multisubstituted carbo- and heterocycles [1-22]. Traditionally, regioselective synthesis of carbo- and heterocycles possessing various functional groups is not a trivial task. We have shown, however, that incorporation of migrating step(s) in the cyclization cascade often helps solving this problem. Thus, it was found that in the presence of Cu-, Ag-, and Au catalysts, a number of groups, such as Hal-, RS-, AcO-, TsO-, Ar-, and SiR_3 could undergo 1,2- or 1,3-migration, or in some cases even double migration, which allows for expeditious synthesis of densely-functionalized carbo- and heterocycles, which are not easily accessible via existing techniques. Most of these transformations proceed via metal-stabilized carbene intermediates. The validity of vinylidene- and carbene intermediates in some of these cascade reactions was tested by means of DFT calculations. We have also developed new tri-component coupling reactions toward expeditious assembly of aminoindoline, aminoindole, and imidazopyridine cores. These methods were used for synthesis of libraries of small heterocyclic molecules for wide biological screening.

The scope of these transformations will be demonstrated and the mechanisms will be discussed.

Keywords: hierarchical catalysts, syngas, dimethylether, zeolite, copper

1 Introduction

Dimethyl ether (DME) is one of the most promising environmentally optimized alternatives to conventional fossil fuels due to its high cetane index, low emission of CO, NO_x and particulates and reduced noise. DME can also be used as a substitute for liquefied petroleum gas (LPG). DME is biodegradable; it has low toxicity and does not corrode any metals. In addition, DME is an important intermediate for the production of useful chemicals (i.e. methyl acetate and dimethyl sulphate) and petrochemicals (light olefins, BTX aromatics). In the industry, DME can be produced from syngas using either two-stage or single-stage direct technologies. The two-stage technology is currently considered as the most mature route. In the first stage, syngas is converted into methanol over copper based catalysts. In the second stage, methanol is dehydrated into DME over acid catalysts. The maximum syngas conversion to methanol is limited by thermodynamics especially at high temperatures. The single-stage direct DME synthesis overcomes these thermodynamic constraints and leads to higher per-pass CO conversions and higher DME productivity. The direct DME synthesis, however, requires an efficient bifunctional catalyst. The crucial issue in catalyst design for direct DME synthesis is optimisation of the catalyst composition and interaction between methanol synthesis and methanol dehydration active phases. Direct DME synthesis faces several challenges. First, the catalyst activity can be improved for more efficient manufacturing. Second, because of very fast reaction of carbon monoxide with released water, significant amounts of CO_2 are produced. This leads to lower carbon efficiency. Third, the activity of the DME synthesis catalyst decreases with time on stream. The catalyst deactivation affects both copper and acid catalyst sites. The deactivation phenomena may include copper oxidation, sintering, coke deposition, contamination by impurities in syngas, etc.

Zeolite based catalysts have several advantages for methanol dehydration to DME relevant to more conventional oxide catalysts. However, the low back-diffusion of DME through the zeolite crystals could lead to post-reactions yielding undesirable by-products and carbonaceous residues. The latter induces plugging of the catalyst's pores and thus progressive deactivation. Therefore it is of interest to develop new zeolite catalytic system with a hierarchical porosity, i.e. micropores connected from each other with a network of meso- or macropores, in order to facilitate the reactant access and product removal.

The present work addresses design of efficient bifunctional catalysts on the basis of copper and hierarchical ZSM-5 zeolites for direct DME synthesis from syngas. In particular, the lecture is devoted to the strategies relevant to the control of catalyst activity, selectivity and stability.

2 Experimental/methodology

The $CuO–ZnO–Al_2O_3$ precursor was prepared by co-precipitation. A series of ZSM-5 zeolites were prepared from Na_2O - SiO_2 -Al_2O_3-TPAOH - H_2O systems. The hierarchical structure was created using sacrificial templates and treatment with HF_2^-. The hybrid catalysts were prepared using kneading. The catalysts were characterized both *ex-situ* using BET, SEM, TEM, XPS, TPR TPO, FTIR with adsorbed molecular probes (CO, Py, lutidine). The catalytic performance was evaluated in a fixed-bed millireactor. The *operando* XRD/XANES/EXAFS synchrotron experiments were carried out at the ESRF (SNBL beamlines) using a high pressure capillary cell with simultaneous on-line MS analysis of reaction products.

3 Results and discussion

Strategies for the activity control

DME, methanol, hydrocarbons, carbon dioxide and water are major products of carbon monoxide hydrogenation over hydride copper-zeolite catalysts. The activity depends on both concentrations of copper active phase and acid sites in zeolites. Our detailed study revealed a strong correlation between the zeolite crystallite sizes and reaction rate. At the same concentration of copper active sites, higher reaction rate is systematically observed over the catalysts containing smaller zeolite crystallites. The equilibrium of carbon monoxide hydrogenation shifts to methanol, because of rapid transfer of methanol molecules for dehydration to the acid site of the zeolite.

Strategies for the selectivity control

Our results suggest that higher concentration of Bronsted acid sites favours DME selectivity and suppress yields of methanol. Carbon dioxide is undesirable products of DME direct synthesis. Carbon dioxide produces in secondary reactions, its selectivity increases with higher carbon monoxide conversion. Two strategies are proposed to decrease the CO_2 selectivity in direct DME synthesis. The first one involves catalyst promotion which might affect the rate of elementary steps of different reactions. Promotion with tin for example resulted in a noticeable drop in carbon dioxide production. The presence of tin in the catalysts seems to considerably slow down the water gas-shift reaction leading to CO_2. The second strategy focuses on the protecting of the active sites for methanol synthesis from exposure to water. Water gas shift reaction in the bifuncntional catalysts for direct DME synthesis occurs on copper phases. Encapsulation of copper in hydrophobic silica nanospheres could result in a decrease in the CO_2 selectivities and enhanced DME productivity.

Strategies for the stability control

A combination of *ex-situ* and *operando* XAS characterization uncovered that copper is present in metallic form under a wide range of operating conditions. Copper sintering could be a major reason for the deactivation of hybrid hierarchical catalysts. The sintering phenomena are significantly accelerated in the presence of co-fed water. Copper sintering results in a decrease in the number of active sites for methanol synthesis. In addition the migration of copper nanoparticles can plug the porous structure of zeolite and reduce the concentration of acid sites for methanol dehydration. Copper sintering is accelerated by higher concentration of Bronsted acid sites on the external surface of zeolite. The *operando* experiments conducted under realistic conditions of DME synthesis did not reveal any noticeable copper oxidation. No significant carbon deposition was also observed. Catalyst deactivation can be accelerated by the heat spots, the reaction is exothermic. The strategies for the catalysts stability control developed in this work address reducing the concentration of Bronstend acid sites on the external surface of zeolite by sylilation or shaping the catalysts on silicon carbide host matrix with high thermoconductivity.

Keywords: photocatalysis, water splitting, charge separation, interface, semiconductor, solar fuel

1 Introduction

Solar energy conversion is must to compensate the gap between energy production and its demand which is increasing with years [1]. A large scale energy generation from solar energy is only achieved by collection of solar spectrum at large scale. Overall water splitting using heterogeneous photocatalysts using a single semiconductor enables to directly generate H_2 from photo-reactor and is one of the most economical technologies in large-scale production of solar fuels [2]. The efficient photocatalyst materials are essential to make this process feasible for future technology. The potential scheme of photocatalytic process at different scale is depicted in Figure 1.

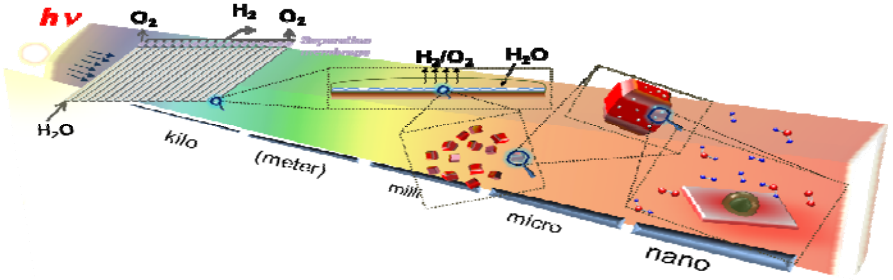

Fig. 1. A schematic of basic concept of overall water splitting at different scale.

2 Discussion

The photocatalysis involves multiple steps of the photophysical and electroccatalytic processes, as depicted by Figure 2. The photocatalytic reaction is initiated by the excited charge carriers (electrons and holes) that are generated by the absorption of the photons in the semiconductor materials (photocatalysts) [3]. Both the generated electrons and the holes move to the surface of the photocatalytic materials and subsequently initiate their respective redox reactions [3]. The photocatalytic process fully utilizes the electronic configuration occurring at the metal–semiconductor and semiconductor–electrolyte interfaces by constructing band structures (the formation of band bending and barriers) [4,5], preferably without introducing p–n junctions that generally increase the process cost. This electronic structure is essential in enhancing the charge separation and in achieving a highly efficient photocatalytic process because the photophysical process, including the generation and recombination of the excited carriers, occurs on a significantly shorter time scale (femto- to-microseconds) than surface electrocatalytic reactions, unless the process is separated effectively (microseconds to several seconds) [3]. The design of the photocatalysts should be focused on the following points [6]:

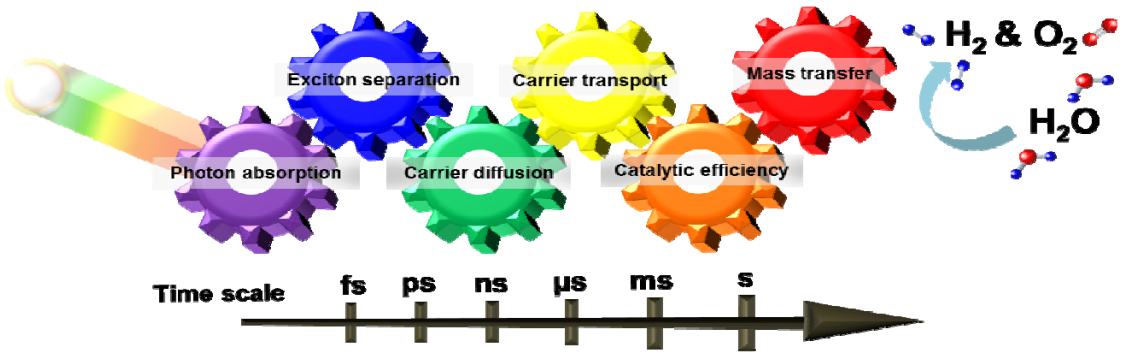

Fig. 2. Six sequential properties that require attentions to achieve efficient photocatalytic water splitting.

1) Select suitable elements to be used as photocatalysts that possess the suitable band positions and band gaps with high absorption coefficients and low exciton binding energy;

2) Synthesize highly crystalline bulk photocatalysts throughout the particle with appropriate concentrations of the majority carriers;

3) Construct band bending in such a way to improve charge separation;

4) Develop highly active cocatalysts for surface electrocatalysis;

5) Effectively locate the sites and maximize the concentrations of the reduction/oxidation cocatalysts on the photocatalyst surfaces.

6) Optimize solution condition for improved water redox reactions (pH, electrolyte etc.).

To understand the properties that affect photocatalytic process, various forms of photocatalytic materials are needed [7]. For example, thin film configuration is effective to measure absorption properties, such as absorption coefficient, refractive index, dielectric constant, and charge carrier concentration, carrier mobility, carrier lifetime and diffusion length. Calculations including density functional theory provide useful information, such as electronic structure (direct/indirect band gap), absorption coefficient, exciton binding energy, and dielectric constant. Photoelectrochemical configuration is effective to measure photoelectrochemical performance at different potential (Fermi level) and at different excitation wavelength. Semiconductor-electrochemistry is also effective to learn flat-band potential and majority carrier concentrations of the semiconductor. Measurements of the electrocatalytic performance give information of overpotential required for the respective redox reactions, and concentration gradient and diffusion of electrolyte. As a consequence of these parameters, photocatalytic powder configuration can only measure hydrogen and/or oxygen with and without sacrificial reagents [8].

To achieve efficient photocatalysis for overall water splitting, all of the parameters discussed above should be improved because the overall efficiency is obtained as the multiplication of all these fundamental efficiencies. Accumulation of knowledge from solid-state physics to electrochemistry and multidisciplinary approach to conduct various measurements are inevitable to fully understand the photocatalysis and to improve the efficiency.

Application of Zeolite Catalysts for the Production of Clean Fossil Fuels and Biofuels

Vasalos I.A.*

Chemical process and energy resources institute, P.O BOX 361 GR-570 01 Thermi Thessaloniki, Greece

* iacovos@vasalos.com

Keywords: Zeolite Catalysts, Biofuels, Clean fossil fuels

Transportation fuels are one of the most important energy carriers used in internal combustion or jet engines. Diesel and gasoline are the key fuels in use today and in the foreseeable future. Zeolites have played a major role in the manufacturing of both fuels for over half a century. In this presentation emphasis will be placed on Fluid Catalytic Cracking (FCC), the workhorse process for the refining industry for many years. We will briefly examine the evolution of the FCC process by reviewing the progress dictated by environmental requirements such as reduction in the carbon dioxide and sulfur dioxide emissions in the refinery and the requirements set by the clean air act for reducing the auto exhaust emissions.

Although future developments in refining catalysts have the potential to play a major role in reducing the carbon footprint of fossil fuels, it is necessary to reduce the carbon intensity (gr CO2e per MJ fuel consumed) of transportation fuels via the gradual introduction of alternative fuels such as electricity/hydrogen and biofuels. Among the biofuels of great interest are hydrocarbon type fuels, because they are compatible with existing infrastructure and internal combustion engines. Main fuels in this category include: Hydrogenated Vegetable Oil (HVO), Fischer Tropsch Liquids and transportation fuels derived from Biomass Thermal Pyrolysis or Biomass Catalytic Pyrolysis.

It will be shown that zeolite catalysts play a major role in upgrading Fischer Tropsch Liquids and producing diesel, aviation fuel and naphtha. Emphasis will be placed on the use of ZSM-5 for the Biomass Catalytic Pyrolysis process, where biomass is processed in a Circulating Fluid Bed reactor using a ZSM-5 catalyst both as heat carrier and as a catalyst for the in situ upgrading of the pyrolysis vapors. Finally, future research directions to improve the economics of biomass derived hydrocarbons will briefly be discussed.

Keywords: nanoparticle, hybride structured support, selective hydrogenation, catalysis, phenols, aromatic compounds, dienes

1 Introduction

The catalyst containing nanoparticles demonstrate high selectivity and activity, recyclable and thus meet the requirements for green catalysts technological application. The principal problem arising at nanoparticles synthesis and their application in catalysis is necessity to stabilize and control their size. The main approaches to solve this problem are incorporation of metal nanoparticles in channels of solid supports with regular structure. Designing novel support materials, having a regular structure and capable of binding the substrate molecule selectively, could be considered as one of the most promising area for creating of new selective catalysts [1-3]. We report herein a number of different approaches for design new hybrid materials for hydrogenation catalysts based on metal nanoparticles and structured supports [2-5].

2 Experimental

The synthesis of hybrid mesoporous supports and catalytic experiments on hydrogenation were carried out as described in [3-6].

3 Results and Discussion

As a catalysts we synthesized a number of hybrid materials (Fig.1-2):

a) **The heterogeneous organic supports synthesized by the covalent binding of dendrimers using diepoxide and diisocianate.** Approach includes prior cross-linking of the dendrimers with subsequent encapsulation of metal nanoparticles. Depending on the generation of the dendrimer, one can obtain particles differing in size (1–4 nm), which may significantly affect the process of catalytic reactions.

b) **The microporous materials synthesized by sol-gel methods in situ using dendrimers.** The preliminary modification of the dendrimer terminal aminogroups by the silyl-containing linkers and synthesis of mesoporous silica channels in presence of a template using sol-gel method and grafting the modified dendrimers to the silica surface formed *in situ*.

c) The combination of silica polyamine composite (SPC) hybrids with dendrimers to provide an easy route to stabilization of nanoparticles on the silica surface, **E.**g. polypropyleneimine (PPI) dendrimers of the third generation that have been covalently grafted to a silica surface modified with polyallylamine (PAA) have been synthesized.

d) Organic polymers with highly ordered mesoporous structure modified by functional groups (resol based mesoporous materials and mesoporous aromatic frameworks). The nanoparticles were included into pores.

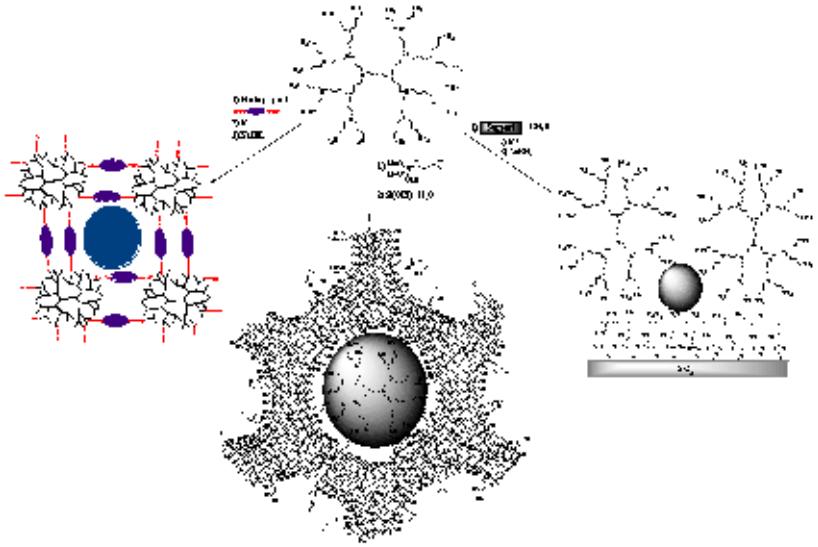

Fig 1. Preparation of hybrid catalyst on the base of dendrimers

The nanopartilces of Pd, Rh, Ru, Pt were encapsulated into the materials using impregnation- reduction method. All materials obtained were identified by the TEM, XPS, FTIR, NMR MAS methods. The size of the particles was shown to be 2-5 nm and could be regulated by the structure of support.

The catalysts synthesized showed superior activity and selectivity in the hydrogenation of different unsaturated and aromatics compounds. The Pd nanocatalysts demonstrated high efficiency in selective semihydrogenation of phenylacetylene to styrene, dienes to monoenes. The turnover number exceeded the 100000 h-1. Ruthenium and Rhodium catalysts exhibit high activity in the hydrogenation of aromatics and phenols. The hybrid catalysts displayed high resistance to metal leaching and could be widely used in green solvents

4 Conclusions

Catalysts based on metal nanoparticles encapsulated into different types of structured hybrid matrices were synthesized. The materials displayed high activity and substrate selectivity in the hydrogenation of various substrates,

Layered Zeolite SRZ-21 for Cumene Production

Wang G.W, Wei Y.L, Gao H.X, Yang W.M*

Sinopec Shanghai Research Institute of Petrochemical Technology, Shanghai, China

* yangwm.sshy@sinopec.com

Keywords: MWW-type zeolites, delaminated zeolites, benzene alkylation, cumene production

1 Introduction

The layer-structured zeolite MCM-22 was invented by Mobil in 1990[1]. Each layer of the zeolite MCM-22 includes a two-dimensional 10-membered ring sinusoidal channel system and a hexagonal-array of cups, having 12-ring openings on the external surface of the layer. The formation of the layer structure and super-cages improves diffusion behaviours of the big organic molecules in micro-pores, which benefits the macro-molecule organic reactions. However, the layer structure of MCM-22 collapses after calcination, forming a uniform three-dimensional framework structure.

Recently, several discrete products with different arrangements of the MCM-22 monolayers were prepared from the MCM-22 lamellar precursors [2-3]. ITQ-2, which is essentially made of very thin layers of MCM-22, was prepared from as-made MCM-22 by delamination in base conditions [2]. However, the serious dealumination may happen during the delamination process. Layered MCM-36 could be also prepared by pillaring as-made MCM-22 with silica but the coverage of acid sites of zeolite is inevitable during the pillaring, which results in the loss of catalytic active sites.

In the present work, a layered zeolite with MWW structure, denoted as SRZ-21, was successfully prepared by using the mixture of organic silane and inorganic silica as the raw materials. The structure of the SRZ-21 zeolite was investigated by X-ray diffraction (XRD), transmission electron microscopy (TEM) and nuclear magnetic resonance (NMR). The SRZ-21 zeolites were evaluated for the benzene alkylation reaction with propylene and the di-isopropylbenzene (DIPB) transalkylation reaction with benzene.

2 Experimental

The SRZ-21 was prepared according to the recipe described in U.S. patent 8,030,508[4]. A mixture of sodium hydroxide, sodium aluminate, silica sol, hexamethyleneimine, organic silicon and water were introduced to a stirred autoclave and held at 130-175 ^{o}C for 20-120 hours. The product was then filtered, washed and dried. The SRZ-21 zeolite with a molar ratio of SiO_2/Al_2O_3 of 42.1 was obtained.

3 Results and discussion

TEM images reveal that the thickness of the single-layer of the SRZ-21 zeolite is around 2.6 nm, which is much thinner than that of the MCM-22. The thinner layers of the SRZ-21 provide a larger pore volume compared to that of MCM-22(1.66 versus 1.20 cm^3/g), which benefits the molecular diffusion and favours the macro-molecule organic reactions. The broad peaks at 8.2, 9.5, 15.9 and 22.6^{o} of the XRD pattern (as shown in Fig. 2) confirm the highly non-uniform layer structure of SRZ-21. Figure 3 compares Si^{29}NMR spectra of the zeolites. The resonance peaks at -5 to -26 ppm observed on the SRZ-21 reveal complex chemical coordination of organic silicon in SRZ-21, while the weaker peaks at -103 and -97 ppm indicate that the addition of organic silane greatly reduces the amount of silicon hydroxyl group on layer surface and therefore suppresses further condensation of layer structure of SRZ-21.

Table 1 lists the reaction results of SRZ-21 for benzene alkylation with propylene. The catalyst was evaluated at 170°C with a benzene/propylene molar ratio of 2.5. The propylene weight hourly space velocity (WHSV) was 5.2 h^{-1}. As Table 2 indicates, after 120 hours reaction, propylene conversion maintains at 100%, cumene selectivity remains around 88% and the concentration of the n-propylbenzene (NPB) in cumene is below 330 ppm. Transalkylation reaction takes place at 190 °C with a benzene/DIPB weight ratio of 2.5. The DIPB WHSV was 2.0 h^{-1}. As Table 2 indicates, after 200 hours reaction, DIPB conversion maintains at around 60%, propyl group selectivity remains nearly 100%, and the concentration of NPB in cumene is below 550 ppm. Therefore, SRZ-21 exhibits excellent activity, selectivity and stability for benzene alkylation with propylene, and also for DIPB transalkylation. In addition, impurity NPB can be controlled at a quite low concentration.

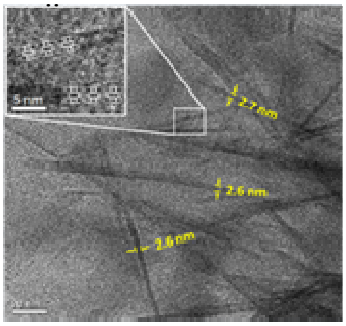

Fig. 1. TEM image of the SRZ-21

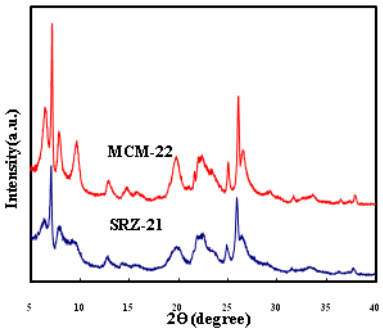

Fig. 2. XRD patterns

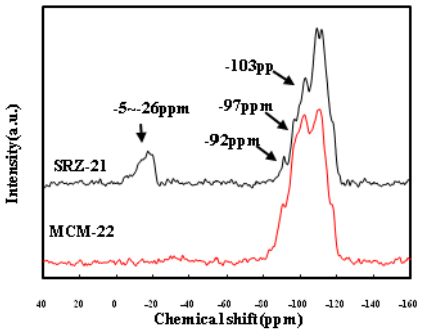

Fig. 3. Si^{29} NMR spectra

Table 1. Benzene Alkylation Reaction with Propylene over SRZ-21.

Reaction time (h)	Propylene conversion (%)	Cumene selectivity (%)	NPB/IPB (ppm)
24	~100	88.5	280
120	~100	88.7	320

Table 2. DIPB Transalkylation Reaction with Benzene over SRZ-21.

Reaction time (h)	DIPB conversion (%)	Propyl selectivity (%)	NPB/IPB (ppm)
48	59.68	~100	565
200	60.40	~100	537

4 Conclusion

Layered zeolite SRZ-21 comprising organic silicon in framework is successfully synthesized by using a mixture of the organic silane and silica sol as the silicon sources. SRZ-21 could be prepared at a wider Si/Al mole ratio range. The layer structure of SRZ-21 is stable during crystallization. The characterization results proved that the layered structure remains unchanged after calcinations and the organic silicon species mainly locates between the layers of zeolite crystal. The catalytic performances demonstrate that SRZ-21 has excellent activity, selectivity and stability for benzene alkylation reaction with propylene, and also is a good catalyst candidate for DIPB transalkylation reaction.

Relationship between the Crystal Morphology and Acidity of the *BEA-type Zeolites and the Resistance to Coke Formation during Ethanol to Hydrocarbons Transformation

Keywords: zeolite *BEA, nano-sponge, deactivation, coke, Ethano to hydrocarbons

1 Introduction

The deactivation of acid zeolites involved in hydrocarbon transformation are mainly due to the retention of carbonaceous compounds (coke) inside the pores. The creation of mesopores by post-synthesis treatments zeolites is both a simple and efficient tool to mitigate catalyst deactivation by coking. The presence of mesopores, close to the Brønsted acid sites, greatly improves the stability of such hierarchical catalyst by favoring the fast desorption of products. This enhanced stability is not due to a decrease in coke toxicity, but rather an inhibition of the growth of coke precursors, in turn related to the shorter diffusion path length (DPL) of reactants and products [1]. But, the reduction of DPL by post-synthesis treatments is limited; indeed, earlier desorption experiments evidenced a 4-fold reduction in DPL upon hierarchization of ZSM-5 zeolites by alkaline leaching, irrespective of their parent's conventional micro- and nano-crystals. The shortest DPL in zeolites can be obtained by reducing the crystal thickness up to a single unit cell dimension. In 2009, Ryoo and co-workers christened the dawn of new zeolitic materials, by using specifically designed bifunctional compounds including at least two quaternary ammonium functions directing the formation of different zeolites (MFI, *BEA), linked by an alkyl spacer, and a hydrophobic alkyl chain inhibiting a further growth of the material [2]. They obtained ultrathin zeolite structures (MFI, *BEA) with a controllable thickness combined with an ordered or desordered mesoporosity. By using gemini-type quaternary ammonium surfactants as a structure–directing agent, DPL in a MFI nano-sheets was only of 2 nm. An ultra-short DPL favors the mass transfer of products enhancing in consequence the zeolite stability in reactions sensitive to coking (e.g. methanol-to-gasoline and methanol to propylene). It should be underscored that the studies concerning the nano-sheet zeolites currently focus rather on the MFI structure than on the *BEA.

In this study, three *BEA zeolites (Si/Al ~ 20) with crystallite size ranging from micrometer to nanometer were synthesized (one micro-crystal (MC), one nano-crystal (NC) and one nano-sponge (NS)) in order to establish a relation between the textural properties of the catalyst and it's lifetime. The transformation of ethanol to hydrocarbons is a reaction highly sensitive to the texture properties of the material. Such a model reaction is therefore a good proxy to investigate the correlation between the crystal morphology of the *BEA-type zeolites and the resistance to coke formation.

2 Results and discussion

A micro-sized, nano-sized and nano-sponge H*BEA zeolites with a Si/Al ratio of 23 were synthetized and tested on ethanol-to-hydrocarbons transformation. The micro-sized *BEA

zeolite is a typical microporous material, whereas the nano-sponge material is a hierarchical material constituted of micropores interconnected to an ordered mesoporores network (Fig. 1).

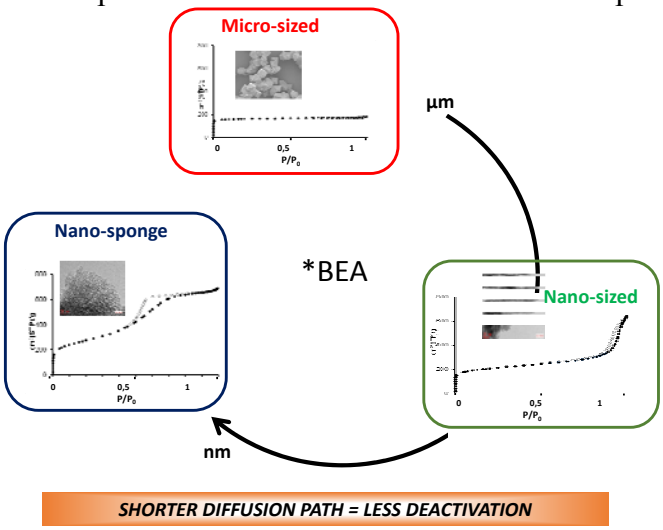

Fig.1. Scanning electronic (SEM), transmission electronic microscopy (TEM) images and Adsorption/desorption isotherms at -196 °C of micro-crystal (MC) , nano-crystal (NC) and nano-sponge (NS) *BEA-type zeolites.

The synthetize of nano-sponge zeolite material needs the use of a gemini-type quaternary ammonium surfactant. Regardless of the textural properties of *BEA zeolites, EtOH dehydrates into ethylene via diethyl-ether, and ethylene oligomerization leads to unwanted formation of coke which provokes a total pore blockage. The dehydration reaction is less affected by carbon deposition, since it occurs on weak acid sites located on the pore mouth and/or on external surface.

The coke composition depends on the shape and dimensions of the *BEA zeolite pores, the structures of molecules trapped inside the zeolite micropore are limited to polyalkyl-benzenes, -naphtene –anthracenes and –pyrenes, but their growth are related to the diffusion path length. The diminution of the crystallite size enhances the molecular traffic of reactants and products. To prevent consecutive reactions such as the autocatalytic formation of poly-aromatics compounds, the diffusion path length must be extremely short. Its dimension does not must exceed the length of few zeolite unit cells (i.e. 2 nm). It should be underscored that the desorbed coke precursor can be trapped on silanols and/or Lewis acid sites; the impact of the external coke has none impact on the catalyst stability.

Unfortunately, the extreme diminution of the crystallite size, obtained only with nano-sponge zeolite, modifies probably the electronic environment of aluminum atoms in the zeolite framework, which weakens the strength of the Brønsted acid sites. Increasing the external surface and consequently the number of pore mouth provides also a signal advantage during catalyst regeneration by coke combustion: the accessibility of reactant (e.g. oxygen) to molecule trapped inside the zeolite micropore is greatly facilitated.

Finally, the catalyst activity as well as coke oxidation rate depend on the strength of acid sites, but the weaker acid on nano-sponge *BEA zeolite is counterbalanced by a better mass transfer of reactants and products in the micropores.

1 Introduction

Gold nanoparticles (Au NPs) have a great potential in many reactions important for environmental protection, such as reduction of nitro-aromatic compounds, CO oxidation, water-gas shift reaction, and different reactions of fine chemistry [1-4]. However, they easily aggregate due to their high surface energy, resulting in changes in the size and shape of the NPs during the catalytic reaction with the consequent decay in their catalytic activity [5]. Yolk-shell materials (nanoreactors, NRs) represent a new generation of heterogeneous catalysts with excellent catalytic stability due to their specific structure, which consists of a core, commonly the active phase, surrounded by a porous shell in a core@void@shell arrangement [6] which acts as a physical barrier between the nuclei preventing their agglomeration and their further deactivation by keeping them isolated from each other.

According to the commonly reported diameter of oxide shell pores (2.5-5 nm), the size of the metal core should be above 5 nm in order to prevent its free release from the porous shell [7]. A significant decrease in pore size causes diffusion problems particular for the reactions of fine chemistry including relatively large molecules. One way to enhance the catalytic performance of NRs with relatively large pores and cores is decoration/doping of their cores [8,9].

Herein, we propose to enhance catalytic performance of $AuSiO_2$ and $Au@ZrO_2$ yolk-shell NRs well presented in the literature via decoration of their Au cores with ceria or Pd.

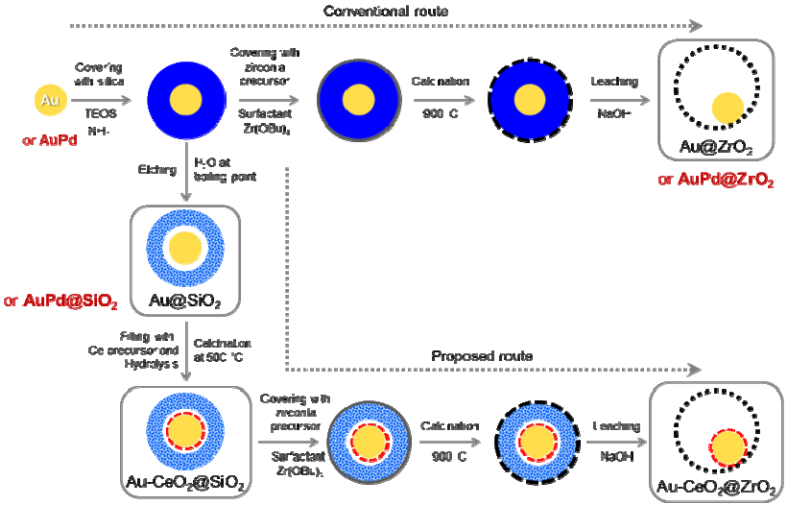
2 Experimental

The non-decorated $AuSiO_2$, $AuZrO_2$ NRs and those decorated with Pd ($AuPd@SiO_2$ and $AuPd@ZrO_2$) were synthesized following the conventional bottom-up route [10] presented in Fig. 1. Au cores partially covered with Pd (molar ratio Au20:Pd1) were homogeneously encapsulated into silica shells to form $AuPd@SiO_2$ NRs via usage of high PVP concentration and prolonged time of nanoparticles treatment with PVP before bimetallic nanoparticles encapsulation. $Au\text{-}CeO_2@ZrO_2$ NRs (gold core encapsulated into porous zirconia shell and doped by ceria) were synthesized via a new proposed route (Fig.1) [11]. Au cores encapsulated into SiO_2 ($Au@SiO_2$) were decorated with ceria via injection of ceria precursor into a void space of silica shell (formed through surface-protected etching of silica by hot water) with its subsequent hydrolysis and thermal treatment ($Au\text{-}CeO_2@SiO_2$). $Au\text{-}CeO_2@ZrO_2$ nanoreactors were obtained using $Au\text{-}CeO_2@SiO_2$ as a template and replacement of SiO_2 by ZrO_2. The prepared NRs characterized by STEM-EDS, XPS, in situ and ex situ UV-Vis spectroscopy, and N_2 thermal ad-sorption were tested in

the reduction of nitrophenols into corresponding amino-phenols and in CO oxidation.

3 Results and discussion

The catalytic activity for decorated Au-CeO_2@ZrO_2 and AuPd@ZrO_2 NRs in the 4-nitrophenol reduction was found to be 3 and 2.6 times higher than for non-decorated Au@ZrO_2 NRs, respectively. The high affinity of ceria for the 4-nitrophenol adsorption strongly enhances the catalytic activity of the decorated Au-CeO_2@ZrO_2 NRs via activation of additional route of the 4-nitrophenol reduction through condensation of the reaction intermediates. Enhancement of the catalytic activity for decorated NRs was found in CO oxidation as well. The enhanced activity of Au-ceria or AuPd NRs in CO oxidation may be explained by activation of oxygen on ceria and by electronic interactions between Pd and Au, respectively.



Thus, herein proposed route of nanoreactor core decoration may be successfully applied for the synthesis of nanoreactors with cores modified with different materials in order to make them highly effective for different catalytic reactions.

1 Introduction

In spite of the great technological, environmental and economic interests, general methods for the stabilization of metal nanoparticles against sintering are missing. Although for some specific systems it has been achieved by optimizing the interaction of nanoparticles with a support material or by encapsulation of the metal particles [1-3]. However, these known catalytic systems are in general rather expensive and difficult to synthesize and they cannot be produced in the industrial scale. Therefore, the development of novel sintering stable heterogeneous nanoparticle catalysts, which find use in the chemical industry, is of great importance.

Recently, we have developed several different catalytic systems where metal nanoparticles are confined in different porous materials. As an example gold nanoparticles were encapsulated inside of the silicalite-1 zeolite [4].

First of all, the aim with encapsulation of metal nanoparticles in a porous matrix like a zeolite is to prevent the nanoparticles from sintering during a high temperature catalytic reaction. Furthermore, the porous matrix can also contribute actively to the catalytic reaction: the presence of charge-compensating cations within the inorganic frameworks introduces additional active sites, such as acid sites for instance and their strength and concentration can to some extent be tailored for a particular application. Moreover, in our work we have shown that the metal nanoparticles encapsulated in zeolite materials are only accessible through the pores, which highly favour size-selective reactions.

Here we present the progress that has been made on the synthesis of metal nanoparticles confined in different porous materials and their application in catalysis.

2 Experimental

All the obtained materials were synthesized from commercially available chemicals. All zeolites were prepared using traditional synthesis methods known from the literature. Preparation of different recrystallized zeolites containing metal nanoparticles were based on the impregnation procedure of recrystallized silicate-1 material obtained by an alkaline dissolution-reassembly process in the presence of the surfactant [4].

We have tested all obtained materials as catalysts in the different selective oxidation and hydrogenation reactions. Furthermore, we have characterized the prepared materials with various techniques including SEM, in situ TEM, STEM, TEM tomography, XPS, XRF, BET and XRD among others.

3 Results and discussion

Here, the progress that we have made on the synthesis of metal nanoparticles confined in different zeolite materials is presented. As an example the composite material containing gold

nanoparticles trapped inside a silicalite-1 zeolite is shown in in Figure 1. The gold nanoparticles are 2–3 nm in diameter and the particles are only situated inside the zeolite. The obtained material was also characterized by X-ray photoelectron spectroscopy (XPS). The XPS also confirms that the metal particles are only located inside of the zeolite framework. Additionally, this prepared material with encapsulated nanoparticles has demonstrated to be highly active and selective for the catalytic gas-phase oxidation of ethanol to acetaldehyde.

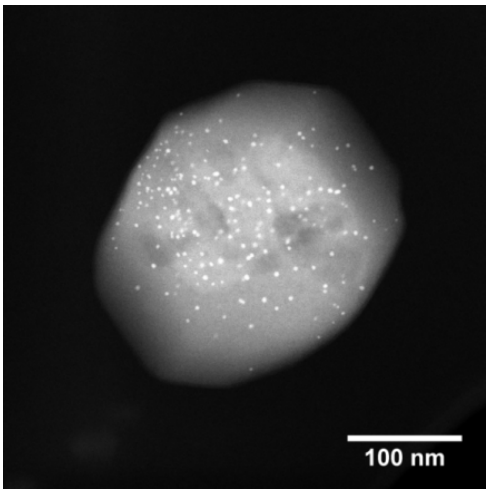

Fig. 1. STEM image of gold nanoparticles encapsulated in silicalite-1.

Furthermore, all obtained materials modified with metal nanoparticles confined in different porous materials were tested as selective catalysts in different reactions and characterized with various techniques including SEM, TEM tomography, XRF, BET and XRD among others.

4 Conclusions

In conclusion, we have developed several simple and effective methods for encapsulation of metal nanoparticles in different porous materials. The methods are cost-effective, practical, and result in a narrow size distribution of small nanoparticles that are situated inside the porous materials. Furthermore, the materials showed catalytic activity and selectivity in a number of test reactions.

Ethene Oligomerization in Ni-based Zeolites: Experimental and Theoretical Investigations of the Reaction Mechanism

Henry R.[1*], Brogaard R.Y.[1], Ganjkhanlou Y.[2], Berlier G.[2], Bleken B. T.[1], Groppo E.[2], Olsbye U.[1], Bordiga S.[1,2]

1 - Department of Chemistry, University of Oslo, Oslo, Norway

Keywords: alkene, oligomerization, nickel, zeolite, reaction mechanism

1 Introduction

Ethene oligomerization is one of the major processes for producing linear and branched higher alkenes such as propene and butadiene, precursors of several commercial chemicals used in plastics, lubricants and surfactants [1]. The process is performed industrially using homogeneous catalysts in organic solvents. Heterogeneous catalysis in principle offers substantial environmental and practical benefits, avoiding use of toxic solvents and facilitating catalyst separation and reusability. However, heterogeneous catalysts for ethene oligomerization generally suffer from low activity compared to their homogeneous counterparts. Presently, Ni-containing inorganic porous materials are the most important heterogeneous catalysts for ethene oligomerization [1]. Both Ni^{+} and Ni^{2+} ions have been proposed as the active sites in the reaction [1,2], but knowledge of the reaction mechanism is quite limited.

In this work we investigate ethene oligomerization in nickel-containing zeolites, combining operando infrared (IR) spectroscopy, periodic density functional theory (DFT) calculations, micro-kinetic modeling and catalytic testing. Based on the results, we propose a catalytic cycle analogous to the traditional Cossee-Arlman mechanism used in homogeneous catalysis (shown for ethene dimerization in Figure 1 (left)).

2 Materials and Methods

The fully periodic, spin-unrestricted DFT calculations employed the BEEF-vdW functional [4] accounting for dispersion interactions and were conducted using Quantum Espresso [5]. The calculations employed the AFI framework. The super cell contains one Al/Si substitution (Si/Al = 47) balancing the positively charged extra-framework Ni species in the catalytic cycle (see Figure 1). Vibrational frequencies were calculated in the harmonic approximation and used to derive free energies and to simulate IR spectra. CatMAP [6] was used for DFT-based micro-kinetic modeling of ethene dimerization, deriving a steady-state solution.

The experiments employed Ni^{2+}-exchanged and -impregnated H-ZSM-5 (Si/Al = 51-59), both as conventional microcrystals and as nanosheets [3]. Catalytic tests were carried out in a plug-flow reactor at temperatures ranging from 50 to 300 °C under atmospheric pressure, with 0.3 bar of ethene and helium as an inert carrier gas. The effluent was analyzed by gas chromatography. Fourier Transform IR spectra were measured in transmission mode both in static and in operando conditions by dosing CO or ethene on samples activated in vacuum/O2 or He/O2 flow, respectively. The evolution of adsorbed species on the catalyst surface was followed by the IR instrument, coupled to a mass spectrometer for gas phase product analysis.

3 Results and discussion

In the IR experiments the CO probe was employed to get information on the nature and

distribution of Ni ions in the ZSM-5 zeolite channels. The results indicate the presence of Ni^{2+} counter-ions, but also of $Ni(OH)^+$ and NiO_x species, stabilized either as counter-ions or grafted to defective hydroxyl nests. When heating the catalysts in vacuum we observed a partial self-reduction of Ni^{2+} ions.

We propose a catalytic cycle as shown for ethene dimerization in Fig. 1 left, based on Ni(II) species charge-balanced by one Al/Si substitution in the zeolite framework. We calculated the corresponding free energy profile using DFT and used it for micro-kinetic modeling. The model suggests that at typical reaction temperatures, around 150 °C the dimerization rate is limited by desorption of the product alkene, indicating that it will keep growing by additional reactions with ethene until it blocks the pore system and deactivates the catalyst. This hypothesis is supported by the operando IR experiments, where long alkyl chains are observed on the zeolite catalysts, and catalytic tests showing rapid deactivation (Fig. 1 right).

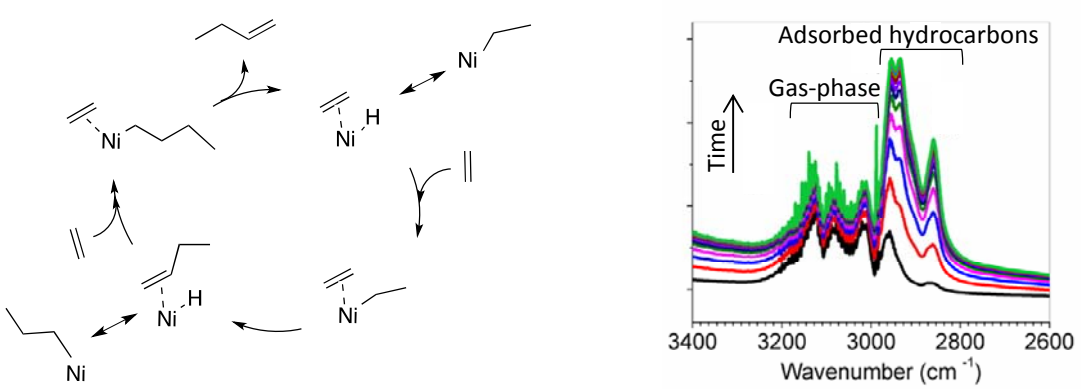

Fig. 1. (left) The catalytic cycle considered in the micro-kinetic model of ethene dimerization catalyzed by zeolite-supported Ni(II) species. (right) IR spectra in operando conditions (150 °C and 20 mL/min ethene), showing build-up of alkyl chains.

4 Conclusions

This work proposes and models a catalytic cycle of ethene oligomerization in Ni-based zeolite catalysts, which is supported by experimental observations. The work hence provides a starting point for identifying rate-limiting factors with the aim of improving the performance of nickel-based zeolite materials.

Keywords: heterogeneous, catalysis, apatites, glycerol steam reforming

1 Introduction

Although rare earth apatites have attracted interest as promising solid oxide fuel cell [1-3] electrolytes, over the last years their catalytic application studies are increased. Recently research groups have reported the use of such materials as a support instead of γ-Al_2O_3 of platinum catalysts at de-NO_X by propylene or propylene oxidation [4-6]. It has been observed that the doping effect of the apatite structure with Al of Fe provides an excess of interstitial oxygen ions in the lattice which contributes to the increase of catalytic activity in the oxidative coupling of methane [7]. Recent research efforts have focused on the surplus of glycerol associated with biodiesel production in order to contribute to the need for hydrogen production from various feedstocks such as hydrocarbons, water and derivatives of biomass. The glycerol steam reforming reaction has been investigated on various catalysts and Ni appears as the most promising active metal, due to its property to promote the C–C rupture. [8].

In this study, $La_{9.83}Si_{6-x-y}Fe_xAl_yO_{26\pm\delta}$, apatites were prepared by solid state reaction and characterized for their structural properties. These materials were impregnated with Ni and were systematically studied for their catalytic activity in the glycerol steam reforming (GSRM) reaction. A comparison with Al_2O_3 supported Ni catalysts is performed.

2 Experimental

$La_{9.83}Si_{6-x-y}Fe_xAl_yO_{26\pm\delta}$ apatite materials e.g $La_{9.83}Si_{4.5}Fe_{1.5}O_{26\pm\delta}$ (LFSO) and $La_{9.83}Si_{4.5}Al_{0.25}Fe_{0.75}O_{26.5\pm\delta}$ (LAFSO) were prepared by solid state synthesis mixing stoichiometric amounts of oxides and annealing at 1000°C for 2h. The powders were mechanically milled and uniaxial pressed into pellets and sintered at 1450°C-1500°C. Crystal phases were identified by XRD and microstructure by SEM. Pellets were crashed and milled. A powder size fraction -425μm +350 μm was used as support for the Ni wet impregnation. Porosity was measured by means of the Archimedes method. The Ni catalysts were prepared by the wet impregnation method using $Ni(NO_3)_2 \cdot 6H_2O$, aqueous solutions to a final catalyst loading of Ni equal to 8 % wt. After impregnation, the catalysts were air-dried overnight and calcinated at 800°C for 4 hours. Reduced samples were produced under 50ml/min of pure hydrogen (H_2) flow for 2 hours at 800°C. Apatite oxides and catalyst (fresh, reduced and used) samples were characterized by means of the XRD and SEM. Catalytic tests were performed using a fixed bed reactor at temperatures ranging from 450°C to 750°C with a feed consisting of $C_3H_8O_3$ (20% v/v.) and H_2O in the liquid phase. The amount of catalyst used in the catalytic bed was 200 mg. Catalytic performance was studied in order to investigate the effect of the reaction temperature on (i) glycerol conversion, (ii) hydrogen yield, (iii) H_2/CO molar ratio, and (iv) gas and liquid products concentration of the produced gas mixtures at the outlet of the reactor.

3 Results and Discussion

Figure 1 shows the XRD spectra of single phase apatite supports and the catalytic results of the concentrations of gaseous products of the GSRM reaction.

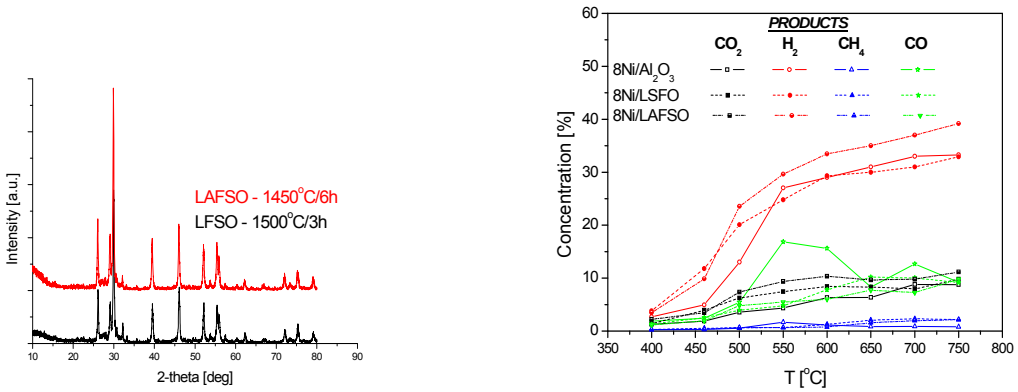

Fig. 1. XRD spectra (left) and catalytic results (right)

Ni/apatite catalysts provided a glycerol conversion close to 100% for the whole range of temperatures and a higher H_2 concentration at the gaseous products even for low temperatures, ranging between 25 and 40 % v/v for 500-750 ^{o}C. Moreover, CO_2 and CO concentrations were rather constant having the values of 10 and 5% v/v for the aforementioned temperature range, respectively. Liquid products as acetol, acetone, allyl alcohol, acetic acid and acetaldehyde were detected only for T<700 ^{o}C and at rather low concentrations.

4 Conclusions

The synthesis and the preparation of Ni/ATLS catalysts were successfully prepared through the wet impregnation technique. The performance of Ni/ATLS catalysts in the GSRM reaction exhibited higher performance in comparison with Al_2O_3 supported Ni catalysts even from lower temperatures.

Renewable Feedstocks for Refineries & Conventional Sulfided Catalysts

Horáček J.*, Kubička D.

Research Institute of Inorganic Chemistry, RENTECH-UniCRE, Litvinov, Czech Republic

* jan.horacek@vuanch.cz

Keywords: hydrotreating, vegetable oils, sulfided catalysts, bio-oil

1 Introduction

The higher use of renewable fuels required by the European directives 2009/28/EC and 2009/30/EC can be met only with increase in these fuels production. The directives promote in particular utilization of biofuels of the 2nd and 3rd generation and limit the use of the1st generation biofuels. The most popular conversion route is hydrothermal conversion of used cooking oils which are easy to convert in revamped common hydrotreating or hydrocracking units directly to diesel fuel. Another promising source is flash-pyrolysis bio-oil which could be obtained in significantly larger quantities than used cooking oils from a wide variety of biomass feedstocks. However, hydroprocessing of bio oils is more complicated because of its variable chemical properties and composition depending on the feedstock pyrolyzed. High water content, acidity and wide range of chemical functionalities are the key challenges. The presentation aims to compare the aspects of complete deoxygenation of the two most probable feedstocks (bio-oil and waste triglycerides) and to discuss the possibilities to improve the stability of hydroprocessing/hydrocracking catalysts.

2 Experimental/methodology

Hydrotreating and hydrocracking experiments of a model compound (rapeseed oil, food quality) were carried out in bench scale reactor with internal diameter 40 mm and overall length 110 cm. a thermowell (7 mm diameter) with thermocouples was installed in the axis of the reactor. Commercial NiW hydrocracking catalyst was crushed and sieved and the fraction 2-3 mm was used for experiments. The catalyst was activated using 1 % H_2S in hydrogen (refinery circulation gas) and feedstock with DMDS addition. Mild hydrocracking was performed at temperatures 350-390 °C and pressure 12.5 MPa. Hydrotreating was performed as coprocessing of atmospheric gas oil (AGO) with 10 % addition of rapeseed oil using a CoMo type commercial catalyst.

Hydroprocessing of bio-oil (purchased from BTG) has been investigated in bench scale reactor (id = 17 mm) at nonisothermal temperature profile using CoMo and NiMo hydrotreating catalysts. The experimental conditions used were analogous to those used in the work published by Elliott et al. [1]. The bio-oil study was focused on evaluating the feasibility of using commercial sulfide catalysts for bio-oil processing. Particle size selected for the tests was 0.5-1.0 mm. The beginning of the catalyst bed has been kept at 220 °C, the middle at 300 and the end at 370 °C. Bio-oil has been fed at WHSV = $0.2h^{-1}$. The performance of the CoMo catalyst has been investigated under hydrogen flow containing 0.08 vol. %, while in case of the NiMo catalyst hydrogen with higher sulfane content (1.6 vol.% in H_2) has been used. Samples of products were collected each 4 hours. Samples of gaseous products were also analyzed.

3 Conclusions

Hydrocracking of rapeseed oil resulted in its total deoxygenation without deactivation observed. SIMDIS (simulated distillation GC analysis) of products showed that middle distillate was the main product, containing only a minor amount of gasoline fraction. GC analyses

confirmed highly paraffinic nature of the product, which resulted in a high melting point of the middle distillate. In all the products, low sulphur content (<10 ppm) was observed.

Coprocessing of AGO with 10 % addition of rapeseed oil resulted in sulphur content bellow 10 ppm at temperatures 345 – 385 °C. Long term experiment showed slow deactivation that could be folowed by the slow change in physical parameters.

Bio-oil conversion over the CoMo catalyst produced a totally deoxygenated organic liquid. Changes in composition of the product pointed to a rapid decrease in the hydrogenation function of catalyst. Based on the observed fully coked catalyst bed (through the whole length of reactor) and rapid decrease in the hydrogenation activity, a higher dosing of sulfane donor agent was applied to improve the equilibrium [2] of competitive adsorptions to anionic vacancies. The following test, performed with a NiMo catalyst and with higher H_2S partial pressure, resulted in extending the test length (until reactor clogging) and changed deactivation specifics. All product samples consisted of clear organic and aqueous phases. The deactivation could be observed by the changing boiling point distribution (Fig. 1) during the time on stream. The change in fractions distributions [Fig. 1] shows a decrease in the cracking activity of the catalyst.

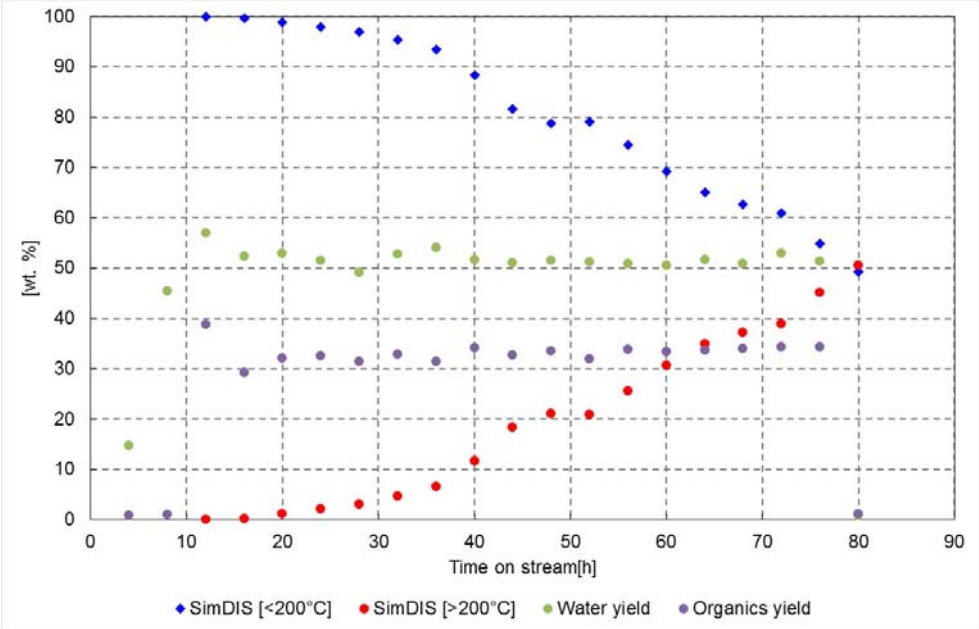

Fig. 1. Yields of products and organic phase fractions distribution

Towards Efficient Hydrodeoxygenation on Transition Metal Phosphides

Peroni M., Huang X., Lee I., Baráth E., Gutiérrez O.Y., Lercher J.A.*

Technische Universität München, Department of Chemistry and Catalysis Research Center, Germany

* Johannes.Lercher@ch.tum.de

Keywords: hydrodeoxygenation, palmitic acid, metal phosphides, citric acid

1 Introduction

Transition metal phosphides are an interesting option as catalyst for hydrodefunctionalization of biomass derived molecules, intrinsically more active than sulfides and more poison tolerant than most base or noble metals [1,2]. As newer synthesis methods have replaced the old high temperature routes, a wider variety of catalytic materials has become available [1]. In order to explore intrinsic catalytic properties of phosphides with high specific surface areas, a series of bulk phosphide catalysts (W, Mo, and Ni) was prepared by a route based on the addition of citric acid in the synthesis [3] and explored with respect to the hydrodeoxygenation of palmitic acid as a model compound for algae based feedstocks.

2 Experimental/methodology

The citrate method was adapted for the catalysts studied based on a temperature-programmed reaction (TPR). Citric acid was added during the precipitation of the precursor salts to obtain a gel, which was further treated sequentially in air and H_2 at 500°C - 650°C [3]. The materials were passivated after synthesis (1 vol.% O_2/N_2) and reactivated in situ in H_2 prior to physicochemical characterization or catalysis. The conversion of palmitic acid was performed in a trickle bed reactor at 180-300 °C and 40 bar.

3 Results and discussion

Two series of W-, Mo-, and Ni-phosphides were synthesized, one prepared by the conventional TPR techniques (denoted in the following as TPR-phosphides), the other with the citrate method described above (denoted in the following as CA-phosphides). In both cases, the phases obtained were WP, MoP, and Ni_2P according to XRD and elemental analysis. Materials synthesized using citric acid had a much higher specific surface area than the TPR-phosphides. Interestingly, the enhancement of the specific surface area depended on the nature of the transition metal, i.e., from < 5 to 11 m^2/g for WP, from 6 to 17 m^2/g for MoP, and from < 5 to 230 m^2/g for Ni_2P. Concomitant changes in the average crystal size were observed, i.e., from 35 to 27 nm for WP, from 29 to 22 nm for MoP, and from 132 to 49 nm for Ni_2P. As expected, CA-phosphides (which did not deactivate under the reaction conditions used) were much more active in the HDO of palmitic acid than the corresponding TPR-phosphides (Figure 1a). The conversion of palmitic acid follows two main routes, hydrodeoxygenation (HDO) and decarbonylation (DCO). The former is preferred and leads to hexadecanol as the main product below 300 °C (Figure 1b). The selectivity was also influenced by the preparation procedure, e.g., the DCO selectivity was lower on CA-phosphides than on TPR-phosphides. Comparing the performances of the CA-phosphides, surprisingly, the HDO activity was not proportional to the surface area of the materials. The activity increased as follows: $Ni_2P < WP \leq MoP$. This contrasting observation is related to residual carbon in the phosphides (quantified by elemental analysis), which forms a mesoporous structure (N_2-physisorption) that disperses the phosphide particles (TEM), but also decreases the available metal surface. Therefore, we conclude that two

opposite effects induced by residual carbon determine the activity. The intrinsic activity (TOF), determined from the concentration of accessible metal and the initial rates, increases with decreasing particle size. Differences in the selectivity to HDO are caused by intrinsic differences in the acid site concentrations of the studied materials.

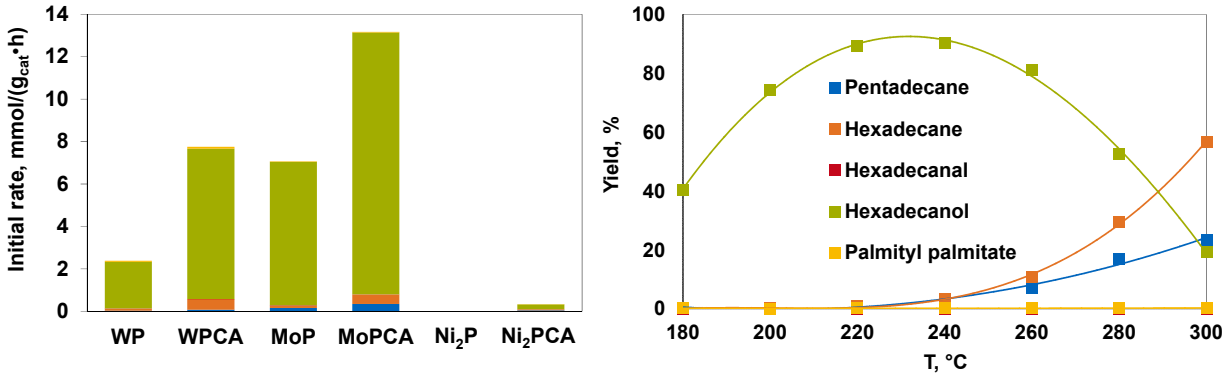

Fig. 1. (a) Comparison of the initial rate on TPR- and CA-phosphides at 240°C, 40 bar and 1h^{-1} (WHSV). (b) Product yield on CA-MoP as a function of temperature at 40 bar and 1h^{-1} (WHSV), H_2/palmitic acid molar ratio: 1000.

4 Conclusions

The use of citric acid during the synthesis leads to smaller crystals and higher specific surface areas of the CA- compared to the TPR-phosphides. This leads to higher intrinsic activity. The overall activity of the samples, however, is also influenced by residual carbon present after the CA-synthesis route. The product distribution depends on the intrinsic activity of the phosphides (Ni_2P, being the most selective material towards decarboxylation), and their acidity, which is required for key dehydration steps.

MoP CA is the most active catalysts. However, W-based phosphides are more selective to hexadecane C16 than Mo- and Ni- based phosphides.

Keywords: oxidative desulfurization, dibenzothiophene family, deep desulfurization, Cu-Zn-Al catalyst

1 Introduction

New requirements for ultra-low sulfur content (10 ppm) in liquid motor fuels demand novel approaches for ultra-deep desulfurization. Thiols, mercaptans, thiophene and benzothiophene families are known to be removed effectively by hydrodesulfurization over sulfide $CoMo/Al_2O_3$ and $NiMo/Al_2O_3$ catalysts. The residuals sulfur (50-350 ppm) left in fuel is represented mainly by dibenzothiophene (DBT) and its derivatives. The compounds of the DBT family are rather resistant to removal by HDS. In addition, alkylsubstituted derivatives of DBT and naphtothiophene have high boiling points, resulting in their accumulation in high-boiling fractions during oil distillation.

The gas phase oxidative desulfurization (ODS) of motor fuels, initially proposed for desulfurizing petroleum fractions, may become a new promising technology for removal of refractory sulfur compounds [1]. Hydrogen peroxide, organic hydroperoxides, nitrous oxide, ozone, oxygen or air are suggested as oxidants. Some of these oxidants provide selective oxidation of heterocyclic sulfur compounds to sulfones and sulfoxides at 30-110°C and atmospheric pressure. Sulfones and sulfoxides, being polar compounds, are easily separated by extraction or adsorption from hydrocarbon fractions. It should be noted that alkylsubstituted DBT derivatives are easier subjected to oxidation in comparison with thiophene and benzothiophene, the steric hindrance becomes apparent only with an increase of the number of alkyl substituents in DBT.

We propose that the selective oxidation of sulfur-containing compounds over catalysts with oxygen is more perspective methods for diesel fuels desulfurization [2, 3]. During this process sulfide and heterocyclic sulfur-compound transform to sulfur dioxide, and hydrocarbon fragments are oxidized to carbon dioxide and water [1]. According to [4] CuZnAl-O catalysts can be promising for ODS.

The goal of this work is to study in detail ODS of heterocyclic sulfur-compounds in gas-vapor phase over CuZnAl-O and Cu/CeO_2 catalysts. The oxidant (O_2, O_3, N_2O), molar ratio O_2/S, LHSV, GHSV and temperature were varied within a wide range for the purpose of increasing sulfur removal efficiency. The data on the efficiency of the gas-phase desulfurization of hydrocarbon fuels will be compared with the literature data on peroxide oxidation of sulfur compounds dissolved in hydrocarbon fuels.

2 Experimental

The catalysts based on oxide Cu-Zn-Al and Cu-Ce compositions have been prepared by precipitation [5] or by incipient wetness impregnation with subsequent calcination at 500°C.

The catalysts were tested at 200-450°C in ODS of thiophene, dibenzothiophene (DBT) and 4,6-dimethyl dibenzothiophene (DMDBT) dissolved in octane or toluene, with oxygen as

oxidant. The optimal catalysts were also studied in ODS of straight-run diesel fraction by oxygen and in ODS of thiophene, DBT with ozone and N_2O as oxidants at 70-400°C.

Samples were studied in a flow reactor placed in a furnace with a fluidized bed of quartz sand. A loading of the catalyst granules (0.5-1.0 mm) was 2 g. The ODS tests were conducted at a ratio of O_2/S=20-240, GHSV=1500-20000 h^{-1} and WHSV=3-10 h^{-1}. Liquid products were collected in the reflux condenser cooled to 5°C. Analysis of total sulfur was performed using a sulfur analyzer ASE-2. GC analysis was performed in a GC Crystal-2000M equipped with TCD and flame photometric detector.

Physico-chemical properties of the CuZnAl-O catalyst before and after ODS reaction were studied by AAS-ICP, CSH-analysis, XRD, DTA-MS, H_2-TPR, FTIR, UV-Vis, ESR and XPS to find correlations between the properties and sulfur reactivity and make assumptions about the reaction mechanism.

3 Results and discussion

The reactivity of different sulfur containing molecules in ODS over catalysts increased in the sequence: thiophene<DBT<DMDBT. The main sulfur containing product of oxidation of these compounds was SO_2. During the ODS reactions, carbon and sulfur accumulated in the catalyst. A method for catalyst regeneration at 300-500°C was developed.

According to DTA-TG, FTIR and XPS, data, at 300-500°C ODS proceeds via the stage of adsorption of sulfur containing molecules, followed by their destruction and evolution of SO_2 into the gas phase. In case of strong interaction of sulfur-containing molecules with the catalyst active sites the accumulation of sulfur on the catalyst surface takes place in the form of metal sulfides, polysulfides and sulfates. Stronger interaction with catalyst surface is observed for thiopnene.

4 Conclusions

The gas phase oxidative desulfurization of refractory sulfur compounds of motor fuels with air was shown to be feasible at atmospheric pressure and moderate temperatures: 350-400°C, which can offer better economic solutions and incentives in fuel desulfurization.

Keywords: biomass, bio-oil, biofuel, hydrodeoxygenation, hydrotreatment catalysts

1 Introduction

The new catalytic technologies of biomass processing should play a key role in the bioenergetics and chemical industry evolution. In Boreskov Institute of Catalysis (BIC) the investigations are carried out in the field of heterogeneous hydrotreatment catalysts development for competent processing of biomass derivatives into valuble chemicals and biofuels. The following catalytic systems are of primary interest: catalysts for selective hydrogenation and complete hydrodeoxygenation of bio-oil components, hydrocracking catalysts for lipids processing into green diesel and kerosene, catalysts for fatty alcohols production via selective hydrogenation of lipids derivatives. Each bio-feedstock has certain peculiarities for processing and as a result definite requirements to the catalysts are established. The latest results of catalysts investigation in the above mentioned types of biomass processing are reported about.

Hydrodeoxygenation of bio-oil (BO)

Bio-oil (BO) being a liquid product of flash pyrolysis of grinded wood is considered to be a perspective alternative feedstock for the petrol production. The main goal of the bio-oil hydrotreatment is to reduce the content of oxygen that is responsible for such negative properties of BO as high viscosity, non-volatility, aggressivity, immiscibility with mineral oil, instability, and tendency to polymerization. Since BO is a very specific aggressive feed, research activities are focused on the development of catalysts with improved stability (resistance to water and acidic medium at elevated temperatures, stability to coking, stability against sintering, etc.). The study of Ni-based catalysts in hydrodeoxygenation of BO and model compounds showed that the increase of Ni content in the catalyst leads to an increase in the H/C ratio of the reaction products, which is a positive factor for the bio-oil hydrotreatment, because of lower viscosity and molecular weight of products obtained [1]. The aspects for an improvement of catalysts stability via modification by Mo and P compounds were discussed separately [2].

Selective hydrogenation of bio-oil components

Present activities of BIC were aimed at Ni-based sol-gel catalysts [3] performance in selective hydrogenation of furfural (representing aldehyde group in pyrolysis oil reactions). The objective of this part was to investigate the effect of the reaction temperature and catalyst reduction temperature on its activity and selectivity. The reactions were carried out at a constant pressure of 6 MPa, isothermal conditions − 110, 130, 150, and 170 ^{o}C for the catalysts reduced at 250 ^{o}C (150 ^{o}C for the catalyst reduced at 300 ^{o}C), iso-propanol was used as a solvent. It was observed that the main product of furfural hydrotreatment basically was furfuryl alcohol (FA), minor components were tetrahydrofurfuryl alcohol, 2-methylfuran and isopropyl ether. The reaction scheme is proposed on the Fig. 1.

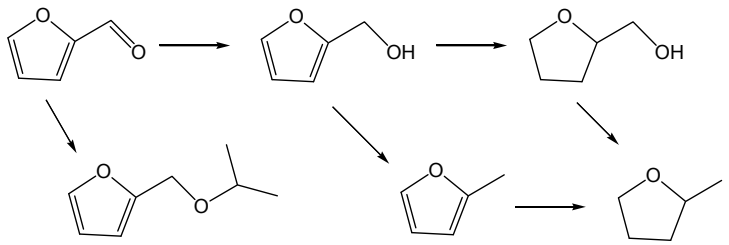

Fig. 1. Scheme of furfural conversion pathways over sol-gel Ni-based catalysts from [3].

According to the kinetic investigations and catalysts study it was concluded that metallic Cu species in the catalysts were favorable for the selective hydrogenation of furfural to FA. It was also noted that if the Ni species on the catalyst surface were reduced during the pre-reduction stage or during the reaction as well, the selectivity was shifted towards the products of further FA hydrogenation. So, the change of Ni-Cu-based catalysts pre-treatment conditions allows variation of hydrogenation processes selectivity.

Selective hydrogenation of lipids into fatty alcohols

Fatty alcohols are valuable products for chemical industry and pharmaceutics. The selective hydrogenation of lipids derivatives (fatty esters and acids) was carried out at 280-330^{o}C and 3.5-5.3 MPa of H_2 [4]. It was shown that oleic acid is a more attractive substrate for achievement of maximum yield of fatty alcohols in the presence of Ru-Sn-B/Al_2O_3. The peculiarity of the process is the presence of additional pathways of acid conversion including direct hydrodeoxygenation into n-alkanes, wax formation and wax hydrocracking to alkanes. The experimental data are correctly discibed by the proposed kinetic model. This model can be used for estimation of products distribution at the process up-scaling.

Hydrodeoxygenation of lipids into biofuels components

Lipids can be converted into fuel components by the catalytic hydrotreatment. In this respect the task is to develop stable non-sulfided catalyst. The effect of molybdenum on activity of Ni-based catalysts in hydrodeoxygenation of fatty acid esters was studied. Catalysts Ni-Cu/Al_2O_3, Ni-Mo/Al_2O_3, Cu-Mo/Al_2O_3, Mo/Al_2O_3, and Ni-Cu-Mo/Al_2O_3 with different Ni/Mo ratios were prepared and tested in hydrodeoxygenation of methyl palmitate and ethyl caprate at 300 °C, 1 MPa. It was found that the increase of Mo content (from 0% to 6.9%) in the Ni-Cu-Mo/Al_2O_3 catalysts leads to an increase of normal alkanes yield. The catalysts were characterized by X-ray photoelectron spectroscopy (XPS), temperature programmed reduction, and X-ray diffraction techniques. The XPS data showed that the increase of fatty acid esters conversion is related to the changes of ratio between different oxidation states of molybdenum (Mo^0, Mo^{4+}, and Mo^{6+}) on the Ni-Cu-Mo/Al_2O_3 catalysts surface [5].

Acknowledgements

The investigation of catalytic bio-oil conversion was carried out under the large scale collaborative project FASTCARD ("FAST Industrialisation by CAtalysts Research and Development"), European Union 7th Framework Programme, Grant Agreement No 604277.

Aldol Condensation of Biomass Derived Aldehydes: Comparison of the Reactivity of Furfural and Hydroximethylfurfural

Cueto J., Faba L., Díaz E., Ordonez S.*

University Of Oviedo, Oviedo, Spain

* sordonez@uniovi.es

Keywords: 2nd generation biofuels, condensation, adducts, MgZr-mixed oxides, MgAl-mixed oxides

1 Introduction

The development of technologies for obtaining energy from renewable resources is nowadays a key scope of the research on heterogeneous catalysis. The transformation of biomass into liquid fuels is a key point in this topic, considering that this is the only renewable alternative to obtain naphtha- and diesel-grade substitutes. Despite of the different biological and thermochemical processes that have been studied, catalytic routes deserve main attention because these processes satisfy the green-chemistry principles and allow obtaining a very specific range of products. One of the most promising process implies the hydrolysis and dehydration of (hemi)cellulosic fraction, the increase of the length of the carbon chain by aldehydes cross-condensation (usually using the acetone as linking molecule) and the complete hydrodeoxygenation of the condensated adducts to obtain linear alkanes in the diesel range [1].

There are several researches about the condensation of furfural and acetone, trying to optimize the catalytic properties to enhance the C13 fraction, to identify the optimum reaction conditions and to study the reaction mechanism and kinetic [2,3]. Furfural is the aldehyde obtained by the dehydration of pentoses. However, the major aldehyde obtained in the dehydration of (hemi)cellulosic fraction is the 5-hydroxymethylfurfural (5-HMF), because the highest percentage of this fraction is hexoses. The higher complexity of this molecule increases the difficult to control its reactivity and there are very few references about its condensation. The deep knowledge of this reaction is compulsory to implement this process with real biomass. The aim of this study is to compare the results obtained in the aldol condensation of furfural and 5-HMF with acetone, identifying the discordances between optimum conditions with one and other derivative, and to relate the differences obtained with the influence of the hydroxyl group.

2 Experimental/methodology

The reactions are carried out in a batch reactor, loaded with 250 mL of aqueous solution with 2.5% of organics (initial mole rate aldehyde:acetone 1:1). The aldol condensation is studied using MgZr and MgAl as catalysts, using 0.5g of mixed oxides in each reaction. MgZr and MgAl are prepared by co-precipitation method [2]. The reactor is pressurized to 10 bar in nitrogen and the condensation temperature is fixed at 50 ºC. The evolution of reactants and products is followed for 8 hours by analysing the samples with a gas chromatograph equipped with a FID detector (Shimadzu GC2010) using ethyl acetate as organic solvent.

The presence of precipitated compounds is analysed by lixiviation experiments using ethanol as solvent and analysing the liquid phase by GC-MS. Possible changes on the catalytic surface and its properties are studied different characterization techniques.

3 Results and discussion

The evolution of aldehydes and acetone with both catalysts are shown in **Figure 1**,

observing different behaviours as function of the reactant and catalyst. MgAl is more active for the condensation of 5-HMF, with higher conversion of both, aldehyde and acetone (final values of 67 and 58 %, respectively). Opposite to this, the furfural condensation is more favoured with MgZr than with MgAl. In all the cases, the aldehyde/acetone ratio condensation is similar, despite that the ratio between C15/C9 or C13/C8 products, suggesting different influences of side-reactions and adsorption processes.

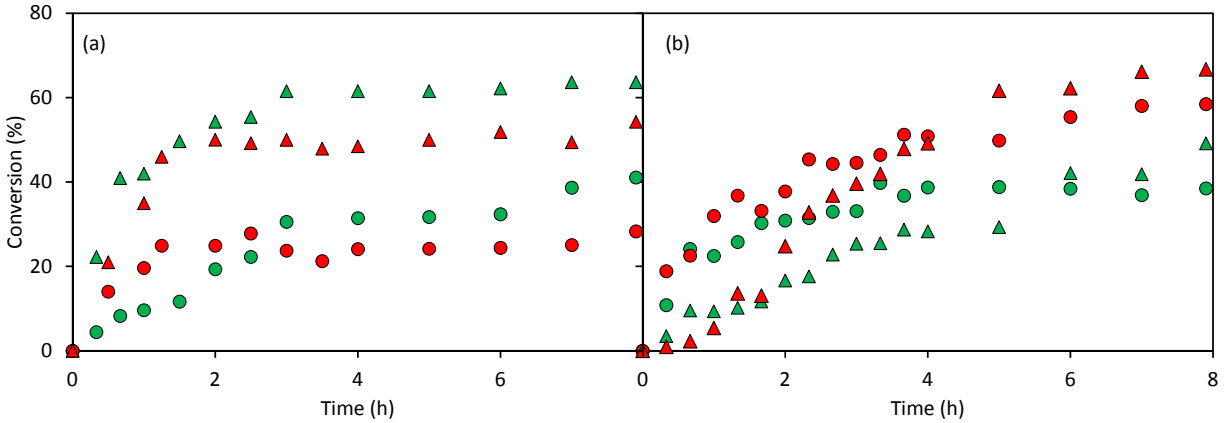

Fig. 1: Conversion evolution in the aldol condensation of acetone with (a) furfural and (b) 5-HMF when MgZr (green) or MgAl (red) are used as catalyst. Symbols: (▲) aldehyde; (●) acetone.

In the furfural condensation, the acetone self-condensation is the only side-reaction identified, obtaining mesityl oxide as by-product. This reaction is more relevant in the case of MgAl, catalyst that also enhances the furfural permanent adsorption (corroborated by analyses of spent catalysts). As consequence, the C13 selectivity with MgAl only reaches values of 11%, whereas this value is six-times higher with MgZr. The analysis of product selectivities is more difficult in the case of HMF condensation because of the low solubility of C15 adduct in aqueous phase. Consequently, only C9 is observed in the liquid phase, obtaining final selectivities of 46.9 and 19.2 % with MgZr and MgAl, respectively. The analysis of solid phase demonstrate a more complex condensation mechanism in which C15 is the major product but other side-products related to the self-reactivity of 5-HMF were also found. The comparison of these solids revealed a C15 production 10 times higher with MgAl than with MgZr. These solubility problems are prevented by carrying out the condensation in a reducing atmosphere using bifunctional catalysts (Pd/MgZr and Pd/MgAl). The partial hydrogenation of aliphatic unsaturations enhances the C15 solubility without affecting to the condensation step. Pd/MgAl is identified as the most active catalyst, selectivity of 27 % of C15 adduct (but less than 5% with MgZr). Activity results were justified by the different distribution of acid/basic sites, in such a way that MgAl distribution stabilizes the C9 adsorption, enhancing its condensation.

4 Conclusions

The condensation of HMF is mechanistically most complicated than the condensation of furfural, leading to the formation of heavier compounds. In the same way, the HMF condensation also leads to the formation of solid products.

Keywords: zeolite, acylation, fatty acid, amino alcohol, surfactant

1 Introduction

Algae are rich in lipids, proteins and sugars and the utilization of lipids for production of fuels has been intensively investigated. On the other hand, the use of proteins abundant in, for example *Chlorella* algae as a feedstock, for production of chemicals has been scarcely studied. The main components in proteins are amino acids, which can be catalytically hydrogenated to the corresponding amino alcohols [1]. Biocompatible surfactants, such as N-alkyl amides, have several application areas in pharmaceuticals and cosmetics [2]. According to our knowledge there is only one publication in the open literature on catalytic acylation of amino alcohols to N-alkyl amides (Fig. 1) [3]. The aim of this work is to study catalytic acylation of amino alcohols with fatty acids using different feedstock.

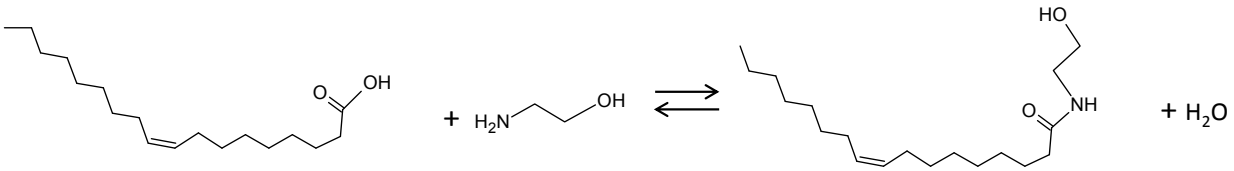

Fig. 1. The reaction scheme for production of oleoyl ethanol amide.

2 Experimental

Zeolite H-Beta-22, in which the number denotes SiO_2 to Al_2O_3 ratio. was synthesized as described in [4] and used as a catalyst. The catalyst was characterized with various physico-chemical methods (pyridine FTIR, XRD, SEM-EDXA, TEM, nitrogen adsorption). Different feedstock, i.e. stearic acid, methyl palmitate and technical grade oleic acid was tested. In addition biodiesel was used, which was prepared via in situ transesterification of algae at 60°C for 4 h with methanol and 20 wt% sulphuric acid as a catalyst. This Chlorella algae derived biodiesel contains 77% FAME (main components being methyl linolenate, linoleate and palmitate) and 7 % fatty acids. The following aminoalcohols were used as a nitrogen source: ethanolamine, alaninol and leucinol. In a typical experiment the initial concentration of the reacting acid was 0.72 M and an equimolar amount of ethanol amine in 100 ml of anhydrous hexane and 500 mg of catalyst were used under 20 bar of argon at 180°C. The kinetic experiments were performed in the kinetic regime using a small catalyst particle size (< 63 μm) and a high stirring speed (1100 rpm). The samples were withdrawn from the reactor, silylated and analyzed in GC using capillary and short GC columns. The reaction products were identified with GC-MS. The biodiesel feedstock was also characterized by ICP-MS method.

3 Results and discussion

H-Beta-22, which was used as a catalyst, exhibited high specific surface area, 686 m^2/g_{cat} and a relatively high amount of Brønsted acid sites compared to Lewis acid sites, being 167 μmol/g_{cat} and 33 μmol/g_{cat}, respectively. XRD pattern of H-Beta-22 zeolite catalysts were similar to those reported in the literature [5].

The conversion in the amidation of technical grade oleic and stearic acids was 74% and 94%, respectively within 3 h using H-Beta-22 as a catalyst. Selectivity to the desired amide was also very high, over 68% and only small amounts of aminoalkylesters were formed (Table 1). Furthermore, also alkylester amides, i.e. molecules containing 38 C atoms in the case of oleic acid and ethanolamine, when both amino- and hydroxyl groups in 2-aminoethanol react with two fatty acid molecules, were formed based on GC short column analysis. Due to a limited amount of purified Chlorella based biodiesel available, the initial biodiesel concentration was 32% of that used for amidation of other feedstock. The conversion of biodiesel was only 28% after 6 h reaction time, most probably due to its low initial concentration as well as possible presence of catalyst poisons, such as sulphur and phosphorus. The main products in the amidation of biodiesel were amides of unsaturated C18 esters.

Table 1. Results from amidation of fatty acids and esters over zeolite beta. Ethanol amine was used as a N-source. Conditions: 180°C, 20 bar total pressure, Ar atmosphere, 0.72 M acid and ethanolamine, 0.5 g catalyst, reaction time 3 h.

Reactant	Fatty acid/ester conversion (mol%)	Selectivity to amide (mol%)	Selectivity to esteramide (mol%)	Selectivity to esteramine (mol%)	Other products (mol%)
Oleic acid[a]	73	73	23	4	4
Stearic acid	94	90	4	2	4
Biodiesel[b]	28	44	n.c.[c]	traces	52[c]

[a]technical grade oleic acid (65 wt%), containing also linoleic, palmitic and palmitoleic acids as well as Me-stearate, [b] biodiesel with initial concentration 0.23 M, catalyst amount 96 mg, reaction time 6 h, [c]esteramines of several different esters were not confirmed (n.c.) by GC-MS, but lumped together with other product

4 Conclusions

Amidation of fatty acids and biodiesel from Chlorella algae was successfully demonstrated over a relatively acidic, medium pore zeolite H-Beta-22 at 180°C using initial reactant concentrations of 0.72 M for both fatty acid (or ester) and aminoalcohol. Conversion of stearic acid after 3 h was 94% giving over 90% selectivity to oleoylethanolamide. Amidation of Chlorella based biodiesel was also demonstrated. In the final work reaction kinetics and reaction mechanism will be discussed.

A Novel Efficient Synthesis of Guaifenesin over Calcined Hydrotalcite

Yadav G.D.*, Bhanawase Sh.L.

Department of Chemical Engineering, Institute of Chemical Technology, Matunga, Mumbai, India

* gdyadav@yahoo.com

Keywords: catalysis, biomass, hydrotalcite, guaiacol, glycidol, green chemistry

1 Introduction

Biomass is abundant and renewable source for energy, chemicals and materials [1]. Guaiacol and glycidol have been obtained from biomass respectively by valorization of lignin and glycerol. However, lignin is waste of the paper and pulp industries and glycerol is co-product during the biodiesel production. Synthesis of guaifenesin from renewable sources should result in a greener and more sustainable process. One of the possible paths to produce guaifenesin based on biomass is from guaiacol and glycidol by using heterogeneous catalysis.

Guaifenesin is an expectorant drug in racemic form; used for treatment of coughing, asthma, gout, fibromyalgia, to facilitate conception and also used by singers to improve voice. Generally guaifenesin is synthesized by Williamson's type of etherification reaction in which nucleophile of guaiacol attacks on glycidol, epichlorohydrin, 1-chloroglycerol, glycerol carbonate, 3-bromo-1-propene and isopropylidene glycerol [2]. Homogeneous catalysts such as triethyl amine, sodium hydroxide, potassium carbonate used in stoichiometric have been reported which are corrosive, toxic, hazardous to health and not easily separated from product, and thus create pollution problems. As far as we know from literature, this reeaction with heterogeneous catalyst has not been published. Now we are reporting a novel protocol catalyzed by calcined hydrotalcite (CHT). Influences of different parameters are studied in the reaction of guaiacol with glycidol to check the activity and selectivity of CHT. Reaction mechanism and kinetics are derived. CHT is highly active and selective towards product and is reusable.

2 Experimental/methodology

2.1 Catalyst synthesis

Following catalysts were synthesized and further characterized: (1) Hydrotalcite (HT) and calcined hydrotalcite (CHT)[3], (2) 10% w/w CHT supported on hexagonal mesoporous silica (HMS); (i.e. CHT/HMS) [4], (3) 8.8% w/w potassium modified zirconium hydroxide; (i.e. K- ZrO_2) [5], (4) Aluminium oxide (Al_2O_3) was prepared by calcination of aluminium hydroxide at 450º in furnace for 6 h.

2.2 Experimental setup, reaction procedure and method of analysis

The reaction was carried in high pressure reactor (Amar Equipments, Mumbai). In a typical reaction, guaiacol (0.0081 mol) and glycidol (0.020 mol), THF (10 cm^3) and 0.03 g cm^{-3} of the catalyst were charged to the reactor. The total organic phase volume was made with THF to 30 cm^3. Then reactor was heated to attain the desired temperature, and an initial sample was collected. Reaction mass was agitated with a mechanical stirrer at desired speed, and samples were collected periodically and analyzed by HPLC (Agilent 1260 infinity HPLC system with C18 column). The reaction was carried out at 120ºC at a speed of agitation of 1000 rpm under autogenous pressure. Product confirmation was carried out by GCMS from Perkin Elmer, Clarius Model 500 on Elite-1 capillary column.

3 Results and discussion

3.1 Catalyst characterization

Prepared catalysts were characterized as reported elsewhere. [3, 4].

3.2 Efficacy of various catalysts and study of effect of various parameters

Activity of different catalysts such as CHT-HMS, K-ZrO_2, MgO, Al_2O_3, HT, and CHT were evaluated for conversion and selectivity. Order of catalysts activity was found as follows: K-ZrO_2 > CHT > HT > MgO > CHT-HMS > Al_2O_3 while order of selectivity for product was found as follows: Al_2O_3 >MgO > CHT >HT > K-ZrO_2 > CHT-HMS. K-ZrO_2 was not reusable. So CHT was found to be the best for the reaction considering activity and selectivity. CHT gave 78.5 % conversion with 88.3% selectivity towards the product. Effect of following parameters was studied: speed of agitation, catalyst loading, mole ratio, temperature, and catalyst reusability. Regenerated catalyst was characterized to verify the properties in comparison with fresh catalyst.

3.3 Reaction kinetics

A possible mechanism based on the synergistic cooperation of the weak acid sites with the basic sites is proposed. In absence of external mass transfer resistance and intraparticle diffusion resistance, Langmuir–Hinshelwood–Hougen–Watson (LHHW) model was developed with weak adsorption. Guaiacol (A) was assumed to adsorb on basic site (S_1) and glycidol (B) on acidic site (S_2). The plot of ln [(M-XA)/M (1-XA)] against t was made at different temperatures to validate the model. Apparent activation energy of reaction was calculated as 9.82 kcal mol^{-1}.

4 Conclusions

Condensation of guaiacol with glycidol was studied using various catalysts. On the basis of catalyst activity and selectivity, CHT was the best. To obtain maximum yield of guaifenesin, the reaction may be done at following conditions: speed of agitation; 1000 rpm, temperature; 120 ºC, catalyst loading; 0.03 g cm^{-3}, mole ratio of guaiacol to glycidol; 1:5. Reaction kinetics was studied and reaction is second order with activation energy is 9.82 kcal mol^{-1}. Catalyst can be reused. Overall reaction is clean and green.

Tuning the Selectivity of the Diols Produced from Cellulose with the Basic Sites of the Catalysts

Van Der Wijst C.[1], Skeie Liland I.[1], Zhu J.[1], Zhang T.[2], Wang A.[2], Chen D.[1*]

1 - Norwegian University of Science and Technology, Department of Chemical Engineering

Keywords: cellulose, conversion, Ni-Zn catalysts, basic sites, diol, distribution

1 Introduction

In complex reactions like catalytic conversion of biomass and biomass derived compounds, a better understanding of the reaction network and factors to control product selectivity is essential. The direct catalytic conversion of cellulose to diols is a complex catalytic liquefaction process. Microcrystalline cellulose must disintegrate and hydrolyze into smaller polysaccharides before the cracking, dehydration and hydrogenation steps yield the diols.

Hot-compressed water has previously been proven to be a good reaction medium for the dissolution and hydrolysis of cellulose. Water heated to 245 ^{o}C and pressurized to remain as a liquid has a high ionic product and can effectively disintegrate and hydrolyze cellulose into smaller oligo- and monosaccharides. In this process, water acts as reactant, catalyst and as a reaction medium [1]. The generated sugars undergo catalytic conversion to various products dependent on the nature of catalytic system. Nickel-tungsten based catalysts and nickel-zinc oxide based catalysts are two systems used in this process, but yield a different diol product distribution. The nickel-tungsten based catalysts yield mostly ethylene glycol (EG) and minor formation of 1,2-propandiol (PG) and 1,2-butandiol while the nickel-zinc oxide based catalysts primary products are EG and PG.

Ni-Zn catalysts supported on carbon nanotubes were selected in the present work with an aim at elucidate reaction network and controlling factors for product distribution. Carbon nanotube was selected as catalyst support to reduce the diffusion limitation in liquid phase reaction compared to conventional activated carbon. The results reveled that Ni-Zn catalysts are highly basic and the basic property of the catalysts is the key parameter for product selectivity.

2 Experimental

Nickel-zinc oxide supported on carbon nanotubes were synthesized with a 30 % nickel loading and a 26 % zinc oxide loading. Nitric acid purified multiwalled carbon nanotubes where first coated with zinc oxide using the Pechini method to ensure a uniform zinc oxide layer. Nickel particles where then impregnated using the insipient wetness impregnation. The catalysts were reduced in 63 mL hydrogen flow for five hours at temperatures of 300 °C, 350 °C, 400 °C and 450 °C. The basic sites were investigated with CO_2-TPD.

The catalytic reactions were tested in a 75 mL stirring batch reactor, using 25 mL water, 0.25 g microcrystalline cellulose, 0.075 g catalyst and an initial 60 bars of H_2. The reactor was closed and heated to 245 ^{o}C generating a pressure of 120 bars, and the system was kept at 245 ^{o}C for 150 minutes.

3 Results and discussion

As can be seen from figure 1, the reduction temperature of the catalyst effects both the amount and type of basic sites generated. The CO_2-TPD profiles are given in figure 1 a). They show that each catalyst has at least two types of sites with different basic strengths. For the

lowest reduction temperature, at 300 °C, the lowest desorption peak is observed at 470 °C, while the catalyst reduced in higher temperatures has the lowest desorption peak at 425 °C. So reducing catalyst above temperatures of 300 °C will yield sites with lower basic strength. A decrease in the amount of desorbed CO_2 with increased reduction temperature can easily be observed in figure 1b).

It was found that the change in reduction temperature of the catalysts, thus the basic sites, did not influence the total yield of diols, but changes significantly the product distribution. Figure 1c) shows the yields of the main products. Here a clear increase in C_3 product formation is observed with an increased amount of basic sites per gram catalyst. According to previous proposed reaction mechanisms for this system, C_3 products are solely produced from fructose [2], meaning that the produced glucose molecules for cellulose must be isomerized to fructose. This is a known base catalysed process. The C-C splitting of the sugars also follows a base catalysed reaction, a retro aldol condensation reaction. This mechanism limit the C-C bond breaking to between the α and β carbons to the carbonyl group of the sugar. Therefore, glucose is split into one glycol aldehyde (C_2) and one erythrose (C_4) molecule, which again splits into two glycol aldehydes and are hydrogenated to EG. Fructose spilt into glyceraldehyde and 1,3-dihydroxyacetone, both C_3 molecules. Glyceraldehyde is hydrogenated into glycerol and 1,3-dihydroxyacetone is dehydrated to acetol (HA) and hydrogenated to PG. So the increased yield of the C_3 products with increasing amounts of basic sites is likely due to the increase in the isomerization of glucose to fructose.

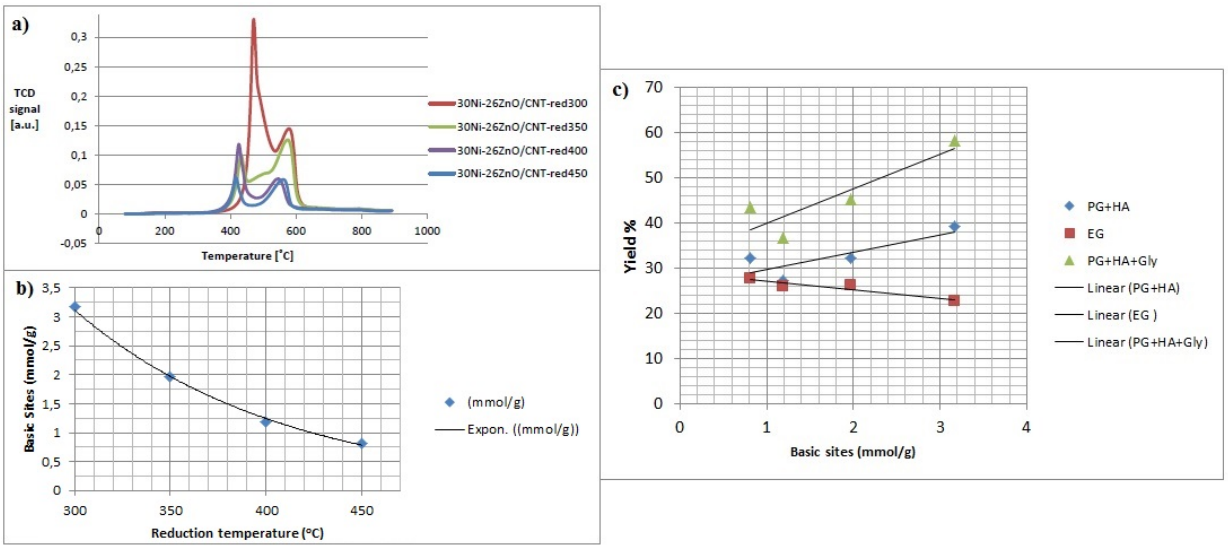

Fig. 1. a) CO_2-TPD and **b)** The amount of basic sites per gram of catalyst as a function of temperature of reduction. **c)** Yield as a function of amount of basic sites per gram of catalyst.

4 Conclusions

Results show a clear correlation between the yield of the C_3 products and the amount of basic sites per gram catalyst. The increase in C_3 yield is attributed to the increase in isomerization of glucose to fructose. This provides principles for rational design of catalysts to tune the product distribution. It rationalizes the acidic promoters such as tungsten oxides for EG synthesis.

Keywords: valeric acid, Pd, Pt, metal oxides, size effect, alkane, fuel, components, FTIR *in situ*, UV-vis

1 Introduction

Lignocellulose derived C5 (valeric) acid, a product of levulinic acid conversion, can be upgraded to *n*-nonane, a green diesel component [1-3]. This work aimed to study systematically C5 acid conversion through the intermolecular coupling into 5-nonanone with CO_2 and water releasing followed by hydrodeoxygenation into *n*-nonane over Pd and Pt catalysts in reductive atmosphere. Spectroscopic methods (FTIR *in situ*, UV-Vis *in situ*) were applied to study a feasible mechanism of ketonization still debated in the literature [4-6]. Both catalytic reactions were explored separately in order to be performed thereafter in a cascade mode over the best bifunctional catalyst, which turned out to be Pt(Pd)/M_xO_y.

2 Experimental

Ketonization of valeric acid was carried out in a fixed bed flow reactor over ZrO_2 and 10 wt.%CeO_2/ZrO_2 ($m_{catalyst}$=0.5g, fr. 0.25÷0.5 mm) at 573-678K and 1 bar, both under H_2 and N_2 (10-33 cm^3/min). Hydrogenation of 5-nonanone was performed over 2 wt.%Pd/ZrO_2, and 10%CeO_2/ZrO_2 at 573-673K under P_{H2} 1-10 bar. The reaction products were analyzed by "Chromos 1000" GC (FID) with fused silica column Stabilwax-DA (50 m/0.32 mm/0.5μm) (USA) at 373-473 K with ramp 10 K/min. The catalysts were treated by hydrogen and vapors of valeric acid or 5-nonanone and analyzed using a UV-Shimadzu UV-Vis spectrometer with IRS-250A prefix diffuse reflection (UV-Vis) and a FTIR-8300 Shimadzu spectrometer with DRS-8000 prefix diffuse reflection (FTIR) at 293-423K.

3 Results and discussion

The effect of the reaction temperature, CeO_2 loading, and residence time on the C5 acid conversion and selectivity to the desired products was investigated in the decarboxylative coupling with 5-nonanone formation followed by its hydrodeoxygentaion to *n*-nonane (Fig. 1).

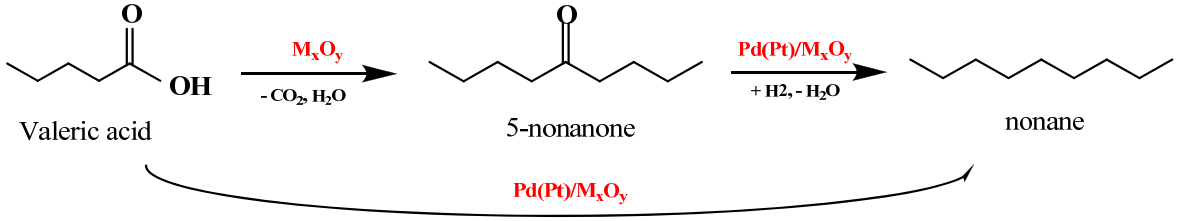

Fig. 1. Scheme of one-pot C5 acid ketonization/hydrodeoxygenation into nonane.

Regardless of the carrier gas, 10% CeO_2/ZrO_2 displayed higher catalytic activity (79% selectivity at 93% conversion) compared to neat zirconia (78% selectivity at 83% conversion) and other ceria modified zirconia, while neat ceria exhibited a very low catalytic activity. All catalysts provided higher valeric acid conversion in H_2 than in N_2 whereas selectivity to 5-nonanone was insensitive to gas atmosphere. XRD, FTIR, UV-Vis DRS, XPS, HRTEM methods

were applied to characterize catalysts in the reduced and unreduced states simulating the corresponding reaction conditions during acid ketonization [7]. Pt(Pd)/M_xO_y catalysts with the highest dispersion showed similar (85-90%) yields of *n*-nonane in deoxygenation of 5-nonanone at 628K and 6 bar. Pd/ZrO_2 catalyst was tested in one-pot transformations of the C5 acid to *n*-nonane *via* ketonization/deoxygenation at T = 628K and P = 6 bar. A correlation between catalytic activity, structural and electronic properties of catalysts was found with an aid of XPS and HRTEM.

The mechanism of ketonization on the basis of FTIR and UV-Vis in-situ study was suggested [8] being consistent with the results previously reported in [4-6]. According to the obtained spectroscopic data two approaches to the mechanism of valeric acid ketonization could be proposed differing in the carboxylate forms arisen in the first reaction stage (Fig. 2 right). After the carboxylates are formed and α-H atom is abstracted from one of them to form an anion radical the latter attacks the second carboxylate adsorbed on the same or neighboring metal species to produce β-ketoacid followed by decarboxylation to form the desired ketone.

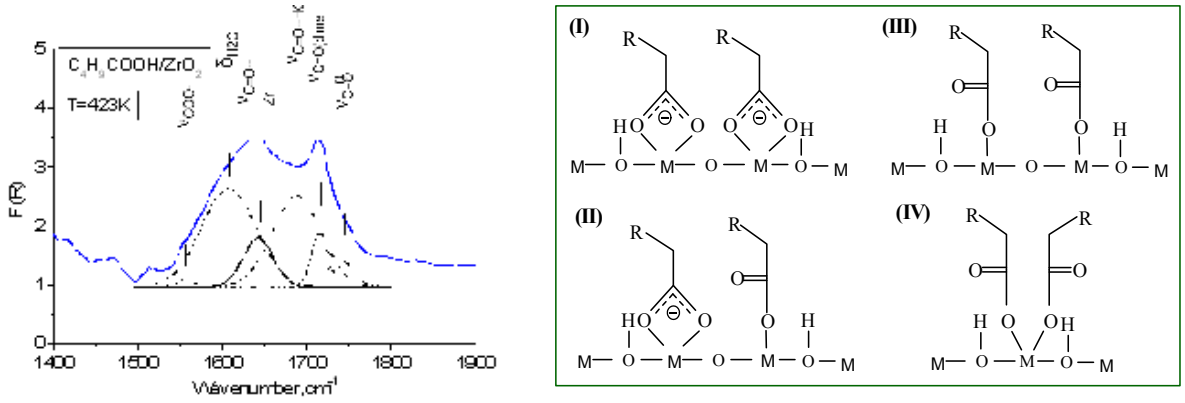

Fig. 2. FTIR spectra of valeric acid adsorbed over reduced ZrO_2 at 423K (left); valeric acid adsorption forms identified over Lewis acid sites by FTIR and UV-Vis (right).

4 Conclusions

Higher activity of ZrO_2 and CeO_2/ZrO_2 in C5 acid decaboxylative coupling in H_2 atmosphere compared to that in N_2 was found. Kinetic regularities and size effect of 5-nonanone hydrodeoxygenation over Pd and Pt on Zr and Ce/Zr oxides was elucidated. Influence of cross-reaction by-products on catalytic behaviour and product distribution was shown. FTIR and UV-Vis study allowed to identify different carboxylates adsorption forms and to reveal their key role in the ketonization mechanism. The reaction conditions were found provided C5 acid cascade mode transformation to C9 alkane with the yield more than 80%.

Keywords: CO hydrogenation, higher alcohols, Ni-Mo catalyst, AC-supported, catalysts, acidity

1 Introduction

Higher alcohols have been identified as highly promising and suitable components for jet fuel [1]. These higher alcohols can be produced thermochemically in a process similar to BtL-Fischer–Tropsch, with an appropriate catalyst to drive CO hydrogenation to higher alcohols formation rather than hydrocarbons. In this study, we investigate the hydrogenation of CO to higher alcohols over K-promoted bimetallic nickel-molybdenum oxide-based catalysts supported on activated carbon (AC), focusing on the effect of acidity. Initially, we studied the role of each active metal (Ni and Mo) separately by preparing and testing monometallic catalysts supported on AC [2]. Both Mo and Ni alone proved to be inactive in CO hydrogenation under the investigated conditions, demonstrating that the Ni-Mo synergistic effect and the formation of Ni-O-Mo functionalities is mandatory in order to produce a fair amount of oxygenates. In this study, the influence of the type of the carbon used as support was examined by employing two activated carbons with significant differences in surface area. The effect of pre-treating the activated carbon with acid to remove ash prior to impregnation and form surface carbon–oxygen complexes was also investigated. Physicochemical characterization data are combined with catalytic results in higher alcohol synthesis in an attempt to identify the different functionalities of the AC support and the nature of active sites.

2 Experimental/methodology

Two activated carbons (Norit) with surface areas 600 (AC1) and 1200 (AC2) m^2/g were used as supports. The activated carbons were used either as supplied (ACXb) or after acid treatment with a 50vol% HNO_3 aq. solution at room temperature overnight (ACXa). The supported K-promoted bimetallic catalysts were prepared by a stepwise incipient wetness method, with a constant K/Ni/Mo molar ratio of 0.05/1/1, followed by drying and calcination at 575°C for 4h under N_2. The loading of the active phase was kept constant to 35wt%. Additionally, a reference NiMoK mixed oxide with the same K/Ni/Mo molar ratio was prepared by evaporation. Physicochemical characterization was conducted by ICP, BET, XRD, TGA, H_2-TPR and NH_3-TPD. Catalyst evaluation in the CO hydrogenation reaction was investigated with a high pressure bench scale unit, in the temperature range 250–280°C at 60bar, W/F ratio 0.74 g_s/cm^3 and inlet feed composition $H_2/CO=2$.

3 Results and discussion

Evaluation of the NiMo catalysts in the CO hydrogenation reaction showed that the main reaction products are dimethylether (DME), alcohols (mainly C_2-C_5), hydrocarbons and CO_2. Although the unsupported K-NiMo phase exhibited the highest activity, it mainly produced hydrocarbons and DME rather than alcohols. The use of activated carbon as support led to a minimum three-fold increase in selectivity toward higher alcohols. Characterization revealed

that the presence of the support reduces the crystallinity of the $NiMoO_4$ phase in the samples and leads to a partial transformation of this mixed oxide from the alpha to the beta-phase. Subjecting the activated carbon to acidic pre-treatment prior to active metal deposition led to double CO conversion for the K-NiMo/AC2a catalyst compared to the untreated one (K-NiMo/AC2b). This could be related to the removal of ash from the activated carbon support and the improved dispersion of the active phase, as indicated by the increased acidity of the catalyst. In terms of products, acid pre-treatment led to reduced methanol and higher alcohol selectivity as a result of the high acidity. Finally, the use of a higher surface area support led to increased CO reactivity, with the K-NiMo/AC2a exhibiting a 45% higher conversion at 280°C compared to K-NiMo/AC1a. The improvement in activity can be ascribed to better dispersion of the active phase on the higher surface area support and therefore higher exposure of active sites on the surface, as indicated by the less crystalline nature of the particles and the acidity results.

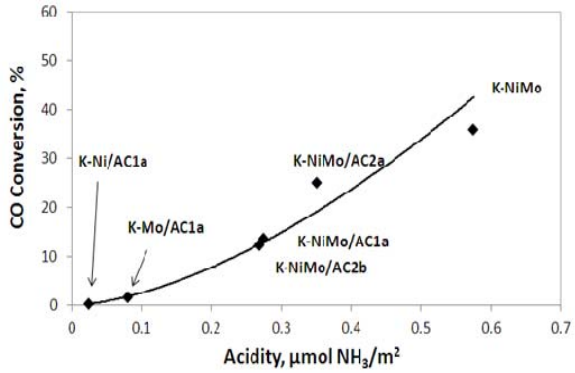

Fig. 1. Total acidity as a function of carbon monoxide conversion at 280°C for the K-promoted mono- and bi-metallic NiMo catalysts unsupported and supported on different AC supports

A clear tendency of increasing higher alcohol with decreasing acidity was evidenced, in agreement with previous results by our group on K-promoted CuZnAl catalysts for higher alcohol synthesis [3]. Moreover, a clear correlation between CO conversion and acidity was established for all catalysts, as shown in Fig. 1, indicating that Ni-O-Mo entities with acidic properties constitute the active centers for CO activation.

4 Conclusions

The use of activated carbon as support for alkali promoted NiMo catalysts was found to be beneficial for the hydrogenation of CO to higher alcohols, probably due to transformation of the active $NiMoO_4$ phase from alpha to beta. The increased activity of the higher surface area acid-treated support can be ascribed to better dispersion of the active phase on the support and therefore higher exposure of active Ni-O-Mo sites. A clear correlation between CO conversion and acidity was established for all catalysts, demonstrating that Ni-O-Mo entities with acidic properties constitute the active centres for CO activation. Overall, the K-NiMo/AC2a catalyst exhibited the optimum performance, with a space time yield of 141.5 mg/$g_{catalyst}$/h to oxygenates at 280°C, which is the highest amongst all the AC supported samples.

Control of Chain Length Distribution of Hydrocarbons during Fischer-Tropsch Synthesis over Co Nanoparticles inside of Nanoreactors

Ordomsky V.V.*, Subramanian V, Khodakov A.Yu., Paul S.

Unité de catalyse et de chimie du solide, Université Lille, Lille, France

Keywords: nanoreactor, Fischer-Tropsch, chain length distribution

1 Introduction

Fischer–Tropsch (FT) synthesis recently has received a lot of attention since it is considered as an effective process to produce wide-range liquid hydrocarbon fuels and valuable chemicals from abundant resources, such as natural gas, coal and biomass, via synthetic gas. One of the main problems of the Fischer-Tropsch synthesis is too broad distribution of the produced hydrocarbons due to the Anderson-Schulz-Flory (ASF) law resulting in a non-selective formation of any hydrocarbons. Many attempts have been made to circumvent the ASF distribution and to selectively produce the necessary range of hydrocarbons. However, these methods like addition of acidic catalyst for cracking of long chain hydrocarbons or promotion with other metals are not very efficient or suffer from formation of side products.

This work aims at developing novel strategy to enhance the control of the FT synthesis by encapsulation of the metal in the nanoreactors. Variation of the size of nanoreactors should result in the restriction of the growth of the hydrocarbons with control of the chain length of the formed hydrocarbons.

2 Experimental/methodology

Silica nanoreactors with encapsulated Co nanoparticles (Co@SiO_2-nanoreactor) have been prepared by application of micelles as a matrix. Fig. 1 shows the scheme of the synthesis of Co nanoparticles encapsulated into the porous silica spheres by application of micelle synthesis. In this case cobalt nitrate present in the aqueous phase localized in the micelles formed by cetyltrimethylammonium bromide in organic phase. Reduction of the cobalt by $NaBH_4$ leads to formation of metallic Co nanoparticles. Addition of tetraethylortosilicate in the system in the presence of trimethoxy(octadecyl)silane (TMOS) leads to its hydrolysis on the surface of micelle with formation of silica spheres with pores formed by TMOS.

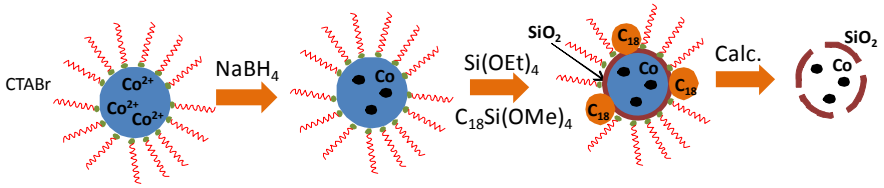

Fig. 1. Scheme of the synthesis of Co nanoparticles encapsulated in porous silica nanoreactors

The materials were characterized by elemental analysis, XPS, XRD, TEM, nitrogen adsorption and SSITKA analysis.

Catalytic experiments were carried out on the REALCAT platform in a Flowrence high-throughput unit (Avantium®) equipped with 16 parallel milli-fixed-bed reactors (d=2 mm) operating at a total pressure of 20 bar, 220°C, H_2/CO= 2 molar ratio. The gas and liquid products have been analyzed after the test by GC analysis for evaluation of the activity and selectivity to hydrocarbons.

3 Results and discussion

Analysis of the nanoreactor catalytic systems shows presence of small porous silica spheres with diameter 5-10 nm with Co nanoparticles inside (Fig. 2). FT synthesis (Fig. 2) over prepared material in comparison with Co nanoparticles prepared in the same way but without addition of TEOS and impregnated over silica support (Co@SiO_2-imp) and standard impregnated catalyst (Co/SiO_2-imp) shows that Co nanoparticles in the silica spheres provide much higher activity and stability. The high activity is the result of well dispersed Co inside of nanoreactors with low interaction with the material of support in comparison with the catalysts prepared by impregnation with high contribution of silicates. The high stability is due to the low segregation of Co nanoparticles separated by the walls of the silica spheres. Analysis of the wax products shows that encapsulation of Co nanoparticles leads to significant shift to the short chain hydrocarbons due to the restriction of the chain growth by the walls of nanoreactors with formation of the liquid hydrocarbons in comparison with solid wax over impregnated catalysts (Fig. 2). The product of the FT synthesis over nanoreactors might be directly used as diesel fuel. It means that it is possible to control the distribution of products by change of the size of the nanoreactors.

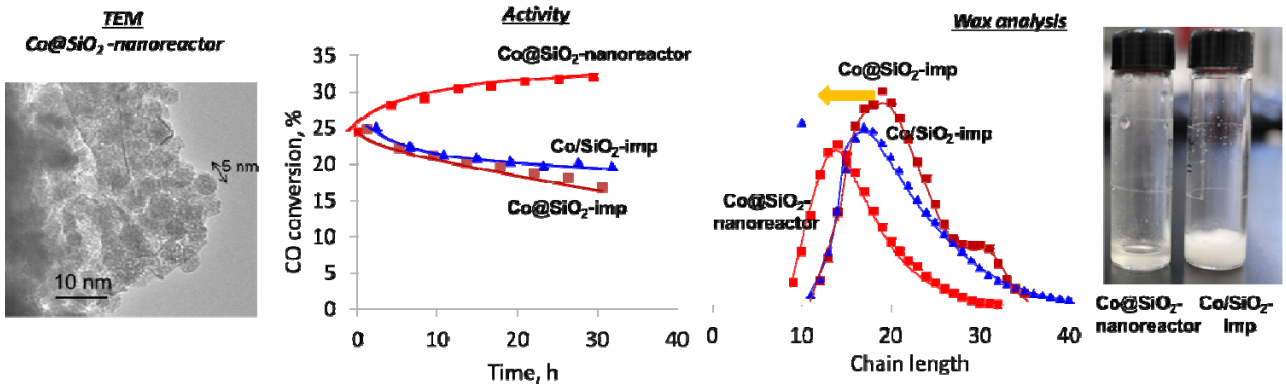

Fig. 2. Comparison of the activity and wax analysis during FT synthesis over standard impregnated Co catalyst (Co/SiO_2-imp), Co nanoparticles impregnated over silica (Co@SiO_2-imp) and Co catalysts encapsulated in nanoreactors (Co@SiO_2-nanoreactor with TEM analysis)

4 Conclusions

Thus, our results show that application of nanoreactors give significant advantages in terms of activity, selectivity and stability in FT synthesis. However, there are much more opportunities for nanoreactors in FT synthesis besides shape selectivity for combination of the processes by control of the access of chemicals in nanoreactors and variation of environment in nanoreactors to control synthesis of the other products.

Keywords: wood, catalytic processing, chemical products

1 Introduction

Wood is the most abundant renewable resource for valuable chemicals and biofuels in the forest regions. Birch tree belongs to the widespread wood species in the Russia. The high content of hemicelluloses complicates the use of birch wood in pulping and hydrolysis industries but makes this wood attractive for production of valuable chemicals.

This presentation describes a novel approach to wasteless processing of birch wood biomass, based on the integration of catalytic methods of hemicelluloses, cellulose and lignin components conversion to xylose, microcrystalline cellulose (MCC), biologically active sulfates of MCC, organic and carbon aerogels.

2 Experimental/methodology

Air dry sawdust (fraction 2–5 mm) of birch wood (Betula pendula) was used as starting raw material. Birch wood composition (% wt.): cellulose – 46.5, hemicelluloses – 27.2, lignin 21.8, extractive substances – 3.6, mineral part – 0.4.

The studied integrated processing of birch wood biomass included the steps of hemicelluloses acid-catalysed hydrolysis to xylose, oxidative fractionation of prehydrolysed wood on microcrystalline cellulose (MCC) and soluble lignin, obtaining of MCC sulfates, synthesis of organic and carbon aerogels from lignin.

Kinetic of wood prehydrolysis and fractionation processes was investigated with the use of batch stirring reactor at intensive agitation. The structure of solid catalysts and products was studied by FTIR, XRD, SEM, AFM and BET methods. Sulfates of MCC, sugars from hemicelluloses and soluble products from lignin were studied by ^{1}H and ^{13}C NMR, HPLC, GC-MS, FTIR and by elemental analysis.

3 Results and discussion

The present study develops our approaches which were used for obtaining MCC and MCC sulphates from aspen-wood [1, 2] and for synthesis of aerogels from polyphenols [3].

Optimal conditions of birch-wood hemicelluloses hydrolysis to xylose were established. For complete hydrolysis with sulphuric acid catalyst the temperature 100 °C, H_2SO_4 concentration 3 % wt. and time 4 hours should be used. Solid acid catalysts (sulphated graphitized carbon and zeolite SBA-15) were less active, therefore the temperature 120 °C was used to achieve the high yield of xylose.

For the first time the kinetic regularities of oxidative fractionation of birch-wood by hydrogen peroxide in the medium of acetic acid – water in the presence of solid (1 % wt. TiO_2) and soluble (2 % wt. H_2SO_4) at the temperature range 70–100 °C were compared. Similar kinetic

parameters (reaction order, rate constant, activation energy) testify in favor of analogous mechanism of lignin oxidation for both catalysts. The optimum parameters of heterogeneous catalytic fractionation of birch-wood on cellulose and lignin were selected: temperature 100 °C, concentrations of acetic acid – 20 % wt. and hydrogen peroxide – 5 %, liquid to solid ratio – 10, time 4 h. At these conditions the effective fractionation of aspen-wood on cellulose and soluble lignin was achieved. The application of solid TiO_2 catalyst instead of sulfuric acid allows to improve the ecological safety of fractionation process and to reduce the corrosive activity of reaction medium.

The new "green" method of MCC sulfates synthesis based on the use less toxic sulfation agent – sulfamic acid in the presence of basic catalyst – urea was developed. In DMF and diglym solvents the degree of substitution of sulfated MCC reaches to 1.40–1.54. The yield of MCC sulfates prepared in diglyme was by 2.5 times higher than the yield of MCC sulfates obtained in DMF. MCC sulfates obtained by developed method have more homogeneous structure and higher anticoagulant activity as compared to sulfates prepared by conventional methods using toxic SO_3–pyridine mixtures.

New types of carbon porous materials with unique properties – carbon aerogels were prepared for the first time by carbonization of organic aerogels from lignin-formaldehyde mixtures. After carbonization at 900 °C aerogels remained fully monolithic and homogeneous despite significant (55–60 % wt.) volume shrinkage. Surface area of obtained carbon aerogels reaches 1000 m^2/g and its value depends on the amount of lignin in an initial organic aerogel. The raise of lignin amount increased the volume of macropores (> 50 nm) but decreased that of small pores (< 2 nm). The density, surface area, porosity and mechanical strength can be varied within broad limits depending on their use. Light weight carbon gels are brittle, whereas the more compact samples a much more mechanically resistant.

4 Conclusions

Main stages of integrated catalytic processing of birch-wood biomass to xylose, MCC, sulphates of MCC, organic and carbon aerogels were investigated. The first stage of studied integrated process – the hydrolysis of birch wood hemicelluloses to xylose at 120 °C was accelerated by sulfated carbon and zeolite SBA-15 catalysts. At the second stage the suspended TiO_2 catalyst was used for prehydrolized wood fractionation on MCC and soluble lignin in H_2O_2–CH_3COOH–H_2O solution at 100 °C. Biologically active sulfates of MCC were firstly obtained with the use of green sulfation agent – mixture of sulfamic acid and basic catalyst urea. Highly porous organic and carbon aerogels were firstly synthesized from soluble lignin-formaldehyde mixtures. They have good prospects for application as sorbents, catalyst supports, thermal insulators etc. Based on kinetic studies the optimal conditions of birch wood fractionation on xylose, MCC and soluble lignin were established.

Keywords: heterogeneous catalysis, gold, methane oxidation

1 Introduction

Methane is our most abundant hydrocarbon. However, this natural resource is not being effectively utilised. Currently, its primary industrial use is the manufacture of methanol through the intermediate formation of synthesis gas (H_2 and CO). This is an energy intensive process requiring temperatures of up to 850 °C and pressures of up to 100 atm. Clearly, a direct method of converting methane to methanol under mild conditions would provide many advantages. Catalysis by gold-palladium nanoparticles has received significant attention in recent years as they have been shown to be highly effective at catalysing the oxidation of primary C-H bonds in toluene, benzyl alcohol oxidation and the direct synthesis of hydrogen peroxide. [1, 2] In this work gold–palladium nanoparticles are shown to be active for the oxidation of methane in water at 50 °C using hydrogen peroxide as the oxidant.

2 Experimental/methodology

Au-Pd nanoparticles were prepared by both the impregnation and the sol-immobilisation methods.[1] For both methods $PdCl_2$ and $HAuCl_4$ were used as precursors. Catalyst testing was carried out in stirred Parr autoclave reactors. Typical reactions were carried out in 10 ml of water, at 50 °C, under 30 bar methane, for 30 min and stirred at a rate of 1500 rpm. At the end of each reaction the reactor was cooled to 10 °C to minimise loss of volatile products. The reaction liquid was filtered and analysed by ^{1}H-NMR to identify all liquid phase products. D_2O (99% D) was used as a solvent and a calibrated insert containing tetramethylsilane (TMS) in deuterated chloroform (99.9% D) was used to quantify the detected products. Gas phase CO_2 was determined by GC analysis on a GC equipped with FID & TCD detectors and a methaniser. The amount of hydrogen peroxide remaining after each reaction was quantified by titration against an acidified $Ce(SO_4)$ solution of known concentration using ferroin as the indicator.

3 Results and discussion

Au-Pd catalysts prepared by the impregnation technique have been found to produce catalysts that have a low rate of hydrogen peroxide decomposition and metal particle sizes in the 5-20nm range.[3] The activity and selectivity of these catalysts are compared with those of supported and unsupported Au-Pd nanoparticles prepared by the sol-immobilisation method. As this method involves the use of a stabilising ligand it affords much greater particle size control, with a narrow particle size distribution and average particle size of 3 nm. The effect of catalyst preparation parameters is investigated with emphasis on the effect of supporting the nanoparticles and its effect on hydrogen peroxide consumption during a reaction. A variety of different supporting materials are investigated and the activity of the Au-Pd nanoparticles supported on each material is compared. The influence of the stabilising ligand on the reaction is

explored particularly in relation to reactions catalysed by Au-Pd nanoparticles prepared by sol-immobilisation.

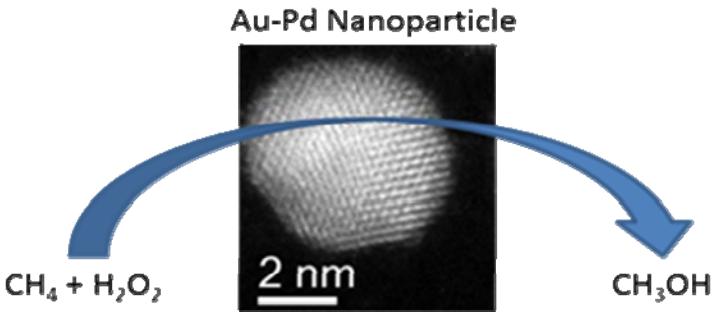

Fig. 1. TEM image of Au-Pd nanoparticles prepared by sol-immobilisation with schematic of methane oxidation reaction with H_2O_2 as oxidant.

Through time on line analysis the primary product of this reaction is shown to be methyl hydroperoxide which undergoes subsequent transformation to methanol, formic acid and carbon dioxide. [4] EPR studies have shown that methyl and hydroxyl radicles are present during the reaction and the presence of hydroperoxy radicals can be inferred from the formation of methyl hydropeorxide.

These results show that this reaction occurs *via* a radical mechanism. The reaction was found to proceed through the same mechanism regardless of whether or not the particles were supported. The reaction has been found to be highly selective for the formation of methyl hydroperoxide and methanol with optimised conditions affording an oxygenate selectivity of ca. 90%. During this presentation the effect of reaction conditions and catalyst preparation will be discussed.

4 Conclusions

Au-Pd nanoparticles have been found to be effective catalysts for the selective low temperature oxidation of methane using hydrogen peroxide as the oxidant. The primary product of the reaction is methyl hydroperoxide which is generated through the reaction of H_2O_2 and $\bullet CH_3$. The method by which the Au-Pd nanoparticles are prepared has been found to have a significant effect on catalyst activity.

Keywords: ethanol, heterogeneous catalysis, linear, alpha alcohols, gold nanoparticles, 1-butanol

1 Introduction

The first reference to gold as a catalyst dates from 1906, when Bone and Wheeler observe the oxidation of hydrogen on a heated gold gauze [1]. The recent progress in heterogeneous catalysis resulted in remarkable investigations, that revealed the high activity of supported gold nanoparticles and synergetic effect of gold with either nickel or copper in a wide range of reactions[2-4].

2 Experimental/methodology

Analytical grade ethanol (99 %) and iso-propanol (99%) were used without further purification. Catalytic tests were performed in autoclave type reactor with magnetic stirrer (Parr 5000 series) under temperature 240-295 °C and pressure 50-120 atm. Reaction products were analyzed with use of GC and MS. Au-Cu/Al_2O_3 and Au-Ni/Al_2O_3 catalysts were produced by deposition-precipitation as described in [2, 5]. As a support γ-alumina SiO_2 and TiO_2 were used. The metal content of the catalysts was determined by atomic absorption on a Thermo iCE 3000 AA spectrometer. XRD analysis was carried out on a Rigaku D/MAX 2500 instrument using Cu Kα radiation with a step size of 0.02 ° two-theta (2θ) ranging from 35 to 70 °. XPS analysis was carried out on a Kratos Axis Ultra DLD spectrometer using Al Kα radiation (1486.6 eV). TEM and EDX analysis of catalysts were carried out on a JEOL JEM 2100F/UHR microscope with 0.1-nm resolution and a JED-2300 X-ray spectrometer, respectively.

3 Results and discussion

During ethanol conversion into olefins C_3-C_8 was found that nickel oxide clusters with a size of 3.5 nm possess low TOF (0.051 s^{-1}) and low selectivity (12.73 wt.%). The TOFs of the gold clusters increases from 0.095 to 0.384 s^{-1} as the size of the gold particle decreases from 13-15.1 to 5 nm. The most probable cause of this positive size effect is the increasing amount of coordinative unsaturated atoms on the surface of the small Au^0 particles. Increasing the gold particle sizes from 5 to 13-15.1 nm results in the selectivity for C_{3+} hydrocarbons increasing from 11.69 to 29.99 mass %, which suggests the participation of multiple active centers in the conversion of ethanol into hydrocarbons. The deposition of nickel oxide particles on the Au/Al_2O_3 catalysts results in the formation of large NiO/Au aggregates consisting of small gold and nickel oxide clusters. These new NiO/Au structures have the TOF of 0.321 s^{-1} and the selectivity of 34.19 wt. %, with a total metal content of 0.13 wt. % and a Au:Ni molar ratio of 1:1. The active catalyst sites become occluded by nickel oxide as the total metal content is increased or when the molar ratio of Au:Ni > 1:1, which is manifested as a decrease in both the TOF and selectivity.

During ethanol conversion into linear alpha alcohols found that optimal temperature is 270 °C and ethanol partial pressure is > 60 atm that provides supercritical conditions. Depending on catalyst nature ethanol conversion varied from 30 to 63,5 % with selectivity on 1-butanol 58-75 %. Over Au-Ni containing catalysts ethanol converts also in hexanol-1 and octanol-1 with selectivity 21,2 and 5,6 % respectively. First time ever α-alkylation of iso-propanol with ethanol was carried out over heterogeneous Au-M containing catalysts with 3-methylbutanol-2 selectivity 55-70 % depending on catalyst composition and reaction conditions. Found that monometallic Au/Al2O3 catalyst possesses lower activity in ethanol conversion than bimetallic ones. Cu/Al_2O_3 and Ni/Al_2O_3 had no activity in butanol-1 formation. Varying of catalysts support showed that usage of TiO2 instead of Al_2O_3 increase selectivity on 10% but decreases conversion rate down to 20 %. Stability test demonstrated that during over 50 h catalysts have constant activity and selectivity.

Structural investigations explains observed synergetic effect of Au with Ni or Cu. Bimetallic catalysts have Au-MxOy nonspherical species like core-shell structures with average linear size 2-6 nm that possesses gold in both metal state and Au^+ state.

4 Conclusions

The strong synergetic effect of Au-M_xO_y containing catalysts wasdetected. Found that ethanol could be incorporated onto either olefins C_3-C_8 fraction or linear alpha-alcohols with even number of carbon atoms up to C_8. Au-Cu containing catalyst possesses the highest selectivity on 1-butanol 75 % with ethanol conversion 33 %. Au-Ni containing catalyst possesses total selectivity on 1-butanol, 1-hexanol and 1-octanol 90 % with ethanol conversion 63,5 %. First time ever α-alkylation of iso-propanol with ethanol was carried out over heterogeneous Au-M containing catalysts with 3-methylbutanol-2 selectivity 55-70 % depending on catalyst composition and reaction conditions. The optimal structural and electronic organization of Au-Cu and Au-Ni catalysts is achieved in the catalysts produced by modification of Au/Al_2O_3 with M_xO_y and implies the high concentration of special sites: $Au^{\delta+}$ atoms at the Au-M interface; partially reduced metal-oxide species at the Au-M interface; atoms with a low coordination number on the surface of nonspherical bimetallic particles.

Obtained data allow suggesting Au-Cu and Au-Ni catalysts as prospective systems for fuels components (butanol-1) producing and valorisation of ethanol into chemicals like hexanol-1 and octanol-1. Combined conversion of ethanol with iso-propanol that leads to 3-methylbutanol-2 formation may be considered as the first step of valuable monomer - isoprene production.

Evolution and Interlayer Dynamics of Active Sites of Promoted Transition Metal Sulphide Catalysts under Hydrogen and Inert Media in the Course of Some Commercially Valuable Reactions

Kogan V.M.[1*], Nikulshin P.A.[2], Dorokhov V.S.[1], Permyakov E.A.[1]

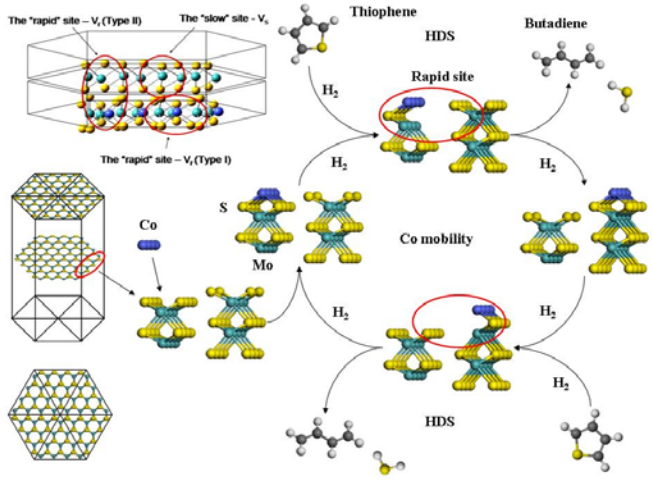
Keywords: active site, alcohols, hydrodesulphurization, syngas conversion, transition metal sulphides

1 Introduction

A concept on the dynamic nature of active sites (AC) of the catalysts based on transition metal sulphides is described. The concept formed the basis of a "dynamic" model, according to which AC formed and functioning under the reaction conditions can oscillate between layers of promoted molybdenum sulphide. The model assumes the existence of "rapid" and "slow" AC and the possibility of their mutual transformation due to the reversible migration of sulphur and promoter between the crystallite layers in a hydrogen atmosphere.



The frequency of these migrations (oscillations) determines the catalyst activity. An assumption is substantiated that the hydrogenation (HYD) and hydrodesulphurization (HDS) sites are localized at the rims of the Co(Ni)MoS_2 crystallites whereas direct desulpurization (DDS) and hydrodesulphurization (HDS) sites are localized on the edges.

Fig. 1. Dynamic model of transformations of the active sites of promoted TMS catalysts in the course of thiophene HDS.

2 Application of the dynamic model to various catalytic processes

2.1. Hydrodesuphurization of various types of crude oil.

The dynamic model explains a series of correlations structure – property that was reported in studies of the catalysts prepared under the laboratory conditions, industrial catalysts and new sulphide catalysts synthesized using heteropolycompounds, organic complexones and carbonized supports. The dependence of the catalyst activity on the number of layers and linear size was studied by the experimental and calculation methods, and the arrangement of AC of different types on the surface of molybdenum disulphide crystallites was determined.

An increase in the average linear size of the slab leads to a drop of HDS and HYD activities. The longer layers in the slabs, the fewer solid angles are, and so the higher the effect of the support. On the contrary, in the multilayered structure the support effect diminishes. The observed high HYD/DDS selectivity of the catalysts synthesized from AHM and nickel nitrate may be caused by low edge surface Ni on the MoS_2 slab which should also form the unpromoted Mo-sites responsible for the HYD reactions on the edges.

The results suggest that the catalytic activity in HDS and HYD reactions depends on the

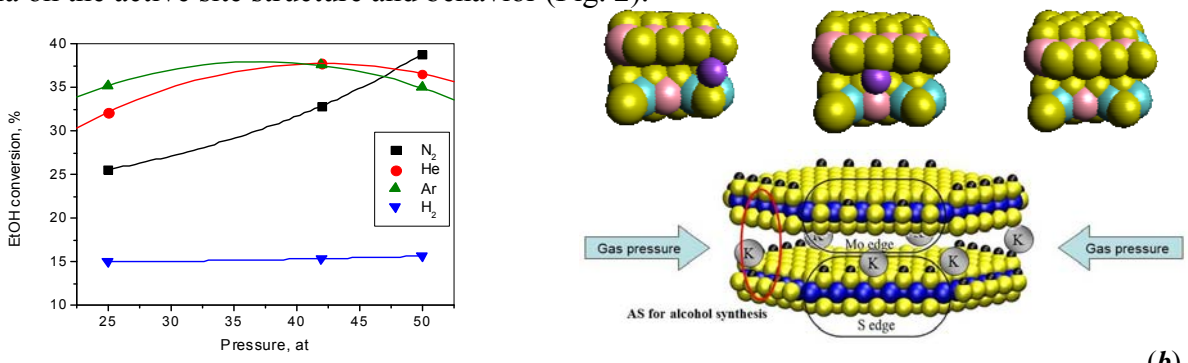
shape of crystallites of the active phase. The results are interpreted using recently proposed concepts of interlayer dynamics. These concepts are helpful in establishing structure-activity relations for TMS

2.2. Synthesis gas conversion

Using the interlayer dynamics model for the explanation of the mechanism of syngas conversion on the sulphidized KCoMo catalysts, we obtained the general regularities governing the action of the AC of transition metal sulphides in the hydrogenolysis of sulphur containing organic compounds and syngas conversion. The role of Co is the activation of a CO molecule. Potassium stabilizes the C-O bond and prevents its cleavage, and the hydroxyl group of alcohol is formed. The ratio of the yield of alcohols to the yield of hydrocarbons decreases with temperature. This indicates that with the temperature rise the formation of alcohols becomes kinetically less favourable than the hydrogenolysis of the C-O bond and hydrogenation of the alkyl fragment to hydrocarbon. If alcohols are formed on the edges of molybdenum disulphide crystallites, the adsorbed alkyl fragment can be involved in the chain growth with another adsorbed particle localized on one of two neighbouring layers of the same edge. Therefore, the probability of carbon chain growth involving the methyl fragment on the edge is higher than that on the rim or monolayered crystallite. This statement is explained in terms of the interlayer dynamics concept by the fact that the rims contain more "slow" AC.

2.3. Alcohol conversion in hydrogen and inert media

It was found that ethanol conversion in H_2 is much smaller than in inert media such as N_2, He or Ar. Hydrogen pressure increase leads to decrease of catalytic activity whereas pressure growth of inert gases does not suppresses it. It is likely that in inert gases it takes place disproportionation of ethanol with formation of oxygenates and hydrocarbons. In contrast, hydrogen suppresses oxidative processes and shifts reaction equilibrium to reduction ones. Possible explanation of the observed phenomena is the effect of the nature and pressure of gas media on the active site structure and behavior (Fig. 2).



(***a***) (***b***)

Fig. 2. Ethanol conversion depending on pressure at 320°C in verious media (***a***); transfere of potussium ions in different positions between MoS_2 slab layers depending on gas medium pressure (***b***).

The obtained results allowed us to develop the methods for product selectivity control. The synthesized products could be used is additives for transportation fuels, solvents and precursors for petrochemical synthesis.

3 Conclusions

The proposed model makes it possible to develop criteria for the evaluation of the efficiency of catalytic performance for hydrodesulphurization (HDS) of hydrocarbon raw materials of various types, for syngas conversion with formation of higher alcohols and their followed conversion into wide range of oxygenates under hydrogen and inert media.

Keywords: egg-shell catalysts, Fischer-Tropsch synthesis, mass transfer limitations

1 Introduction

The low temperature Fischer-Tropsch synthesis (FTS, T< 250°C, P>20 bar) aims at converting synthesis gas into long-chain hydrocarbons through the adoption of heterogeneous catalysts based on cobalt or iron. In packed bed reactors, where the adoption of "big" catalyst pellets is mandatory to limit ΔP, the performances of FTS catalysts may be significantly worsened by strong mass transfer limitations, which affect both the CO conversion rate and the C_{5+} selectivity. In the case of state-of-the-art Co-based catalysts, such restrictions occur when the characteristic length of diffusion (δ) overcomes the threshold value of 50-60 microns [1,2]. Eggshell catalysts, in which the active phase is located only in the outer region of the catalytic support, represent an engineering solution to limit both δ and pressure drops in packed-bed reactors [2]. In those catalysts, in fact, the diffusion characteristic length and the pellet diameter become two independent parameters to be optimized. In this work, a "small" Co/Al_2O_3 eggshell catalyst, to be used in compact and intensified multitubular FTS reactors, has been prepared by following an innovative preparation method. Then, its catalytic activity has been tested in a lab-scale fixed bed reactor at industrially relevant process conditions [3]. Eventually, its performances have been compared with that of a powdered catalyst. It has been found that the optimal design of the catalyst brings to outstanding C_{25+} yields, even higher than those obtained with a catalyst operating under kinetically controlled regime.

2 Experimental/methodology

The preparation method developed to synthetize a small Co/Al_2O_3 eggshell catalyst involves a few, simple steps. At first, Al_2O_3 microspheres are soaked in *n*-undecane for 40 min so to fill their pores; then, they are drained from the excess liquid and placed into a fritted glass funnel mounted on a vacuum flask. At this point, a solution of $Co(NO_3)_2{\cdot}6H_2O$ in ethanol (1.27 $ml_{ethanol}/g_{salt}$) is poured onto the microspheres and, after a short time (τ), the excess solution is removed from the flask by evacuating the system. The impregnated spheres are dried in static air at 393 K for 2 h and eventually calcined at 673 K in static air for about 12 h. By (i) using microspheres with a diameter of 600 microns, (ii) keeping τ= 2s and (iii) repeating 9 times the impregnation procedure, eggshell pellets (ES600) with a Co loading of 9 wt.% (16 wt.% in the active shell) have been obtained. A powered sample (POW100) has been obtained by grinding a fraction of the eggshell microspheres and sieving in the range 75-106 microns. Both the catalysts have been reduced in situ flowing H_2 at 400°C for 17 h and then tested at 25 barg, GHSV= 46.01 $L(STP)h^{-1}g_{Co}^{-1}$, H_2/CO molar ratio = 1.7, N_2+Ar in the feed = 24 vol.%, in the T-range 220-240°C.

3 Results and discussion

Thanks to (i) the presence of an hydrophobic liquid filling the Al_2O_3 pores, (ii) the adoption

of an hydrophilic impregnating solution and (iii) the control of the contact time between the support and the impregnating solution, the adopted preparation method allowed to obtain eggshell Co/Al_2O_3 pellets with a uniform thickness (t) of the sharp active shell region (t=75 microns). An average Co_3O_4 cry-size of 7 nm has been estimated, a value granting the optimal compromise between active phase dispersion and TOF [4] and a high reduction degree (55-67%) of the cobalt oxides upon heating the sample in H_2 up to 400°C, without the need of any promoter. When tested in the FTS, ES600 catalyst shows higher CO conversion and a slightly higher C_{5+} selectivity than POW100 sample (Figure 1), with the products containing much less olefins. According to our understanding, these results can be explained by assuming the occurrence of weak mass transport limitations in the case of ES600 catalyst, which is characterized by a value of δ (58microns) higher than POW100 (δ<15microns) and very close to the threshold limit of 50-60 microns [2,3]. The CO conversion with ES600 sample is higher than with POW100 because the local H_2/CO ratio in close proximity of the active centers is higher than in the bulk phase (H_2 diffusion in the waxes is twice as fast as that of CO), thus resulting in a speed-up of the CO conversion kinetics which is negative order with respect to CO and positive order with respect to H_2. The lower content of olefins in ES600 catalyst is related instead to the longer diffusion length, which enhances the probability of the olefins to be re-adsorbed and to undergo secondary reactions. Among these, the hydrogenation of C_n olefins to the corresponding paraffin is dominant, even though we also observed an increase of the chain growth and an increase of hydroformylation to the C_{n+1} alcohol. As a confirmation of our explanation for the observed data, while an apparent FTS activation energy of 100 kJ/mol has been estimated for POW100 sample, a value as low as 87 kJ/mol has been estimated for the ES600 catalyst.

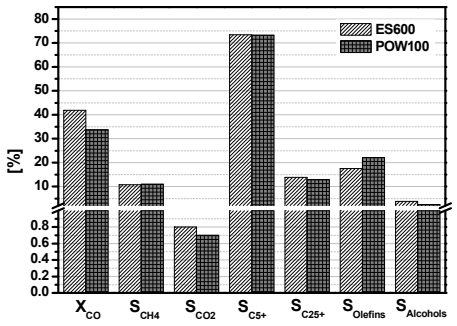

Fig. 1. CO conversion (X_{CO}) and selectivity (S_i) to the main reaction products

4 Conclusions

All the obtained results, confirming the presence of mass transfer restrictions which falsify the CO conversion kinetics for δ > 50 microns, point out that engineered eggshell catalysts suffering of "weak" mass transfer restrictions represents an optimal solution to achieve a high C_{25+} yields, while limiting the pressure drops in compact Fischer-Tropsch packed-reactors.

Intensification of Strongly Endo- and Exo-Thermic Catalytic Processes through the Adoption of Highly Conductive "Packed Foams" Reactors

Visconti C.G., Groppi G., Tronconi E.*

Politecnico di Milano, Department of Energy, Laboratory of Catalysis and Catalytic Processes, Milano, Italy

Keywords: packed foams, structured catalysts, process intensification, heat transfer

1 Introduction

Even though it is widely recognized that spatially structured reactors are at the very heart of process intensification [1], and it has been shown that significant enhancement of radial heat transfer rates in technical multitubular catalytic reactors with external cooling can be achieved if the random packings of catalyst pellets are replaced by structured catalysts with thermally connected, highly conductive support matrices [2], some issues still exist that prevent the application of this technology at the industrial scale. For example, in the case of non-adiabatic reactors loaded with highly conductive washcoated open-cell foams (or sponges), due to the thin catalyst layer, the catalyst inventory is often insufficient, which may limit the potential advantages associated with the adoption of conductive structured reactors. Also, the catalyst loading and unloading in the reactor, as well as the replacement of the spent active phase, are particularly critical in such a technology. To overcome those issues the adoption of "packed structured" reactors has been recently proposed [3,4]. In such reactors, particularly interesting for compact scale applications (i.e. short tubes), the catalyst is loaded in the form of small pellets (e.g. microspheres) packed in the voids of highly conductive structures. Herein we investigate the concept applied to open-cell metallic foams, which has not been proposed before to our knowledge: we assess the heat transfer performances of packed sponges and compare them to those of conventional packed beds of pellets and of bare open-cell foams.

2 Experimental/methodology

Comparative heat transfer experiments have been performed in a lab-scale test rig consisting of a finned stainless steel pipe (28 mm I.D.) placed in an oven, using three different types of packings: *i)* packed beds (**PB**) of spherical pellets with **0.3** and **3** mm diameter; *ii)* bare open-cell foams (**VF**, void foams) made of two different materials (aluminium, **Al**, and FeCrAlloy®, **FeCr**), and with different geometries (cell densities 10-40 PPI and relative densities 5-6%); *iii)* packed foams (**PF**). During the experiments, carried out heating the oven at different temperatures (200-500°C), two different gases (**He** and $\mathbf{N_2}$) at different flow rates (representative of those used in compact industrial reactors) have been fed to PB, VF and PF and steady-state axial and radial T-profiles inside the packings and at the pipe skin were measured. A classical 2D two-parameters pseudo-homogeneous heat transfer model was then fitted to the experimental T-profiles to estimate the effective radial thermal conductivity of the bed, k_{er}, as well as the wall heat transfer coefficient, h_w. The overall heat transfer coefficient, U, was also calculated.

3 Results and discussion

Figure 1 shows the estimates of the overall heat transfer coefficient obtained for the different configurations using He and N_2 as flowing gas. Lines are used to group 4 different

packing configurations particularly relevant to be compared. For each configuration, a cloud of points is shown, representing data collected at different gas flow rates.

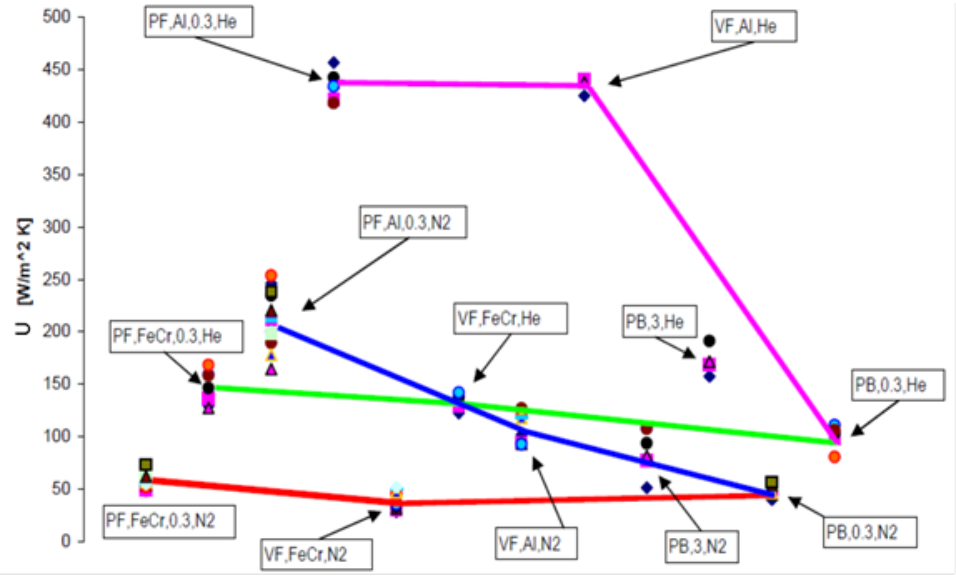

Fig. 1. Heat transfer performances of different packings upon varying the flowing gas and its flow rate

Data in Figure 1 show that at the adopted conditions heat transfer in a PB is comparable to that in a low conductive VF (FeCr). In this case, PF with a poorly conductive structured substrate performs similarly to the corresponding PB and VF. On the contrary, due to the high value of $k_{e,r}$ [2], heat transfer in a highly conductive VF (Al) is much better than in PB, which on the contrary shows higher h_w at high flow rates. In this case, a PF with a highly conductive structured substrate performs much better than both the corresponding PB and VF, due to the synergy of the enhanced conductive heat transfer in the solid structure of the foam and the convective heat transfer at the wall-bed interface of packed spheres. The former mechanism, which is flow independent, controls the effective radial conductivity. The latter one enhances the wall heat transfer coefficient and contributes to increase the overall heat transfer coefficient, particularly at high flow rates. A circuit of equivalent resistances has been identified to describe the heat transfer mechanisms within packed foams.

4 Conclusions

Our results suggest that "packed foams" may be particularly advantageous in compact reactors requiring short tubes, in view of their flow-independent, conductive heat transfer mechanism which adds to the convective heat transfer typical of packed-beds of pellets.

Keywords: fast pyrolysis oil, hydrodeoxygenation, anisole, intrinsic kinetics

1 Introduction

In recent years, due to the depletion of fossil fuels and environmental concerns, biomass valorization looks as an attractive alternative route for fuels production. Among several techniques proposed for lignocellulosic biomass valorization, the most promising one is fast pyrolysis followed by catalytic upgrading to reach the desired oil quality. While a lot has already been done in the field of fast pyrolysis itself, bio-oil hydrotreatment still represents significant challenges .

A non-sulfided 15wt.%Co-3.8wt.%Mo/Al_2O_3 hydrotreating catalyst has potentially a relatively low cost in comparison to noble metal based catalysts and doesn't require sulphiding pretreatment as do conventional hydrotreating catalysts. Anisole was used as a model compound for assessing the various elementary steps by systematically varying the operating temperature, pressure and inlet composition at different space times. The obtained experimental results are expected to provide insight into the reaction mechanism, input for kinetic model construction and constitute a basis for further catalyst and process design.

2 Procedures

Intrinsic anisole HDO kinetics on a non-sulphided 15wt.%Co-3.8wt.%Mo/Al_2O_3 catalyst have been acquired in a plug flow reactor at gas-phase conditions . Off-line GCxGC-TOF-MS analysis was used for detailed product identification. For all the experiments the intrinsic kinetics regime was verified by testing the relevant criteria for mass and heat transfer limitation assessment.

3 Results and discussion

Based on the GCxGC-TOF-MS analysis of the product mixture, complemented by literature information , the following reaction network was proposed for anisole hydrotreating (Fig.1):

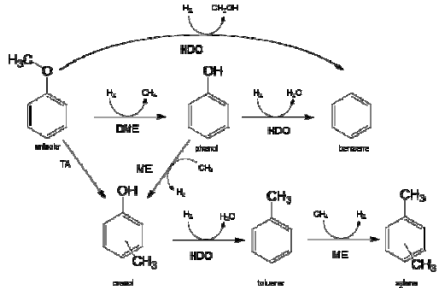

Fig. 1. Anisole HDO reaction network.

Demethylation and isomerization, including, (trans)alkylation reactions were found to occur to a significant extent. Apparently, metallic CoMo is a better isomerisation than hydrogenation or hydrodeoxygenation catalyst . The main reaction products on this catalyst were found to be

phenol and its methyl substituted analogues, c.q., cresols, while the selectivity towards benzene and toluene is less than 5% (Fig. 2).

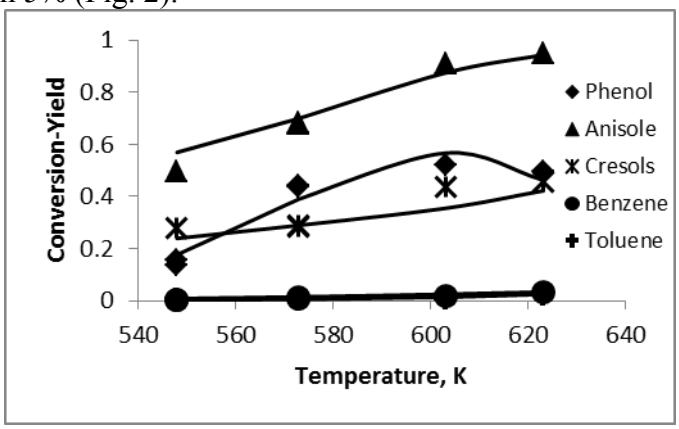

Fig. 2. Temperature effect on anisole hydrotreating conversion and product yield (symbols: experimental; lines: model simulations).

From kinetic model regression to experimental data values for activation energies and reaction rate coefficient at average temperature were estimated (Table 1). The limited hydrodeoxygenation extent is in line with the high activation energy obtained for it, compared to the other reactions.

Table 1. Parameter estimates obtained from kinetic model regression to the experimental data.

	k_{Tavr}, [mol $s^{-1}kg_{cat}^{-1}$]	Ea, [kJ mol^{-1}]
Transalkylation	$2 \cdot 10^{-6} \pm 1.6 \cdot 10^{-7}$	99±24
Methylation	$2.9 \cdot 10^{-7} \pm 1.3 \cdot 10^{-7}$	*34±40*
Demethylation	$2 \cdot 10^{-6} \pm 1.6 \cdot 10^{-7}$	55±9
Hydrodeoxygenation	$1.4 \cdot 10^{-8} \pm 0.9 \cdot 10^{-8}$	130±19

4 Conclusions and future work

A reaction network and corresponding LHHW kinetic model have been proposed for anisole hydrotreating over a non-sulphided $CoMo/Al_2O_3$ catalyst. The catalyst mainly exhibited demethylation and isomerization, rather than hydrogenation or hydrodeoxygenation behaviour, even at very high anisole conversions. The acquired data have been adequately described by kinetic model. Alternative catalysts will be explored to enhance our understanding of the determining catalyst features for the isomerization versus hydrogenation/hydrodeoxygenation selectivity. An adequate kinetics model will assist in reaching this understanding and optimizing the corresponding catalysts and process.

Keywords: Rh, RhNi, electrosynthesis, structured catalyst, catalytic partial oxidation, syngas

1 Introduction

Metal structured catalysts allow the design of more compact reactors for the conversion of fossil fuel or biomass-derived feedstocks into H_2 or syngas [1], with lower pressure drop and enhanced heat transfer. For instance, hot spots in the catalytic partial oxidation (CPO) of CH_4 are reduced. Open-cell metallic foams are optimum 3D supports, the main challenge is achieving similar performances with structured catalysts compared to pelletized ones. The catalyst performance is determined by the composition, thickness and adhesion of the coating, as well as stability of the metallic support under reaction conditions. The amount of active species (mainly Rh) is controlled by pore size, layer thickness and active phase loading; while its dispersion and stability depends on the preparation method and oxide support.

Rh catalysts, coated on FeCrAlloy foams for the CPO of CH_4, were prepared by thermal decomposition of electrosynthesized hydrotalcite-type (HT) compounds [2,3], since the latter compounds give rise to catalysts with small and stable Rh^0 particles. The FeCrAlloy foam was used as working electrode in an electrochemical cell containing Rh^{3+}, Mg^{2+} and Al^{3+} nitrates; the pH required for the HT compound precipitation on the foam surface was generated by the reduction of these nitrates. However, to balance the formation of thin layers, during the optimization of the synthesis parameters, high loaded Rh solutions were used, leading to the formation of large Rh particles [3]. Here, the metal particle size distribution, coating thickness and activity of Rh-structured catalysts were optimized by modifying the Rh/Mg/Al atomic ratio percent (a.r.%), total metal concentration and inclusion of Ni as second active phase.

2 Experimental

Electrosyntheses were performed in a three-electrode single-compartment cell on 60 ppi FeCrAlloy foam cylinders (1.0 x 1.19 cm) at -1.2 V vs SCE for 2000 s [3]. The electrolytic solution contained $Mg(NO_3)_2$, $Al(NO_3)_3$, $Rh(NO_3)_3$ or $Ni(NO_3)_2$ with 0.03M total concentration, varying the atomic ratios: Rh/Mg/Al = 11/70/19, 5/70/25, 2/70/28 a.r.% or Rh/Ni/Mg/Al = 5/15/55/25 a.r.%. Syntheses with the 5/70/25 a.r.% solution were also performed with total concentrations of 0.06 or 0.10M. Catalysts were obtained by calcination at 900 °C for 12 h. Samples were characterized by SEM/EDS, FEG-SEM and μXRF/XANES at ID21 beamline (ESRF). CPO of CH_4 tests were performed, after catalyst reduction at 750 °C for 2 h, at T_{oven}=750 °C, GHSV = 11,500-63,300 h^{-1}, CH_4/O_2/He = 2/1/20 or 2/1/4 v/v.

3 Results and discussion

The same general features were observed in electrosynthesized samples regardless of the Rh/Mg/Al a.r.% in the solution: i) the foam surface was almost entirely coated by a solid (Fig. 1a); ii) preferential precipitation on the tips of the struts, resulting in a 5-15 μm film; iii) the initial deposition of a film with a composition close to the expected one, followed by the precipitation of a film enriched in Al and Rh.

The Rh content in the precipitated solid correlated with the Rh loading in the solution. Hence, the amount of Rh species in calcined samples, identified as $Mg(Rh_xAl_{1-x})_2O_4$ by μXANES (Fig. 1b), and the Rh particle size and dispersion in spent catalysts depended both on the Rh content and layer thickness. Smaller and highly dispersed particles were observed by decreasing the Rh concentration and in thin layers. A narrow particle size distribution centred at 10 nm was measured for the spent Rh/Mg/Al = 2/70/28 a.r. % (Fig. 1c). However, the CH_4 conversion to syngas was negatively affected by the lower amount of active sites in the coating. Conversion values were 92, 85 and 72% for Rh/Mg/Al = 11/70/19, 5/70/25 and 2/70/28 a.r.%, respectively, at $CH_4/O_2/He$ = 2/1/20 v/v and 15,250 h^{-1}. The high metal support interaction that decreased the Rh reducibility, the possible oxidation of metallic particles during concentrated tests and carbon formation also determined the catalytic performances.

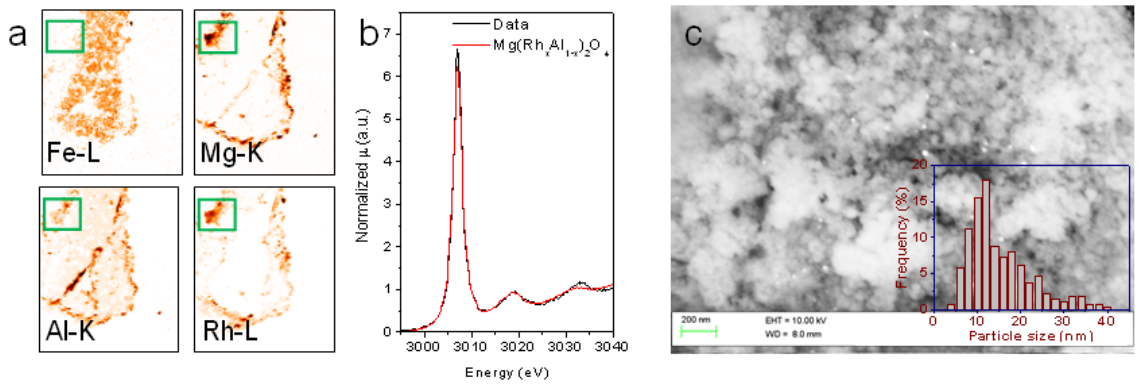

Fig. 1. Rh/Mg/Al= 2/70/28 a.r.% sample. Elemental XRF maps (a) and Rh-L_3 XANES spectrum (b) of fresh catalyst; FEG-SEM image and particle size distribution (c) of spent catalyst.

By increasing the total metal concentration from 0.03 to 0.06 M with the Rh/Mg/Al = 5/70/25 a.r.% solution a larger amount of solid containing well dispersed Rh particles was deposited and catalytic performances enhanced (Conv. CH_4 = 92 %, $CH_4/O_2/He$ = 2/1/20 v/v, 15,250 h^{-1}). On the contrary, a further increase in the concentration to 0.1M had a negative effect on coating properties.

The inclusion of Ni as second active phase produced very active RhNi bimetallic catalysts, CH_4 conversion and selectivity to syngas were above 90 % for all the reaction conditions, although it showed a lower stability with time-on-stream.

4 Conclusions

Catalysts with smaller, more dispersed and stabilized Rh metallic particles in the coating, and therefore improved catalytic performances, were prepared by tailoring the Rh content and concentration of metals in the electrolytic solution. The formation of bimetallic RhNi particles largely increased the activity, although the stability has to be still improved.

Keywords: Beta, MCM-22, Core-shell, Composite, zeolite, Plasma

1 Introduction

Alkylation of benzene with propylene is an industrially important reaction for the production of isopropylbenzene, an intermediate for the production of acetone and phenol. Beta and MCM-22 zeolites as solid acid catalyst, have been successfully applicated in the processes of alkylating benzene with propylene to form isopropylbenzene[1,2]. A comparative study with Beta and MCM-22 zeolites to product cumene showed that beta has a little more active and less stable than MCM-22[3], although they are excellent catalyst. Recently, composite zeolites, Y/Beta, Y/ZSM-5 and ZSM-5/SAPO-11, have been receiving much more attention especially in the field of petroleum pro-cessing and deep processing of petrochemical products, owing to its bimicroporous structures and adjustable composite acidities [4-6].

In this paper, a briefly study to obtain core-shell Beta/MCM-22 micro-microporous composite zeolites is reported. We expect it will have an advanced physical structure and exhibit higher activity and selectivity in the reaction of alkylation of benzene with propylene.

2 Experimental

Beta/MCM-22 composites were produced by conventional hydrothermal process. Chemical materials, silicasol, $NaAlO_2$, NaOH, HMI and Beta zeolites were purchased. Beta calcined in air at 300℃ for 3h, were pretreated through the Ar-H_2 plasma (50W, H_2/Ar=1.25, 70mTorr) at room temperature using Gatan 950 plasma system [7]. The typical batch composition in terms of molar ratio was: SiO_2: Al_2O_3: OH-: HMI: H_2O=1: 0.033: 0.10: 0.35: 25, Beta excluded here.

The As-synthesized powders calcined at 550℃ in air for 5h in a muffle furnace to remove organics, were charactered via various methods such as XRD, SEM, TEM, FT-IR.

3 Results and discussion

The XRD patterns of Beta, plasma-pretreated Beta, MCM-22, and Beta/MCM-22 are shown in Fig. 1. The patterns of both Beta zeolites are in good agreement with those reported previously, indicating plasma treating does not damage the crystalline structure of Beta. The patterns of Beta/MCM-22 are very complex. The peaks at 7.7°, 21.7°, 22.4°, 25.4°, 26.8° and 29.6°were assigned to the diffraction of Beta- rays, while these peaks at 7.1°, 7.2°, 8.1°, 10.0°, 14.2°, 26.1° and 28.1° can be assigned to MCM-22.

SEM and TEM results as shown in Fig. 2. The images of the composite with uniform morphology are obviously different from the Beta zeolites which look smooth (Fig. 2b). The surface morphology of the composite shows flakes similar to MCM-22 in Fig. 2c and 2d. The results of EM exhibit the Beta/MCM-22 composite core-shell structure instead of physical mixture.

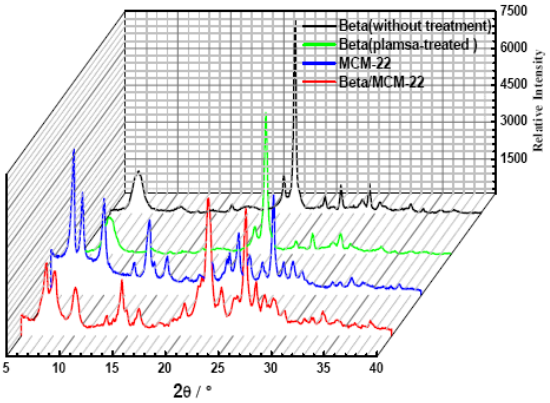

Fig. 1. XRD patterns of Beta, plasma-treated Beta, MCM-22, and Beta/MCM-22 zeolites

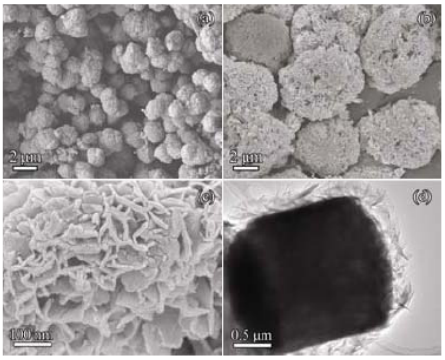

Fig. 2. SEM and TEM images of Beta (a) and Beta/MCM-22 zeolites(b, c, and d)

Brönsted acidity is a key factor controlling catalytic performance of zeolites in many technological processes. The Brönsted acid strength and distribution of the composite are shown in table 1. The total acid amounts of Beta/MCM-22 are between Beta and MCM-22. However, Medium acidity distribution of the composite reaches 40.1% higher than Beta and MCM-22, 30.0%, 38.2%, respectively. It is positively amazing for us to find CB/CL amount to13.8, which may signify the transfer of the "Al" in Beta and MCM-22 zeolites.

In brief, the reasons for our uniform Beta/MCM-22 composite zeolites attribute to the surface energy, Si-OH groups and surficial positive charges of Beta zeolites, which pre-treated by Ar-H_2 plasma.

Table 1. Acid distribution of Beta, MCM-22 and composite zeolites

Acid distribution	Beta		MCM-22		MCM-22\ Beta	
	%	$C_B\backslash C_L$	%	$C_B\backslash C_L$	%	$C_B\backslash C_L$
Total acidity (mmol/g)	0.63	1.09	0.91	3.53	0.74	2.56
160-250℃(weak)	29.0	1.27	17.4	3.27	17.7	1.76
250-350℃(medium)	30.0	1.21	38.2	5.33	40.1	13.8
350-450℃(strong)	41.0	0.99	44.4	2.71	42.2	1.64

4 Conclusions

The core-shell Beta/MCM-22 composite zeolites were successfully synthesized by hydrothermal synthesis. Beta and MCM-22 zeolites acted as core and shell, respectively. The total acid amount of Beta/MCM-22 is between Beta and MCM-22, and the medium strength distributions of the Brönsted acid are reinforced accompanying with the proportional relations of Brönsted and Lewis increased markedly to 13.80.

In Situ Hydrogenation and Desulfurization of Heavy Hydrocarbon Feedstocks with Addition of Zinc in Supercritical Water Flow

Fedyaeva O.N.*, Vostrikov A.A.

Kutateladze Institute of Thermophysics SB RAS, Novosibirsk, Russia

* fedyaeva@itp.nsc.ru

Keywords: supercritical water, hydrocarbon feedstocks, hydrogenation, desulfurization

1 Introduction

Continuous increase in energy consumption and exhaustion of natural reserves of light oils contribute to both the searching for alternative sources of hydrocarbons and the development of new energy-efficient and environmentally friendly methods of upgrading. Recently, much attention has been paid to the involvement of heavy oil and bitumen with high viscosity, high asphaltene and heteroatom content into the energy production and petrochemical synthesis. One of the ways to upgrade the heavy hydrocarbon feedstocks (HCFs) is their conversion in supercritical water (T>374°C, P>22.1 MPa).

2 Experimental

The results of investigation of effect of zinc shavings additives (the weight ratio of zinc to HCFs organic matter corresponds to an increase in H/C atomic ratio in the products and residue to ≈2) on conversion of oxygen-free bitumen [1], sulfur-rich asphaltite [2], and liptobiolith coal [3] in supercritical water flow (400°C, 30 MPa) and also the results [4] of zinc sulfidation by supercritical hydrogen sulfide without and with addition of water (400°C, P^0_{H2S}=11.8-15.2 MPa) are presented. When zinc is added, hydrogenation of HCFs is possible owing to hydrogen evolution during zinc oxidation by supercritical water. The oxidation occurred via ZnO nanoparticles formation in terms of the following reaction [5]:

$$Zn + (H_2O)_g = ZnO + H_2, \qquad \Delta H^0_{298} = -109 \text{ kJ/mol.} \qquad (1)$$

Degree of HCFs hydrogenation by hydrogen evolved during zinc oxidation by supercritical water is determined based on the hydrogen balance by means of the equations below:

$$\delta = \{([H]_L+[H]_V+[H]_R-[H_2]- [H]_0)/[H]_0\}\cdot 100\%, \qquad (2)$$

where $[H]_L$, $[H]_V$, $[H]_R$ and $[H]_0$ is the weight of hydrogen in the liquid and volatile products, conversion residue and raw HCF, respectively; $[H_2]$ is the weight of molecular hydrogen. It was found that the δ value decreases in the following series: C > A > B and corresponds to decrease in the weight ratio of metal to HCFs organic matter m_{Zn}/m_{HCF} (Table). As a whole, hydrogen and heat evolution during the reaction (1) provided for a significant increase in the yield of light hydrocarbons and increase in the oils fraction in HCFs liquid conversion products.

Table 1. Degree of hydrogenation (δ) and desulfurization (ψ) of bitumen, asphaltite and liptobiolith coal at their conversion with addition of zinc in supercritical water

HCF	Gross-formula	m_{Zn}/m_{HCF}, g/g	δ, %	ψ, %
Bitumen (B)	$CH_{1.56}N_{0.02}S_{0.006}$	1.02	13.5 ± 1.4	13 (7)*
Asphaltite (A)	$CH_{1.23}N_{0.02}S_{0.038}O_{0.02}$	1.77	30.1 ± 2.7	60 (21)
Coal (C)	$CH_{1.17}N_{0.005}S_{0.007}O_{0.04}$	1.96	36.4 ± 3.1	42 (−)

*In parentheses are the ψ values calculated for HCFs conversion without addition of zinc.

It is shown that addition of zinc shavings to sulfur-rich asphaltite resulted in significant decrease in the amount of H_2S in the volatile products during asphaltite pyrolysis (T≤400°C). During conversion of bitumen, asphaltite, and coal with addition of zinc shavings in

supercritical water flow the desulfurization degree ψ (the weight portion of sulfur atoms of raw HCFs passed into ZnS) of conversion products increases (Table). It is revealed that at supercritical water conversion of HCFs the bulk of sulfur atoms located in the aliphatic C−S bonds passes into H_2S. The desulfurization of conversion products is caused by the interaction of H_2S with zinc and zinc oxide formed by the reaction (1) in situ as a result of the following reactions:

$$Zn + (H_2S)_g = ZnS + H_2, \qquad \Delta H^0_{298} = -184 \text{ kJ/mol}, \qquad (3)$$

$$ZnO + (H_2S)_g = ZnS + (H_2O)_g, \qquad \Delta H^0_{298} = -76 \text{ kJ/mol}. \qquad (4)$$

3 Results and discussion

It is found out that ZnS nanoneedles with the diameter up to 100 nm and length up to 3 μm are synthesized at zinc sulfidation by H_2S, while the equiaxial ZnS and ZnO nanoparticles with the size up to 200 nm are formed in the presence of water. In the presence of water the average specific rate of ZnS formation calculated per unit of geometric surface of the zinc initial sample is increased by more than two orders of magnitude compared with the rate of zinc sulfidation by supercritical H_2S. This effect is caused by the fact that the rate of ZnO nanoparticles synthesis in the reaction (1) is higher than that of ZnS nanoparticles in the reaction (3). Also, it consists in the regeneration of water by the reaction (4) and its subsequent participation in ZnO nanoparticles synthesis resulting in continuous increase in the ZnO contact surface with H_2S.

Keywords: catalyst, zeolite, conversion, nanoparticles, aromatization

1 Introduction

Natural and associated petroleum gases are the most important potential sources for production of valuable petrochemical products including those of organic synthesis. A development of one-step catalytic process for conversion of methane, the main component of natural and associated gases, into aromatic compounds is important to solving the problem of their rational use and environmental protection. Dehydroaromatization of methane is effective due to the use of catalytically active high silica zeolites modified with transition metal ions. Regarding that the zeolite H-ZSM-5 containing molybdenum exhibit higher CH_4 conversion and selectivity to benzene than other type's zeolites. Generally, the catalysts are produced via zeolite impregnation by metal salt solution or via mechanical mixing of a zeolite with a metal oxide. The purpose of the present investigation is to examine the influence of different Mo forms and the method for their introduction into the zeolite matrix on acidic properties, catalytic activity and stability of Mo/ZSM-5 catalysts in the process of methane dehydroaromatization (DHA) under non-oxidative conditions. Using high-resolution transmission electron microscopy (HRTEM) and energy-dispersive X-ray (EDX) spectroscopy, we studied the nature and distribution of active sites on the surface of Mo/ZSM-5 catalysts.

2 Experimental

Catalysts were prepared by mechanically mixing zeolite ZSM-5 with the molar ratio SiO_2/Al_2O_3 = 40 and nanosize powders of Mo (K-1), MoO_3 (K-2), Mo_2C (K-3) and MoO_3 reagent grade (K-4) in KM-1 vibratory ball for 2 h. Thereafter, the resulting mixtures were calcined at 540 ^oC for 4 h. The Mo nanopowder was prepared by electric explosion of wires in an argon atmosphere. MoO_3 и Mo_2C samples were prepared on the basis of Mo nanopowders. Catalyst sample (K-5) were prepared by zeolite impregnation with an acidified solution of $(NH_4)_6Mo_7O_{24}$. The concentration of Mo in the zeolite was 4.0 wt %.

The nonoxidative conversion of methane (99.99% purity) was performed in a flow setup at 750°C and atmospheric pressure. A catalyst sample (1.0 cm^3) was placed in a quartz tube reactor 12 mm in diameter. Before the onset of reaction, the catalyst was heated to 750°C in a flow of helium and kept for 20 min at this temperature; thereafter, methane was supplied at a space velocity of 1000 h^{-1}. The reaction products were determined by gas chromatography. The acid characteristics of the samples were studied by the temperature-programmed desorption (TPD) of ammonia, which allowed us to determine the strength distribution and concentration of acid sites. Specific surface area and pore volume of the samples was obtained by BET method at liquid-nitrogen temperature with a Micromeritics ASAP-2020 instrument. All the date were collected and processed by an IBM computer.

HR TEM images were obtained on a JEM-2010 electron microscope (JEOL, Japan) with a lattice resolution of 0.14 nm at an accelerating voltage of 200 kV. The high-resolution images of regular structures were analyzed using the Fourier method. Energy-dispersive X-ray analysis (EDX) on an EDAX spectrometer (EDAX Co.) equipped with a Si(Li) detector with an energy resolution of no worse than 130 eV was used to perform the local elemental analysis of the

samples. The samples for HR TEM were prepared on perforated carbon substrates fixed on copper gauzes.

3 Results and discussion

The acid characteristics of the samples show that the initial HZSM-5 has the greatest amount of acidic sites, which may be attributed to two types: weak acidic and strong acidic sites. At the introduction of Mo in a zeolite a reduction of the concentration of acidic sites of both types occurs and the decrease in the amount of strong acidic sites, especially at nanopowder of Mo, is the most marked. The decrease in the concentration of acidic sites in modified zeolites is probably determined by the interaction between OH groups connected with lattice Al and Mo forms during calcinations. Thus, the modification of a zeolite catalyst by molybdenum result in the change of its acidic properties and to the formation of novel active and inactive sites connected with different Mo forms. Comparison between the BET surface area and pore volume of the HZSM-5 and Mo/HZSM-5 indicate that the surface area and pore volume of initial zeolite are large than that of modified zeolites. Thus, it was show that the BET surface areas and the pore volumes decrease for Mo/ZSM-5 catalysts.

The methane conversion curves for Mo/ZSM-5 catalysts prepared by different method are presented in Fig.1. The catalyst prepared by zeolite mixing with the nanosized Mo powder exhibited the highest activity. With this catalyst, the methane conversion reached its maximum (16.7%) in 20 min and then gradually decreased. The catalyst obtained by zeolite impregnation with an acidified solution of $(NH_4)_6Mo_7O_{24}$ was somewhat less active, and the lowest activity was observed for the catalyst prepared by dry mixing of the zeolite with Mo_2C and MoO_3.

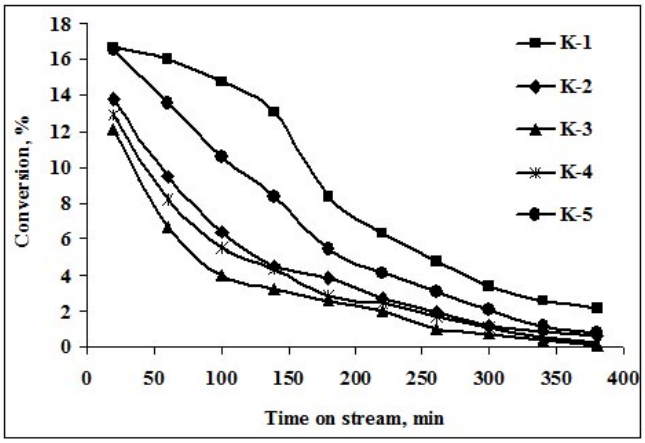

Fig. 1. Changes in the methane conversion during DHA on the 4.0% Mo/ZSM-5 catalysts

In accordance with HRTEM date in the Mo/ZSM-5 catalyst Mo is stabilized at least in two forms. The first form consists of 2-to 10-nm Mo_2C particles stabilized on the outer surface of the zeolite. The second form consists of clusters of oxidized Mo, which are detected in Mo/ZSM-5 channels.

4 Conclusions

Thus, our study showed that the method of Mo introduction into the zeolite is important for the preparation of the Mo/ZSM-5 catalysts. The most active catalyst samples were obtained with nanosized Mo powder, which is probably due to its more uniform distribution on the zeolite surface upon mechanical stirring and to its small particle size, facilitating its penetration into the zeolite channels during calcinations and during the DHA reaction.

Reaction Mechanism of Dry Reforming of Methane on Rh Doped Pyrochlore Catalysts: a DFT Approach

Polo-Garzon F., Bruce D.A.*

Department of Chemical and Biomolecular Engineering, Clemson University, USA

* dbruce@clemson.edu

Keywords: dry reforming of methane, syngas, pyrochlore, DFT, reaction mechanism

1 Introduction

The dry reforming of methane (DRM) using CO_2 has long been considered a viable method for converting methane from geological or biological sources into syngas, which can then be readily used in the production of a variety of chemicals and particularly liquid fuels that can more readily be shipped via pipeline. Though DRM holds great promise, the high temperatures required for the reaction have made it very difficult to find catalysts that exhibit high activity for extended periods. To date, many catalyst materials have been investigated for this reaction. In this study, however, we have chosen to develop optimized pyrochlore catalyst materials. [1]

Pyrochlores are crystalline oxides having high thermal stability and a general formula of $A_2B_2O_7$, where *A* represents a rare-earth metal and *B* represents a transition metal. Initial experimental efforts by others showed that pyrochlores are active for DRM but the tested catalysts exhibited poor long term stability [2]; however, more recent data suggest that this trend in deactivation may not be applicable to all pyrochlores. $La_2Zr_2O_7$ (LZ) is a pyrochlore structure which has shown good long term stability, so that efforts have been made to tailor its catalytic properties, showing Rh as a promising dopant to enhance catalytic performance for DRM [3, 4]. In order to determine the role of Rh in the reaction performance and understand how the reaction proceeds, we are using first principles methods employing Density Functional Theory (DFT) to analyze structural stability, species adsorption, and calculate transition state energies for the elementary reaction steps on this catalyst material.

2 Experimental/methodology

Computational: First principles calculations were performed employing the Vienna *ab initio* simulation package (VASP), which is based on a plane-wave DFT code. The exchange correlation functional used is the generalized gradient approximation using the implementation of Perdew, Burke and Ernzerhof (GGA-PBE). Activation energies were calculated for selected elementary reactions using the climbing image nudged elastic band method (CI-NEB) and the remaining activation energies were estimated by a Bronsted-Evans-Polanyi (BEP) relation derived from our DFT data.

Experimental: The catalyst synthesis is performed using the modified Pechini method. The metal precursors (for La, Zr, Rh) were the corresponding nitrates. After the appropriate heat treatment is carried out on the material, characterization is performed by means of XRD, SEM and EDX.

3 Results and discussion

Fig. 1 shows the main reaction pathway on two different planes of the pyrochlore. These pathways were identified by means of the activation energies of a proposed reaction network (not shown). On the one hand, the plane (011) appears as inactive for DRM. More specifically, on the plane (011), the carbon atom proceeding from gaseous CH_4 is unable to fully

dehydrogenate to form CO. Thus, this plane is poisoned by unreacted carbon proceeding from CH_4, and H_2 production is limited to the point at which the catalytic sites are covered by partially oxidized carbon species.

On the other hand, the plane (111) provides a lower activation energy (ΔE_{act} = 2.38 eV) route for CHO dehydrogenation to produce CO, compared to the barrier on the plane (011) (ΔE_{act} = 3.08 eV). Along with this barrier reduction, most of the steps on plane (111) possess lower activation barriers compared to the plane (011), and more species (CH_2, CH_2O, CHO, CO, COOH) present their most stable configurations on Rh-containing active sites compared to the plane (011) (CHOH).

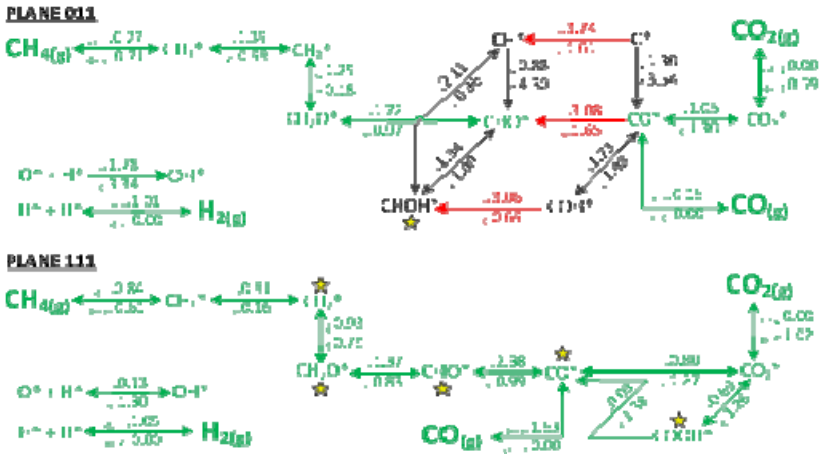

Fig. 1 Main reaction pathway on plane (011) and plane (111) for the 2 wt% Rh-substituted LZ. The values above, below and next to the arrows are activation energies in eV.

The stars (☆) represent active sites where Rh is present.

4 Conclusions

The reported CH_4 and CO_2 conversion at 550 °C at 1 atm and GHSV = 48,000 mL/g_{cat}/h, after 200 min time on stream, are 12.3% and 19.7% respectively. This difference in conversion having a stoichiometric feed is due to certain amount of CH_4 bypassing the catalytic sites, the identified reaction pathway suggests that the CH_4 dehydrogenation is a slower process compared to the CO_2 dissociation, which is reflected in the H_2 to CO ratio 44:100 found experimentally, being this ratio 1:1 theoretically. [3]. Identifying the CHO dehydrogenation as a key step and showing the importance of Rh in the reaction mechanism elucidates a way to improve the reaction performance by looking at new dopants that specifically target the CHO dehydrogenation step.

1 Introduction

This paper studies the catalytic activity of transition metal nanoparticles - nickel and copper obtained by different methods in the hydrogenation of unsaturated and aromatic hydrocarbons.

2 Experimental

Nickel nanoparticles were deposited on silohrom C-120. Part of the nickel nanoparticles was pretreated with AOT (sodium bis (2-ethylhexyl) sulfosuccinate) / heptane in the presence of ammonia (C-120-AOT-Ni-NH_3-D). Another part of the nanoparticles deposited on silohrom without prior impregnation (C-120-AOT-Ni-D). Specific surface of the samples are presented in Table 1.

Table 1. The specific surface area of catalysts containing nickel nanoparticles.

samples	S, m^2/g
C-120	150
C-120-AOT-Ni-D	147
C-120-AOT-Ni-NH_3-D	141

Hydrogenation of octene-1 was conducted on nickel nanoparticles with impulse method by introduction reactant into the column-reactor.

Copper nanoparticles obtained Levitation-jet [1] method were deposited to inerton. Hexyne-1 was hydrogenated with this catalyst in static. This reaction was realized with our original device that provided a direct injection to a chromatographic column.

3 Results and discussion

In this work, the rate constants and activation energies of the reactions were determined.

The rate constants were determined by changing the peak areas of reactants and products. Fig. 1 shows the chromatogram of the reaction mixture after the hydrogenation of hexyne-1 with copper nanoparticles after 10 min. from start of the reaction.

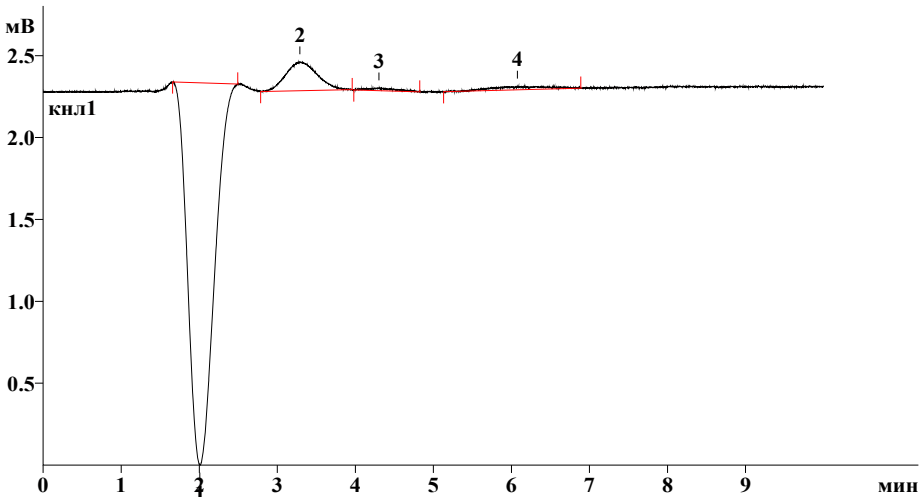

Fig. 1. Chromatogram of the reaction mixture after the hydrogenation of 1-hexyne with copper nanoparticles after 10 min. from the start of the reaction. T = 363 K. 1- hydrogen 2 - hexane, 3 – hexene-1, 4 – hexyne-1.

Table 2 shows the rate constant of hydrogenation of octene-1 with the catalysts containing nickel nanoparticles.

Dehydration of Alcohols over Heteropoly Acid Catalysts in the Gas Phase

Alharbi W., Brown E., Kozhevnikova E., Bond G., Kozhevnikov I.*

University of Liverpool, Liverpool, United Kingdom

* kozhev@liverpool.ac.uk

Keywords: alcohol, dehydration, dimethyl ether, diethyl ether, acid catalysis, heteropoly acid

1 Introduction

Dehydration of methanol and ethanol has attracted much interest in the context of sustainable development, not only to produce hydrocarbons from non-petroleum feedstock but also to produce dimethyl (DME) and diethyl (DEE) ethers (eq. 1 and 2) [1]. These ethers, especially DME, are expected to play important role in the future energy sector as clean fuel alternatives. The dehydration reaction is usually carried out in the gas phase in the presence of solid acid catalysts such as metal oxides and zeolites.

$$2\,CH_3OH \longrightarrow (CH_3)_2O + H_2O \qquad (1)$$

$$2\,CH_3CH_2OH \longrightarrow (CH_3CH_2)_2O + H_2O \qquad (2)$$

Here we report the dehydration of methanol and ethanol at a gas-solid interface over a wide range of solid Brønsted acid catalysts based on Keggin-type heteropoly acids (HPAs), focussing on the formation of DME and DEE. The catalysts included $H_3PW_{12}O_{40}$ (HPW) and $H_4SiW_{12}O_{40}$ (HSiW) supported on SiO_2, TiO_2, Nb_2O_5 and ZrO_2, as well as bulk acidic Cs salts of HPW. Isopropanol dehydration was also studied in order to gain mechanistic insights.

2 Experimental

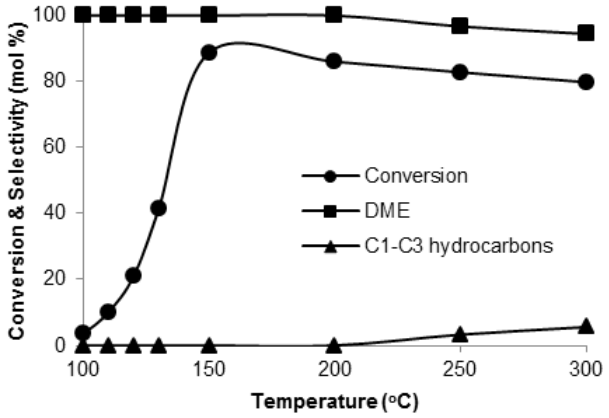
Details on catalyst preparation, characterization (BET, ^1H and ^{31}P MAS NMR, XRD, FTIR and NH_3 adsorption microcalorimetry) and catalyst activity testing are given elsewhere [2-4]. The dehydration of alcohols was studied in a continuous flow fixed-bed reactor in the temperature range of 90-300°C and alcohol partial pressure of 1-17 kPa in nitrogen flow.

3 Results and discussion

DME and DEE are the thermodynamically favored products and predominantly form at lower temperatures, whereas increasing reaction temperature leads to formation of hydrocarbons at the expense of ethers. Fig. 1 and 2 show the effect of temperature on alcohol conversion and product selectivity for alcohol dehydration over 15%HSiW/SiO_2. The conversion of methanol reaches equilibrium value 89% at 150°C, with a slight decline at higher temperatures probably due to catalyst coking. DME is the only product up to 200°C, with C_1-C_3 hydrocarbons also forming at higher temperatures (Fig. 1). Similarly, ethanol conversion reaches 100% at 180°C with high DEE selectivity at 90-120°C and ethane becoming the main product at higher temperatures (Fig. 2). The catalyst showed very good performance stability; no catalyst deactivation was observed at 120-150°C for at least 20 h time on stream. In these reactions, the HPA catalysts exhibit significantly higher activity than zeolite HZSM-5 due to the stronger acidity of HPA. With HPA, full alcohol conversions are reached at temperatures about 50°C lower than with HZSM-5.

The formation of DME and DEE may be represented by two different pathways termed the associative pathway and the dissociative pathway [5]. Both pathways are thought to involve

alcohol adsorption on Brønsted acid sites. Under the conditions studied, the dehydration of alcohols was zero order in alcohol, i.e., catalyst active sites were saturated with alcohol. This allowed for easy determination of catalyst turnover frequencies (TOF). The acid strength of HPA catalysts was determined by ammonia adsorption microcalorimetry in terms of the initial adsorption enthalpy. A fairly good correlation between the catalyst activity (TOF) and the catalyst acid strength was established (Fig. 3), which demonstrates that Brønsted acid sites indeed play important role in these reactions over HPA catalysts.



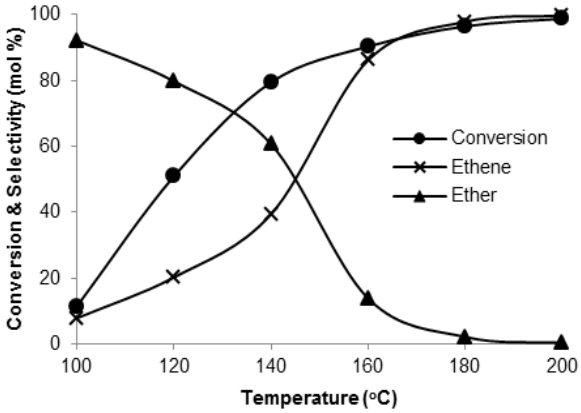


Fig. 1 (left). Effect of temperature on methanol dehydration over 15%HSiW/SiO_2 (0.2 g catalyst, 3.83 kPa MetOH partial pressure, N_2 carrier gas, 20 mL min^{-1} flow rate).

Fig. 2 (right). Effect of temperature on ethanol dehydration over 15%HSiW/SiO_2 (0.2 g catalyst, 1.48 kPa EtOH partial pressure, N_2 carrier gas, 20 mL min^{-1} flow rate) [2].

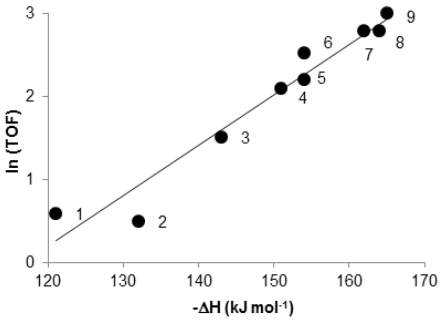

Fig. 3. Plot of ln (TOF) for ethanol dehydration (TOF in h^{-1}) over HPA catalysts at ethanol conversion range $X = 0.07 – 0.53$ vs. initial heat of NH_3 adsorption (120 °C, 0.2 g catalyst, 1.48 kPa ethanol partial pressure, N_2 carrier gas, 20 mL min^{-1} flow rate): (1) 15%HPW/ZrO_2, (2) 15%HPW/Nb_2O_5, (3) 15%HPW/TiO_2, (4) 15%HPW/Cs_3PW, (5) 15%HSiW/SiO_2, (6) 15%HPW/SiO_2, (7) $Cs_{2.25}H_{0.75}PW$, (8) $Cs_{2.5}H_{0.5}PW$, (9) 25%HPW/Cs_3PW.

Kinetics of isopropanol dehydration over HPA catalysts was also studied in order to gain mechanistic insights. The kinetic results and ^1H MAS NMR catalyst characterization point to different chemical structure of Brønsted acid sites in bulk and supported HPA catalysts, resulting in differing reaction mechanisms [4].

4 Conclusions

Solid Brønsted acid catalysts based on Keggin-type HPAs show high activity in the methanol-to-DME and ethanol-to-DEE dehydration reactions in the gas phase. The activity (TOF) of the HPA catalysts correlates with the catalyst acid strength.

I-PP07

Hydrodeoxygenation of Biomass-derived Ketones over Bifunctional Metal-acid Catalysts in the Gas Phase

Alharbi K., Alotaibi M., Kozhevnikova E., Kozhevnikov I.*

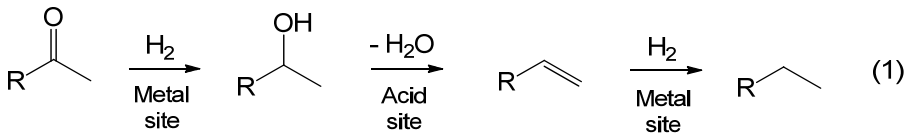
University of Liverpool, Liverpool, United Kingdom

* kozhev@liverpool.ac.uk

Keywords: ketone, hydrodeoxygenation, platinum, zeolite, heteropoly, acid, bifunctional catalysis

1 Introduction

Oxygen-containing organic compounds such as ketones, carboxylic acids, alcohols, phenols, etc., readily available from natural resources, are attractive as renewable raw materials for the production of value-added chemicals and biofuels [1]. For fuel applications, they require reduction in oxygen content to increase their caloric value. Much current research is focussed on the deoxygenation of organic oxygenates using heterogeneous catalysis, in particular for the upgrading of biomass-derived oxygenates obtained from fermentation, hydrolysis, and fast pyrolysis of biomass. Biomass-derived ketones can be further upgraded by aldol condensation and hydrogenation to produce alkanes that fall in the gasoline/diesel range. Hydrogenation of ketones on supported metal catalysts (e.g., Pt/C) to form alcohols is feasible, but further hydrogenation to alkanes is rather difficult to achieve on such catalysts. The ketone-to-alkane hydrogenation can be achieved much easier using bifunctional metal-acid catalysts ([2-4] and references therein).This process occurs via a sequence of steps involving hydrogenation of ketone to alcohol on metal sites followed by dehydration of secondary alcohol to alkene on acid sites and finally hydrogenation of alkene to alkane on metal sites (eq. 1).



(1)

Here, we report on hydrogenation (hydrodeoxygenation) of a variety of aliphatic and aromatic ketones in the gas phase using bifunctional metal-acid catalysts comprising a metal (Pt, Ru, Ni, Cu) supported on acidic caesium salt of tungstophosphoric heteropoly acid $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (CsPW) and Pt supported on zeolites (HZSM-5, HY, HBeta). It is demonstrated that 0.5%Pt/CsPW is a highly efficient and versatile catalyst for the ketone-to-alkane hydrogenation, and an insight into reaction mechanism is gained.

2 Experimental

Details on catalyst preparation, characterization (BET, XRD, H_2-TPR and metal dispersion) and catalyst activity testing using a continuous flow fixed-bed reactor are given elsewhere [2-4].

3 Results and discussion

It was found that the activity of CsPW-supported metal catalysts in ketone hydrohenation decreased in the order: Pt > Ru >> Ni > Cu. Pt/CsPW showed the highest catalytic activity, giving in most cases almost 100% alkane yield at 100°C and 1 bar H_2 pressure (Table 1).

Table 2 shows the hydrogenation of methyl isobutyl ketone (MIBK) using Pt supported on zeolites and CsPW. Amongst the Pt/zeolite catalysts studied, Pt/H-ZSM-5 clearly stands out giving >99% selectivity to methylpentanes at 100% MIBK conversion at 200°C. The Pt/H-ZSM-5 catalyst showed excellent performance stability. It reached steady state in about 2 h and

operated without deactivation for at least 16 h [2]. 0.5%Pt/CsPW exhibited even higher activity, with stable performance for at least 14 hours on stream, yielding 99% of 2-methylpentane (2MP) at 100°C, with 100% 2MP selectivity at ≥ 99% MIBK conversion [3]. This is in agreement with the stronger acidity of CsPW compared to zeolites. Importantly, no 2MP isomerisation was observed at this temperature, thus allowing synthetically viable complete transformation of ketone to alkane without carbon backbone alteration.

Evidence was obtained that these reactions occur via the bifunctional mechanism (eq. 1), with the rate-limiting step of ketone hydrogenation on metal sites, followed by fast alcohol dehydration and olefin hydrogenation [2-4].

Table 1. Hydrogenation of ketones over 0.5%Pt/CsPW [4].[a]

Ketone	Conversion (%)	Selectivity (mol%)		
		Alkane	Alcohol	Other[b]
Acetone	98	87	9	4
2-Butanone	100	99	0	1
3-Pentanone	100	100	0	0
2-Hexanone	100	99	0	1
MIBK	100	100	0	0
Cyclohexanone	99	99	0	1
2-Octanone[c]	95	98	0	2
Diisobutyl ketone	99	93	0	7
Acetophenone	78	98	0	2[d]

[a] Reaction conditions: 100°C, 0.2 g catalyst, 2.0% ketone in H_2 flow, 1 bar pressure, 20 mL min^{-1} flow rate, 3 h time on stream, catalyst pre-treatment at 100 °C/1 h in H_2 flow. [b] C_1-C_5 cracking products together with small amount of ketone condensation products. [c] 5 h time on stream. [d] Ethylbenzene.

Table 2. Hydrogenation of MIBK over bifunctional catalysts [2,3].[a]

Catalyst	Temp. (°C)	Conv. (%)	Selectivity (%)			
			2MP	3MP	MP-ol[b]	Other
H-ZSM-5	200	20	9	0	7	84[c]
0.30%Pt/H-ZSM-5	100	94	65	0	34	1
0.30%Pt/H-ZSM-5	200	100	83	17	0	0
0.39%Pt/H-Beta	200	44	70	4	0	26[d]
0.45%Pt/H-Y	200	81	55	2	0	43[d]
0.50%Pt/CsPW	100	99	100	0	0	0
0.50%Pt/CsPW	200	95	88	12	0	0

[a] 0.2 g catalyst, 3.6% MIBK in H_2, 20 ml/min flow rate, 4 h time on stream. [b] 4-Methyl-2-pentanol. [c] C_1-C_5 cracking products and C_{6+} condensation products. [d] Mainly C_{6+} condensation products.

4 Conclusions

Aliphatic and aromatic ketones can be efficiently hydrogenated under mild conditions via metal-acid bifunctional pathway on a single bed containing 0.5%Pt/CsPW catalyst to give the corresponding alkanes a high yield.

Ketonisation of Carboxylic Acids over Metal Oxide and Zeolite Catalysts in the Gas Phase

Bayahia H., Kozhevnikova E., Kozhevnikov I.*

University of Liverpool, Liverpool, United Kingdom

* kozhev@liverpool.ac.uk

Keywords: ketonisation, carboxylic acid, heterogeneous, catalysis, Zn-Cr oxide, silicalite

1 Introduction

Carboxylic acids, readily available from natural resources, are attractive as renewable raw materials for the production of value-added chemicals and bio-fuels [1]. Ketonisation of carboxylic acids, 2 RCOOH → $R_2CO + CO_2 + H_2O$, is employed as a clean method for the synthesis of ketones and upgrading biomass-derived oxygenates, e.g., bio-oil obtained from fast pyrolysis of biomass. Much current research is focussed on ketonisation of carboxylic acids using heterogeneous catalysis [2].

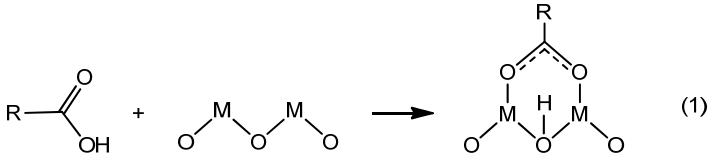
Here we report that Zn^{II}-Cr^{III} mixed oxides are active and durable catalysts for ketonisation of carboxylic acids (acetic and propionic) in the gas phase to yield acetone and 3-pentanone, respectively. Previously, Zn-Cr oxides have been used as catalysts for various reactions such as synthesis of methanol from the synthesis gas, fluorination of hydrocarbons, dehydrogenation of alcohols, etc. [3], but not for acid ketonisation so far. Additionally, we report on silicalite-1 as an environmentally benign non-metal ketonisation catalyst. Insights into reaction mechanisms are also provided.

2 Experimental

Details on catalyst preparation, characterization (BET, XRD, TG-DSC, FTIR and NH_3 adsorption microcalorimetry) and activity testing in a fixed-bed reactor are given in papers [3,4].

3 Results and discussion

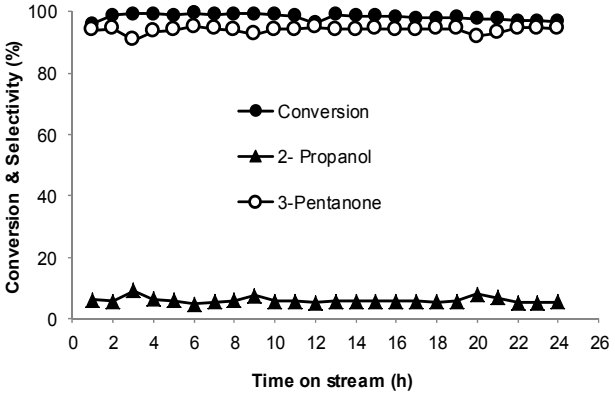
Bulk Zn-Cr mixed oxides with a Zn/Cr atomic ratio of 1:1–20:1 were found to be active catalysts for the gas-phase ketonisation of acetic and propionic acids to form acetone and 3-pentanone, respectively, at 300–400°C and ambient pressure [3]. Zn-Cr (10:1) oxide showed the best performance, significantly exceeding that of the parent oxides ZnO and Cr_2O_3. The catalytic activity was further enhanced by supporting Zn-Cr (10:1) oxide on TiO_2 and Al_2O_3. With 20%Zn-Cr(10:1)/Al_2O_3, ketonisation of propionic acid occurred with 97% selectivity to 3-pentanone at 99% conversion at 380°C and stable activity for at least 24 h on stream (Fig. 1). The high activation energy (124 kJ/mol) and Weizs-Prater analysis indicate no diffusion limitations. By the yield of 3-pentanone obtained, Zn-Cr (10:1) oxide is on a par with the best ketonisation catalysts reported so far, e.g., CeO_2-Mn_2O_3.



(1)

Fig. 2 shows the FTIR spectrum of acetic acid adsorbed on Zn-Cr (10:1), which is similar to those reported previously for other metal oxides. The bands at 1553 and 1462 cm^{-1} can be attributed to the antisymmetric and symmetric vibrations of the OCO group of acetate, which

indicates the bridging mode for acetate bonding (eq. 1) [3]. It is conceivable that over Zn-Cr oxides ketonisation occurs via the β-ketoacid intermediate route, which is considered to be favourable for amphoteric oxides [2].



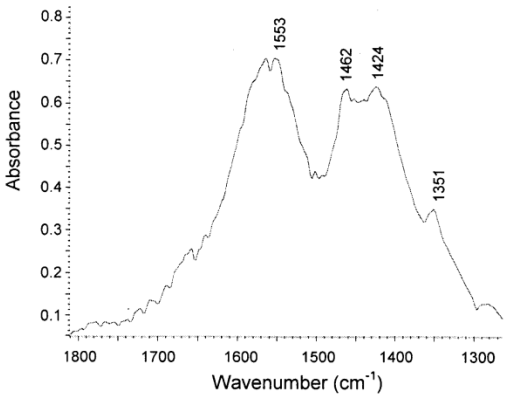


Fig. 1 (left). Propionic acid conversion and product selectivity over 20% Zn-Cr(10:1)/Al_2O_3 vs. time on stream (0.2 g catalyst, 380°C, 1 bar pressure, 20 mL/min N_2 flow rate, 2 vol% propionic acid) [3].

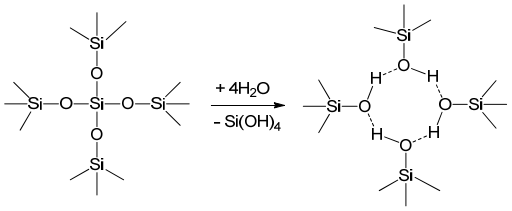
Fig. 2 (right). FTIR spectrum of acetic acid adsorbed on Zn-Cr (10:1) oxide after evacuation at 160°C/10^{-5} bar/1 h [3].

Amorphous silica and crystalline silicalite-1 (MFI structure) are demonstrated to be active and environmentally benign non-metal catalysts for propionic acid ketonisation at 450-500°C [4]. Silicalite-1 was particularly efficient, and its ketonisation selectivity increased by a base modification (3.7 M NH_3(aq) + 0.7 M NH_4NO_3) probably through generation of silanol nests (Scheme 1), which may be the active sites in the base-treated silicalite-1. Evidence for silanol nest formation was obtained by FTIR spectroscopy. The silicalite catalyst showed a stable performance at 500°C for at least 28 h with 84-92% 3-pentanone selectivity at 93-80% propionic acid conversion.



Scheme 1. Formation of silanol nest.

4 Conclusions

Bulk Zn-Cr oxides are active and durable catalysts for the gas-phase ketonisation of acetic and propionic acids at 300–400°C and ambient pressure. A mechanism for ketonisation of carboxylic acids via β-ketoacid intermediate route is proposed. Silicalite-1 is an environmentally benign non-metal catalyst for propionic acid ketonisation at 450-500°C. Ketone selectivity is increased by base treatment generating silanol nests in silicalite-1.

Keywords: ferrites, hydrogenation, carbon monoxide, olefins

1 Introduction

An important task for the creation of an industrial process synthesis of olefins from carbon oxides and hydrogen is the development of high-performance and low-coked catalyst systems, as well as the study of the mechanism of this reaction. This work is devoted to the study of physico-chemical and catalytic properties of new materials - perovskite strontium ferrite gadolinium and having mixed ionic and electronic conductivity in the catalytic hydrogenation of carbon monoxide, as well as to study the influence of composition and method for producing iron on their activity and selectivity to light olefins.

2 Experimental/methodology

Studied in this work complex oxides $GdFeO_3$, $SrFeO_3$ + x, $GdSrFeO_4$, Gd_2-xSr_1 + xFe_2O_7 were prepared by solid and sol-gel synthesis. Monitor the results of the synthesis was carried out using the methods of X-ray diffraction (XRD) diffractometer ARL X'TRA with CuKα-radiation and DTA derivatograph Termoskan-2.

Determination of particle size was using the methods of X-ray diffraction of the crystals, a scanning electron microscope (Zeiss EVO®40 microscope with an accelerating voltage of 10 kV microscope Carl Zeiss Supra 40VP to 20 kV), photon correlation spectroscopy (Malvern Zetasizer Nano analyzer with a helium-neon laser capacity of 4 mW, λ = 633 nm, the algorithm Multiple Narrow Modes).

Valence state of iron atoms was studied by Mossbauer spectroscopy spectrometer Wissel (57Co in a matrix of rhodium with activity 10 mKu), isomer shifts were calculated relative to the α-Fe.

The catalytic activity is determined by feeding the gas mixture with the ratio of components [CO: H_2] = 1: 1, 1: 2 and 1: 4. Experiments were conducted in a flow apparatus at a catalytic atmospheric pressure, and space velocities 1.5 - 3.0 l / h, in the temperature range 423-723 K. Analysis of the products was carried out by chromatography on crystal device 5000 with a column of stainless steel packed poropack Q.

3 Results and discussion

Synthesized by the sol-gel and ceramic technology nanostructured perovskite ferrites $GdFeO_3$, $SrFeO_3$ + x, $GdSrFeO_4$, Gd_2-xSr_1 + xFe_2O_7 are Raddlesdena-Popper phases (An + 1BnO3n + 1, n = 1,2,3, ..., ∞) and built block architecture (Figure 1). Using the methods of XRD revealed the presence of a phase with perovskite-like layered structure for both samples obtained by solid-phase synthesis and sol-gel method.

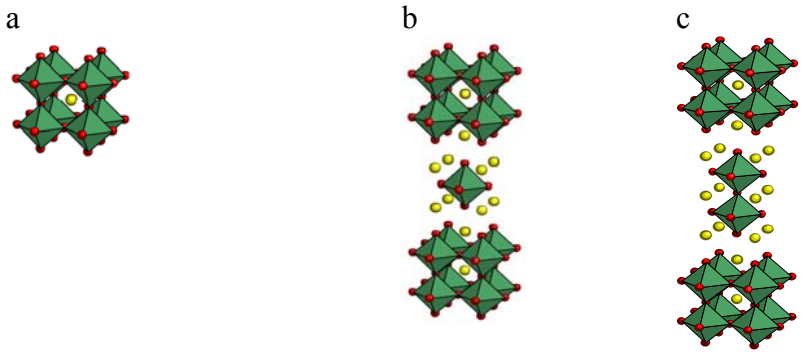

Fig. 1. Structure of the distorted perovskite ferrite GdFeO3 (a), a layered oxide $GdSrFeO_4$ (b), layered oxide Gd_2-xr_1 + hFe_2O_7 (c) (●- Sr^2 +, Gd^3 +, Fe^3 + are inside the octahedron)

Using XRD method, photon correlation spectroscopy, scanning electron microscopy revealed that the oxides synthesized by the the ceramic technology are in the microcrystalline able average crystallite size of 10 microns, and a sol-gel method - have a porous structure and crystallite length - 200 nm.

Methods of nuclear gamma resonance (Mossbauer spectroscopy) found that in complex ferrites $GdFeO_3$, $Gd_2SrFe_2O_7$, obtained by the ceramic technology, the iron atom is in a magnetically ordered state, Fe^{+3}. Increase in strontium Gd_2-xSr_1 + xFe_2O_7 lowers the symmetry of atoms Fe^{+3} (up to three fields of different symmetry), which is explained by the presence of oxygen vacancies. The Mossbauer spectra of solid solutions Gd_2-xSr_1 + xFe_2O_7, synthesized using sol-gel technology, showed that in addition to Fe + 3 in three different fields of symmetry (associated with an increase of the nanodispersion surface state) coexists in these compounds and Fe + 4.

Reaction products of the hydrogenation of carbon monoxide are hydrocarbons C_1 - C_5 basic - methane, ethylene, propylene. It is shown that the catalytic activity (rate of formation of products) affects the number of alternating layers of perovskite and it increases in the series: $SrFeO_{3-x}$ <$GdSrFeO_4$ (n = 1) <$Gd_{1,6}Sr_{1,4}Fe_2O_7$ (n = 2) <$Gd_{1,8}Sr_{1,2}Fe_2O_7$ (n = 2) <$Gd_2SrFe_2O_7$ (n = 2) <$GdFeO_3$ (n = ∞). In the temperature range 523-548 K for olefins selectivity $Gd_2SrFe_2O_7$ was 50-63%, higher values $GdFeO_3$ samples with n = ∞. Ferrites synthesized by sol-gel method had higher catalytic performance that may be associated with their nanocrystalline state with a porous structure, as well as heterovalent state iron (Fe^{+3}, Fe^{+4}), which is favorable for the activation of CO, leads to the formation of C * and CHx -radicals.

4 Conclusions

New complex perovskite ferrites was obtained (An + $_1BnO_{3n+1}$, where n = 1,2,3, ..., ∞, A = Gd, Sr, B = Fe). It was found that the oxides synthesized by the ceramic technology are in the microcrystalline state with Fe + 3 in one magnetically ordered state, and by the sol-gel method - in the nanocrystalline state and heterovalent Fe^{+3}, Fe^{+4} with oxygen vacancies. Catalytic performances are obtained in the hydrogenation of carbon monoxide. The relationship was found between the catalytic activity and physico-chemical properties of ferrites.

Influence of Pressure to the Hydrocracking Process of Goudron in the Presence of a Modificated Suspended Halloysite

Mukhtarova G.S.*, Efendiyeva N.Kh., Kasimova Z.A., Abbasov V.M., Ibrahimov H.C.

Azerbaijan NAS Institute of Petrochemical Processes, Baku, Azerbaijan

* gulermuxtarova@yahoo.com

Keywords: hydrocracking, suspended, catalyst, diesel, fraction, modificated halloysite, goudron, pressure

1 Introduction

Developmentof the existing refinery technologies and creating of new technological processes allowing to increase the depth of oil refining and to improve the quality of oil products – the urgent economical and technical problems of oil-refining industry, the solution of which is associated with the involvement in the processing of residual oil feedstock types.

Thermal and thermal-oxidative processes of oil residua refining arecharacterized by low quality of the obtainedproducts and limited possibilities to enhance the depth of oil refining and production of valuable motor fuels and feedstock for petrochemistry. Hydrocracking process is one of the most efficient processes for obtaining high-quality motor fuels from heavy oil residues (fuel oil, goudron) [1-2].

2 Experimental / methodology

The purpose of the work is to investigation the obtaining process of fuel components from low-pressure hydrocracking of the goudron obtained from Baku oils in the presence of modificatedsuspended halloysite with transition metals (Ni, Co) for obtaining additional (extra) light oil products in order to deepen the oil refining. The influence of the pressure in the range of 1.0-4 MPa at 450 ^{o}C to the processing of the goudron hydrocrackingin the presence of the modificatedsuspended high-dispersed halloysite with transition metals has been investigated. It was investigate the influence of pressure to hydrocracking process of tar.

3 Results and discussion

It was determined that with increasing of pressure from 0.5 to 4 MPa the yield of light oil products increased from 47,0 to 58% mass. So that, the yield of gasoline decrease from 30 % to 27 %, but the yield of diesel fraction increased from 16 % to 30,52 %. Further, at the increasing pressure from 4 MPa to 6 MPa the yield of light oil products increased a few, but amount of cock is decrease from 13 % to 9 %. The change of pressure also influence to the hydrocarbon composition of obtaining products. So that, with increasing of pressure from 0.5 MPa to 6.0 MPa (temperature – 430 ^{0}C) amount of sulfur, iodine number, aromatic hydrocarbons containing in the gasoline decrease. The viscosity, amount of resins, amount of sulfur and iodine number of diesel fraction are decrease.

The analysis of the quality of gasoline and diesel fractions shows that after the additional light hydrotreatment the obtained products can be recommended as component to fuels.

Keywords: Olefin, Paraffin, Cracking, long-chain, Conversion, disequilibrium

1 Introduction

Development and intensification of hydrocarbon processing industry is the creation of new active and selective catalysts that can reduce energy consumption while increasing the activity and selectivity. Long chain α-olefins can be produced by the catalytic cracking of paraffins, dehydrogenation of a mixture of light olefins and alkanes obtain hydrogen. Heteropolyacid (HPA) is now widely used for various catalysts [1]. We have previously [2] proposed based catalysts decationized on natural zeolite of Shankanaysky of Almaty region, synthetic GIC and aluminum oxide. The reviews [3,4] presented provisions paraffin cracking catalyst and synthesis on the basis of long-chain α-olefins.

A mixture of light alkanes simulates passing gases and oil refinery gases fat. Creating catalysts conversion to simple olefins and hydrogen solves the problem of processing and free fatty gases. For the conversion of a mixture of light, we used the latest achievements of theoretical chemistry, in particular, we carry out the process under conditions of disequilibrium [5]. If the surface of the catalyst is to create conditions for the appearance of dissitive structures that give rise to an imbalance, the reaction shifts to the formation of reaction products. We set ourselves the task in the conversion of a mixture of light alkanes on the catalyst surface conditions of disequilibrium and unsteadiness in order to receive from alkanes olefins and hydrogen.

This article presents the data on the cracking catalysts in the synthesis of long chain paraffins α-olefins and the conversion of alkanes into a mixture of light reducing medium.

2 Experimental/methodology

Experiments were carried out in a flow reactor on stationary catalyst bed at atmospheric pressure and a temperature range of 450-550^{0}C. During the cracking of paraffins process implemented in the reaction - regeneration. Melted paraffin was supplied at a rate of 0.1-1.0 cm^3/min. Regeneration was performed with a mixture of steam-air mixture to the total absence of carbon dioxide gases in the contact. In the conversion of a mixture of light alkanes, the catalyst is pre-reduced in flowing hydrogen and the reactive gas mixture was fed to the reduced catalyst. Experiments were conducted in four modes: supplying the mixture of light alkanes to reduced catalyst; gas together with hydrogen; gas together with the water; gas together with hydrogen and water. The feed rates of the reacting gases was varied in the range of 10 - 100 h-1. When changing the modes of the catalyst was reduced in hydrogen for 30 minutes.

3 Results and discussion

Long-chain α-olefins are intermediates in the synthesis of base oils, surfactants and other

products of basic and fine chemicals. For long-chain α-olefins include catalysts based on natural zeolites, synthetic heteropolyacids (HPA) 12-molybdenum and tungsten series and Wide Pore Aluminum Silicates (WPAS). Combination of synthetic GIC with decationized natural zeolite consisting of clinoptilolite and WPAS obtained catalysts for the production of long-chain α-olfinov paraffin cracking. Cracking was carried out in a reaction-regeneration mode to the fixed bed at temperatures 450-550^{o}C and atmospheric pressure. Long-chain α-olefins were isolated by vacuum distillation of the cracking products of the wax.

A mixture of light alkanes simulating passing gases and fatty oil refinery gases are converted under reducing conditions to produce a mixture of light olefins and hydrogen disequilibrium mode. Ruthenium catalysts supported on alumina and WPAS have been used. To achieve an imbalance in the system used disequilibrium adding water and hydrogen, which are not participating in the reaction itself may be formed on the surface of the uniformly adsorbed dissipative structure, which shifts the equilibrium toward the formation of olefins and hydrogen. Were prepared and tested 3% Ru, Pt, Pd, supported on γ-Al_2O_3 in the conversion of a mixture of light alkanes into a flow system at a stationary bed of catalyst in the temperature range 350-500°C and atmospheric pressure in the four modes with clean gas and in the presence of hydrogen and water.

Catalysts certified complex physical methods to identify their physical and chemical characteristics. It was shown that surface cracking of paraffins is necessary to create additional acidic sites. To increase the conversion of a mixture of light alkanes to the surface of the catalyst necessary to create conditions for the emergence of imbalances.

One-Step Synthesis of Dimethyl-Ether from Biogenic Syngas on Mixed Metal/Alumina Mixtures

Pelaez R., Marin P., Ordonez S.*

University Of Oviedo, Oviedo, Spain

* sordonez@uniovi.es

Keywords: biomass, gasification, biofuels, thermochemical, routes, equilibrium-limited, reactions

1 Introduction

Dimethyl Ether (DME) is receiving great attention as a clean alternative fuel, owing to the increasing energy demand. DME can take the place of light naphthas due to the similar physicochemical properties. Besides, DME derivates can also be used as diesel fuel aditives of high cetane number, especially with very low soot emission in the exhaust gas from diesel engine as it has no C-C bond structure. In addition, it is quickly decomposed if leaked into the environment.

In spite of this, catalytic synthesis of DME via a high efficient route remains a great challenge, most of the efforts being paid to the synthesis from methanol. However, commercial methanol production from syngas operates under high pressure (50-150 bar) with very low one-pass reactant conversion due to severe thermodynamic limitation on this exothermic reaction. Therefore, direct DME synthesis from syngas is of great importance, where methanol synthesis from syngas is coupled in situ with methanol dehydration to DME. This scavenger effect on methanol can lower the catalyst surface concentration of the intermediate methanol and break the thermodynamic limitation on the overall CO conversion. Consequently, CO conversion in the direct DME synthesis can be up to 80% in fixed bed reactor or slurry-phase process, significantly higher than that in regular methanol synthesis such as 20% [1].

The scope of this work is to experimentally determine the efficiency of this reaction by operating with mechanical mixtures of a $CuO/ZnO/\gamma\text{-}Al_2O_3$ catalyst (the most recommended catalysts for methanol synthesis) and $\gamma\text{-}Al_2O_3$. This last material presents medium strength acid sites, active for methanol condensation into DME.

2 Experimental/methodology

Experiments were performed in a fixed bed isothermal reactor operating at 30 bar. The reactor was charged with 4 g of $CuO/ZnO/\gamma\text{-}Al_2O_3$ (ChemPack) and 2 g $\gamma\text{-}Al_2O_3$ (BASF) catalysts, ground to 250-355 μm. The catalysts were pretreated in situ with a 4% H_2/N_2 stream at a heating rate of 2 K/min until 493 K, holding for 2 h. Syngas was fed to the reactor with CO/H_2 volume ratio of 40/60.

Online analysis of the reactor feed and effluent streams were carried out using a HP 6890N gas chromatograph, equipped with HP Plot Q and MolSieve columns, and TCD and FID detectors.

3 Results and discussion

Firstly, the influence of temperature on catalyst activity and stability was studied. The reaction was carried out with a syngas flow rate of 0.5 L/min (n.t.p.), space velocity 0.22 mol/h g, at two different temperatures, 523 K and 543 K. Catalyst stability was obtained after 10 h on stream. The results show that conversion almost doubled with this increase in temperature (25-47%) while DME selectivity remained at 70%. According to these results, the following tests were done at 543 K.

Figure 1 shows the data of the catalytic test using different space velocities. The feed flow was decreased by 80% and 50%: 0.38 and 0.25 L/min (n.t.p.), respectively, 0.17 and 0.11 mol/h g. It can be seen that conversion values increase when decreasing space velocity. However, DME selectivity remained constant around 69%.

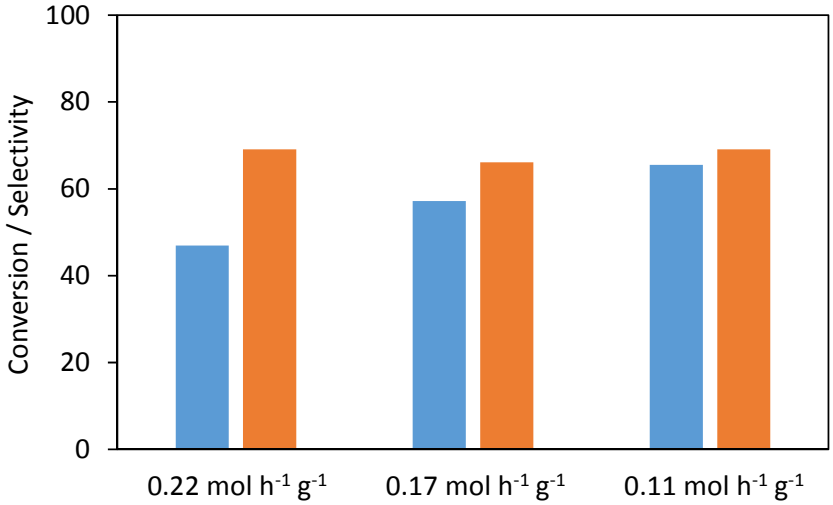

Fig. 1. Catalytic data at different space velocities (30 bar, 543K): ■ Conversion, ■ DME Selectivity

In the same way, the evolution of the reaction performance was followed for times on stream of 80 h. Although conversion decreases were observed (about 30 %), DME selectivities remain almost constant on these experiments.

Characterisation of the used catalyst (both metal oxides and alumina), suggest than the loss of activity is mainly related with chemical (copper oxidation) and morphological (copper sintering), whereas alumina does not show significant changes upon reaction, neither morphological nor chemical (distribution of acid sites).

4 Conclusions

The use of mechanical mixtures of a methanol synthesis catalysts and γ-alumina has been show as an efficient way for obtaining DME from biogenic syngas. Higher and almost constant selectivities were obtained in the reported experiment, in spite of the observed deactivation.

1 Introduction

Hydrogen production from renewable resources offers enormous benefits for the energy sector, the environment, and the chemical industry. Photocatalytic H_2 production over irradiated semiconductors is receiving particular attention because is based on the Sun, which is a perpetual source of energy [1, 2]. Photocatalytic processes involve excitation of a semiconductor with photons of equal or higher energy than the bandgap energy producing electron-hole pairs. TiO_2–based photocatalysts are among the most attractive due to their availability, corrosion resistance, non-toxicity, low price and high photoactivity and stability. Incorporating organics such as alcohols as sacrificial electron donors into the photocatalytic process increase charge-separation efficiency and give higher H_2 generation rates. Ethanol is one of the most promising hole scavengers because it is available, easy to obtain from biomass (bioethanol) and to transport, CO_2–neutral and safe to handle. Au/TiO_2 has also the ability to increase the photoresponse of TiO_2 [1].

Slurry photoreactors facilitate mass transfer, but they are limited by poor light penetration in the suspension, no matter how active a photocatalyst, if photons are not effectively transmitted to its surface the system efficiency will be lowered. An ideally intensified photoreactor should be able to integrate both, maximized light efficiency and mass transfer simultaneously [3]. Microreactors allows a high degree of process intensification, they appear as a technology for boosting the implementation of on- site and on- demand generation of hydrogen for portable applications, thus avoiding limitations imposed by hydrogen storage [4]. In this work polydimethylsiloxane (PDMS, a silicone elastomer) microreactors were fabricated, coated with Au/TiO_2 photocatalyst and tested in the photogeneration of hydrogen from water-ethanol mixtures at room temperature under dynamic conditions. PDMS has numerous advantages, such as simple and inexpensive fabrication process, which enables rapid prototyping, and optical transparency, which is very interesting for photocatalytic process.

2 Experimental/methodology

Polydimethylsiloxane (PDMS) microreactors were fabricated from patterns made using a 3D printer (Figure 1a). Dimensions of the channels were: 500 μm (width) x 1mm (depth) x 47 mm (length) with a total volume of 0.21 cm^3.

Gold nanoparticles were loaded onto TiO_2 by impregnation from a toluene solution containing preformed Au nanoparticles [3, 4]. The Au loading was 1- 2 wt. % with respect to TiO_2. Catalysts were calcined at 673 for 2 h (2 K min^{-1}) to assure a good contact between the Au nanoparticles and TiO_2 support. A suspension of Au/TiO_2 in ethanol was prepared and deposited onto the surface of the microchannels to reach ca. 0.5 mg cm^{-2} of Au/TiO_2. The bonding between PDMS pieces was performed by corona discharge (Figure 1b).

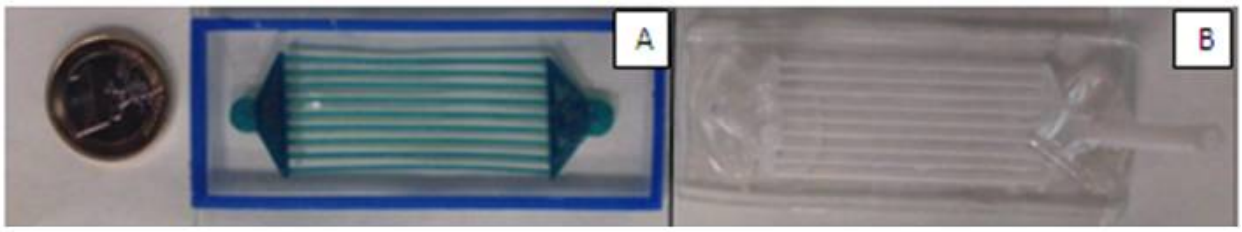

Fig.1. (a) Pattern printed with a 3 D printer. (b) PDMS microreactors loaded with Au/TiO_2.

For the photoreaction experiments, a light source consisting of two UV LEDs emitting at a wavelength of 365 nm over the microreactors was mounted. The irradiance over the microreactors was varied from 0 to 20 mW cm^{-2}. Photoreactions were carried out at 298 K. The gaseous reactants were introduced continuously by bubbling Ar through a saturator containing ethanol and water, with ethanol molar contents of 1-100% and VHSV from 5000 to 10000 h^{-1}.

The photoreactor effluents were monitored online every 2 min by gas chromatography. Blank experiments with only TiO_2 were also carried out.

3 Results and discussion

Deposition of the Au/TiO_2 photocatalyst on the microchannels was analyzed by microscopy. XRD profiles showed the presence of both anatase and rutile with a ratio of anatase:rutile 80~20. The BET surface area of TiO_2 was 90±20 m^2g^{-1} and size particle ca. 14 nm. UV-Vis reflectance spectra showed a localized surface plasmon resonance of Au at about 567 nm. Photoproduction rates of 10 μmol H_2 min^{-1} g^{-1} were obtained at 10000 h^{-1} and 15 mW cm^{-2} with a EtOH: H_2O mixture of 1:9 molar.

4 Conclusions

We have manufactured polydimethylsiloxane (PDMS) microreactors containing channels of 500 μm in diameter by designing patterns with a 3D printer. This design allows a high degree of process intensification, with an optimum mass transfer and a good light penetration. The silicone channels have been coated with ca. 0.5 mg cm^2 of Au/TiO_2 (1-2 wt% Au). Several operational conditions have been selected for the photoproduction of hydrogen, including UV dose (0-20 mW cm^{-2}), contact time (5000-10000 h^{-1}), catalyst load, and water-ethanol ratio (1-100% C_2H_5OH). The results show a very easy operation and a significant enhancement of the hydrogen photoproduction rate compared with conventional photoreactors.

Influence of Suppores's Nature on the Activity of Hematin Catalysts

Memmedova M.T.*

The Azerbaijan NAS Institute of Petrochemical Processes, Baku, Azerbaijan

* memmedova-melahet@mail.ru

Keywords: natural gas, hematin, methanol, hydrogen, peroxide, aluminosilicates

1 Introduction

The production of various intermediate petrochemical products and liquid fuels from natural gas by catalytic procedures is an important problem related to high effectiveness chemical technologies. One of the pressing problems and rapidly developing domains of modern applied catalysis is oxidative activation of methane, which is main component of natural gas and the lower olefins.

Metalloporphyrin-based catalytic models of monooxygenases were used in many works. These studies showed that, monooxygenase model reactions largely occurred in nonaqueous solvents, and the active center in such reactions was hemin characterized by the formation of an H^{+}_{m} intermediate, in which the hematin form was naturally absent.

In this work, the influence of support properties on the activity of hematin-containing (biomimetic) catalysts in methane hydroxylation by hydrogen peroxide was investigated.

2 Experimental

Materials. The granulated supports used for the perparation of biomimetic catalysts were neutral and activated Al_2O_3, zeolite NaX and synthtic amorphous magnesium- and chromium-containing aluminosilicates (AlSiMg and AlSiCr, respectively).

Hemin from BDH containing 8.64% iron was used as an active center on the supports. Chemically pyre hydrogen peroxide of kh. ch. (chemically pure) grade was purified from possible impurities, in particular, stabilizers by distillation under vacuum. The row material was natunal gas containing 96% CH_4. The gas was passed through a purification system to remove small amounts of impurities.

Methods. Gas-phase hydroxylation of methane (natural gas) by hydrogen peroxide was performed in a flow quartz reactor.

Biomimetic catalysts were prepared by the adsorption of hematin on the above shown anulated neutral and activated Al_2O_3, zeolite NaX and synthtic amorphous magnesium- and chromium-containing aluminosilicates (AlSiMg and AlSiCr, respectively)

Hematin-containing catalysts were prepared by the procedure described in.

The products of the monooxygenase reaction were analyzed by gas chromatography.

3 Results and discussion

The acid-base carriers specified above were used to study the effect of the nature of an inorganic matrix on the activity of the iron protoporphyrin catalyst in methane oxidation to methanol. According to the data given in Tables 1 and 2, the biomimetic catalyst on these supports simulates both the catalase activity and the monooxygenase function of cytochrome P-450.

Table 1. Number of catalyst turnovers (n) in the catalase reaction (V_{H2O2} = 20 *ml*,*t* = 12ºC, m_{cat} = 0.5*g*, $[H_2O_2]$ = 5*wt*%); W_{H2O2} is the rate of hydrogen peroxide consumption

Sample	[Fe], mol	$W_{H_2O_2}$, $\frac{mol}{h}$	n, h^{-1}
$PP\frac{Fe3+OH}{AlSiCr}$	$0.55\cdot10^{-5}$	$0.38\cdot10^{-2}$	700
$PP\frac{Fe3+OH}{AlSiMg}$	$0.70\cdot10^{-6}$	$0.12\cdot10^{-3}$	171
$PP\frac{Fe3+OH}{Al2O3}$	$0.26\cdot10^{-5}$	$0.90\cdot10^{-3}$	347
$PP\frac{Fe3+OH}{NaX}$	$0.20\cdot10^{-5}$	$0.15\cdot10^{-3}$	75

Table 1 shows that $PPFe^{3+}OH$/AlSiCr is most active and gives 700 turnovers per hour. These results lead us to conclude that ions substantially influence the catalytic activity of supported metalloporphyrins by changing the acid-base characteristics of aluminosilicate carriers. It cannot, however, be ruled out that the ions added can themselves participate in H_2O_2 decomposition .

Table 2. Number of catalyst turnovers (n) in the monooxygenase reaction (t = 180ºC,τ = 10 *s*,$[H_2O_2]$ = 20*wt*%,N_{CH4}:N_{H2O2} = 1 : 0.5); W_{CH4} is the rate of methane consumption.

Sample	[Fe], mol	W_{CH_4}, $\frac{mol}{h}$	n, h^{-1}
$PP\frac{Fe3+OH}{AlSiCr}$	$0.30\cdot10^{-4}$	$0.13\cdot10^{-2}$	43
$PP\frac{Fe3+OH}{AlSiMg}$	$0.63\cdot10^{-5}$	$0.77\cdot10^{-3}$	122
$PP\frac{Fe3+OH}{Al2O3}$	$0.20\cdot10^{-4}$	$0.19\cdot10^{-3}$	10
$PP\frac{Fe3+OH}{NaX}$	$0.20\cdot10^{-4}$	$0.76\cdot10^{-4}$	4

Experimental data show that aluminosilicate-based biomimetic catalysts are more active in methane hydroxylation than those on Al_2O_3 and zeolite NaX (Table 2). $PPFe^{3+}OH$/AlSiCr, which is most active in the catalase reaction, shows considerably lower monooxygenase activity in comparison with $PPFe^{3+}OH$/AlSiMg. The high catalase activity of $PPFe^{3+}OH$/AlSiCr is likely to be retained in the presence of the substrate (CH_4), which makes the monooxygenase reaction less completitive . Although the alumina-based catalyst is highly active in the catalase reaction, it exhibits a moderate monooxygenase activity towards CH_4. This behavior of the biomimetic catalysts may be explained by the properties of the support proper, because the active centers ($PPFe^{3+}OH$) were the same on all supports.

Regeneration and Activation Studies with NiMo/(Al-MCM-41/ZSM-5) Catalyst System for Hydrocracking of Biogenic Residues

Gille T., Busse O.*, Reschetilowski W.

Technische Universität Dresden, Department of Industrial Chemistry, Dresden, Germany

* oliver.busse@chemie.tu-dresden.de

Keywords: renewables, light olefins, green chemistry, micro-/mesoporous, hydrocracking, non-food

1 Introduction

The bifunctional catalyst system can be used for the selective catalytic conversion of vegetable oil by hydrocracking. Thereby high olefin yields could be reached but deactivation of catalysts is a major problem. Accordingly, regeneration and activation of used catalyst samples are necessary. Furthermore, conversion of non-food sustainables, like biogenic residues is of particular interest.

The present work studies the influence of regeneration and activation of NiMo/(Al-MCM-41/ZSM-5) on catalytic properties in hydrocracking of biogenic residues. In this context, special attention is directed to product distribution (especially the yield of light olefins), deactivation of the synthesized catalyst sample and shortening of regeneration program.

2 Conclusion

The conversion of biogenic residue results in high yields of gaseous hydrocarbons at temperatures of 500°C, WHSV of 5 h^{-1} and pressure of 5 bars. These gaseous products consist mainly of light olefins (C_2-C_6). In this way valuable base chemicals could be produced from waste materials. The yield of olefins could keep at constant level by different regeneration programs for over 24 hydrocracking tests. Furthermore, the time of regeneration and activation steps were significantly reduced.

Ru Nanoparticles on Acid-Modified Carbon Materials for the Hydrolytic Hydrogenation of Cellulose

Adsuar-Garcia M.D., Rufete-Beneite M, Roman-Martinez M.C.*

Department of Inorganic Chemistry, University of Alicante, Alicante, Spain

* mcroman@ua.es

Keywords: cellulose, carbon, materials, ruthenium, acidic, functionalities, sorbitol

1 Introduction

The limited supply of fossil fuels and the emissions of greenhouse gases have led to a great interest in the use of biomass as a fuel source. Cellulose is one of the most abundant compounds of biomass and it can be converted to fuels and other chemical products by means of hydrolytic hydrogenation, in which cellulose is hydrolized to glucose that is further hydrogenated to other products like sorbitol [1]. The hydrolytic hydrogenation process can be considered as composed by two steps: hydrolysis, which requires an acidic catalyst and hydrogenation for which a noble metal is necessary.

This work focuses, thus, on the preparation of bifunctional catalysts able to carry out the two mentioned steps of the process. These catalysts consist of ruthenium nanoparticles supported on carbon materials modified with acid functionalities, either created by oxidation or by the anchorage of a heteropolyacid.

2 Experimental/methodology

The carbon materials used as support are two samples of commercial multiwall carbon nanotubes of different surface chemistry named C and C_{OH}(Chengdu Organic Chemicals Co. Ltd. Chinese Academy Sciences (Timesnano)) of average outer diameter of 10-20 nm and inner diameters of 5-10 nm,and a spherical shaped activated carbon (Gun-ei Chemical Industry (Japan)), named GeA, with average diameter of 150 μm. The as-received carbon nanotubes were purified by a treatment in concentrated HCl (37wt.%) at room T for 48 h (samples identified as CD and C_{OH}D). Sample CD was treated with nitric acid solution (69%) at 120 ºC under refluxing conditions for 8 h and then named CDN. Sample GeA was oxidized with a saturated solution of $(NH_4)_2S_2O_8$ in H_2SO_4 1M at room T for 24 h (sample GeAS). The heteropolyacid $H_4O_{40}SiW_{12}$ (HPA) was anchored on support C_{OH}D according to the procedure described in the literature [2] and the sample is named C_{OH}D-HPA. HPA loading is 36wt%.

The Ru nanoparticles were prepared either by impregnation of the support with an aqueous solution of $RuCl_3$ followed by reduction with H_2 (T= 250°C 4h), or directly by solution reduction using also $RuCl_3$ as precursor and ethylenglicol[3]. Ru loading was 5 wt%.

Activity experiments were carried out in a Parr reactor (50 mL). In a typical experiment 0.500 g of ball milled cellulose, 125 mg catalyst and 25 mL water were used. The reaction conditions were 190°C and 50 bar H_2.After reaction, cellulose conversion was determined by weighting the sample and the solution was analysed by HPLC.

Characterization was carried out to analyse the chemical and textural properties of the prepared samples, using TPD and titration, and gas adsorption, respectively.

3 Results and discussion

Table 1 shows data of BET surface areas, CO_2 and CO desorption in TPD experiments and amount of acid groups determined by titration.

Table 1. Textural and chemical properties of supports.

Sample	S_{BET} (m^2/g)	V_{tot} (cm^3/g)	CO_2 (μmoles/g)	CO (μmoles/g)
CD	214	1.10	214	1507
CDN	266	1.09	1360	1916
C_{OH}D	194	0.88	290	1297
GeA	1918	0.937	327	817
GeAS	1142	0.540	3810	3105

The treatment with nitric acid increases the acidity of the CD sample with a low modification of the textural properties. As expected, sample C_{OH}D contains a large amount of oxygen groups desorbing as CO; and oxidation of sample GeA strongly increases the surface chemistry and the acidity with some reduction of the pore volume.

Table 2 shows data of catalysts acidity, cellulose conversion and selectivity to sorbitol.

Table 2. Catalytic activity in the hydrolytic hydrogenation of cellulose

Sample	*Acidity (mmol/g)*	*Conversion%*
Ru/CDN	1.00	30
Ru_d/CDN*	2.22	27
Ru_d/C_{OH}D-HPA*	1.60	42
Ru_d/GeAS*	2.48	55

*$_d$means reduction in solution

These results show that in the case of the carbon nanotubes supported catalysts the solution reduction process does not improve the catalytic activity in spite of leaving a higher acidity. However the presence of anchored HPA leads to higher activity. Support oxidation with ammonium persulfate solution leads to the most active catalyst and this is likely due to the higher development of acidity by this way.

4 Conclusions

The bifunctional catalysts prepared with acidic functionalities and Ru nanoparticles give an acceptable cellulose conversion and good selectivity to sorbitol. Among the prepared catalysts, the one with the highest developed surface chemistry is the most active.

Keywords: bitumen, heavy oil, FeOx catalyst, catalytic cracking, sub- and super-critical water

1 Introduction

From the perspective of diversification of energy resources, it has been required that a technological development to convert unused fossil resources into useful fuels. Oil sand bitumen (abbreviated as bitumen) is one of the promising candidates, the deposit of which is larger than that of crude oil. Consequently, we have developed iron oxide (FeOx) composite catalysts that convert heavy oil into lighter fuels in superheated steam condition [1]. In cracking system with this catalyst, the lattice oxygen in FeOx is main active sites to decompose heavy oil. When the lattice oxygen is consumed during the oxidative reaction, the crystal structure of FeOx changes from hematite to magnetite and the catalyst is deactivated. Therefore, zirconia (ZrO_2) and ceria (CeO_2) that exhibit activity to produce active oxygen species from water are loaded on FeOx, and the lack of the lattice oxygen due to the consumption was re-generated by the oxygen species [1]. Moreover, we have succeeded in improving the tolerance to sintering of FeOx by alumina (Al_2O_3) addition [2].

On the other hand, the bitumen reserved in deep layer has been produced by steam assisted gravity drainage (SAGD) method, where the bitumen with steam is obtained. Accordingly, on-site upgrading process for bitumen under sub- and super-critical water conditions is an effective approach, because the bitumen with steam thus obtained can be applied as feedstock [3]. In this study, catalytic cracking of bitumen into lighter fuels such as gas oil and vacuum gas oil (denoted as VGO hereafter) was carried out under sub- and super-critical water conditions using the FeOx catalysts. The effects of reaction atmosphere on the yields of the light fuels and the amounts of coke formed on the catalyst were examined.

2 Experimental/methodology

CeO_2-ZrO_2-Al_2O_3-FeOx catalyst (FeOx-based catalyst as here after defined) was prepared by co-precipitation method with each metal nitrates. The catalysts thus obtained were calcinated at 773 K for 2 h. The structures of the catalysts were analyzed by X-ray diffractometer.

Semisolid bitumen diluted with benzene at 10 wt% was used as a feedstock. The catalyst was confirmed in advance to be inactive to benzene. The catalytic reactions under sub-critical water (19.0 MPa) and super-critical water (26.9 MPa) atmospheres were carried out in a fixed-bed flow type reactor. The time factor, W/F (W: catalyst amount /g, F: bitumen flow rate /g h^{-1}), and F_{H2O}/F (F_{H2O}: water flow rate /g h^{-1}, F: bitumen flow rate /g h^{-1}) were 4 and 20, respectively, reaction temperature was 693 K. In addition, catalytic reaction was carried out atmospheric condition (0.1 MPa), for comparison. The obtained gaseous and liquid products were analyzed by gas chromatographs, and high-performance liquid chromatography (HPLC), respectively. The amount of coke loading on the catalyst after reaction was measured by elemental analyzer.

3 Results and discussion

Figure 1 shows the carbon yield of the catalytic cracking of bitumen under sub- and super-

critical water atmosphere over the FeOx-based catalyst. At 0.1 MPa, yield of carbonaceous materials (coke and residue) is about 40 mol%-C. In contrast, the yield of the solid products decreased to about 15 mol%-C under a high pressure condition. Specifically, a difference in the coke amount between atmospheric and high pressure condition could be observed. Under 0.1 MPa, since benzene as solvent was vaporized and bitumen was adsorbed on the catalytic surface, a heavy component (Vacuum residue: VR) in bitumen would easily change into carbonaceous residue followed by coke formation at 0.1 MPa. On the other hand, super-critical water could wash out a coke precursor from the catalytic surface, leading to suppression of coke formation.

The yield of lighter fuels such as Gas oil and VGO were increased from 35 mol%-C (Feed) to 50 ~ 70 mol%-C, and gaseous products, consisting mainly of H_2 and CO_2, were generated. Because the FeOx-based catalyst exhibits an oxidative activity, the bitumen was oxidatively-cracked, yielding the lighter fuels and CO_2. In subcritical condition of 19.0 MPa, decomposition of bitumen over the catalyst effectively proceeded as compared with super-critical water condition (26.9 MPa). The difference in the lighter component yields between sub-critical and super-critical conditions was ascribed to re-polymerization reaction of produced lighter fuels. Though the decomposition of bitumen occurred over the catalyst, it was considered that the re-polymerization reaction tended to occur with increasing the reaction pressure, leading to increase in the yields of heavy components (VR). As a result, subcritical water condition of 19.0 MPa is effective pressure for upgrading of heavy oil using FeOx-based catalyst.

Figure 2 shows the XRD patterns of the FeOx-based catalysts prior to and after the reaction of bitumen. The FeOx-based catalyst showed the peaks corresponding to hematite before reaction. This structure, however, changed into magnetite after the reaction at 0.1 MPa. This result was ascribed to insufficient re-generation of the consumed lattice oxygen in FeOx due to coke deposition on the catalyst surface. On the other hand, structure of catalyst was stable in hematite under sub- and super-critical water conditions in which the lattice oxygen of FeOx was efficiency regenerated. These results suggest that the FeOx-based catalyst is stable for upgrading bitumen under sub- and super-critical water conditions.

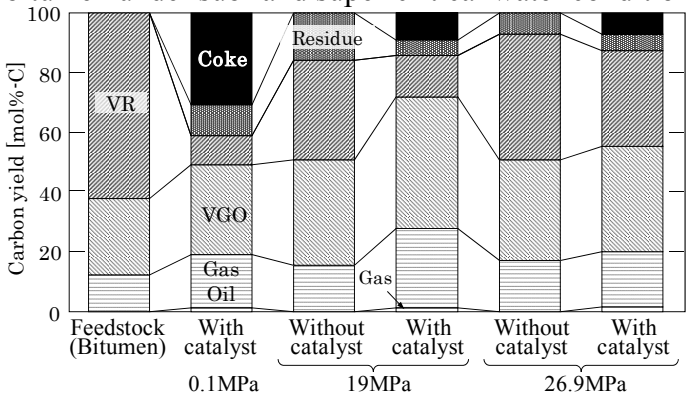

Fig. 1 Carbon yield after the catalytic of bitumen

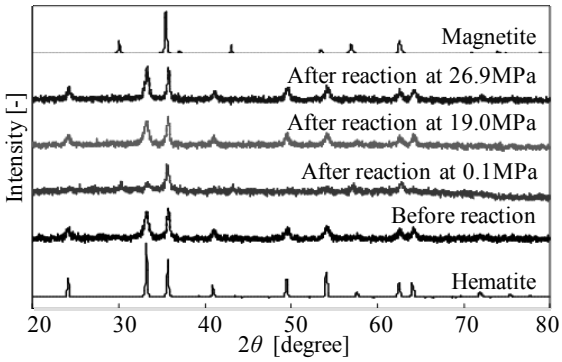

Fig. 2 XRD patterns of the catalyst before and after reaction

4 Conclusions

Bitumen was effectively decomposed over FeOx-based catalyst under sub-critical water condition. FeOx-based catalyst worked well and maintained the high activity during the upgrading of bitumen under sub-critical water.

Keywords: furfural hydrogenation, catalyst, biomass

1 Introduction

The sustainable supply and use of energy for transportation represents a real challenge. Terrestrial as well as aerial mobility are strongly affected by petrol shortage. 84% of all petroleum extracted is processed as fuels, including gasoline, diesel, jet, heating and other fuel oils and liquefied petroleum gas. Burning oil releases carbon dioxide into the atmosphere contributing to global warming. The growing social, economical and political interest for the development of alternative fuel sources is not only due to general concerns of sustainability, but also related to human development and geopolitical stability. Bio-fuels are the only alternative to fossil fuels for car powering. Since the carbon backbone is ultimately produced at the expenses of photosynthesis, burning these fuels does not contribute to increase the concentration of CO_2 in the atmosphere and, consequently, to global warming [1].

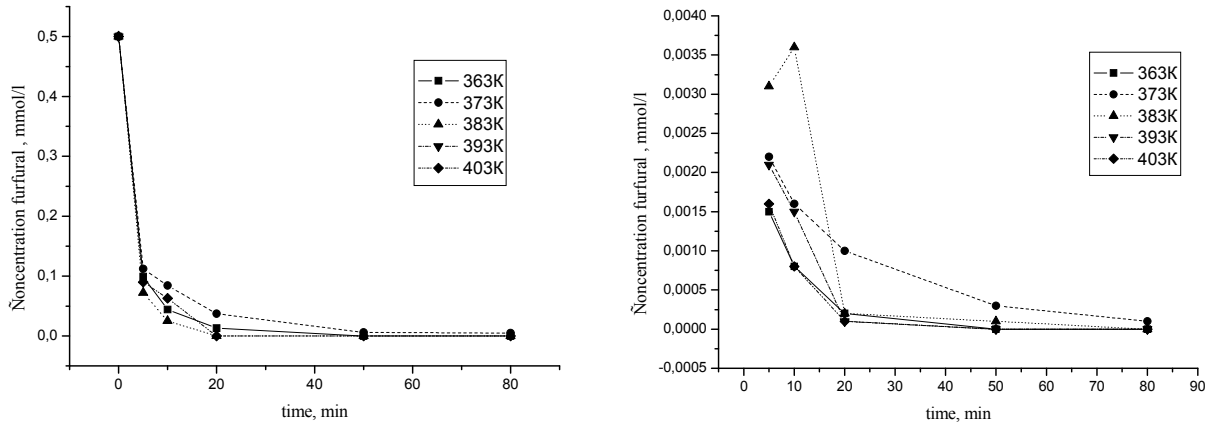
Common availability of biomass (especially the non-food waste type), caused the trend for reduction of dependency from petroleum resources and increased responsibility for the environment. This factors can be the driving forces behind the development of technologies that use derivatives of furfural, which are called, not without a reason, the “sleeping giants”. One might assume that a lot of interest in furan compounds may contribute to the development of new catalytic conversion processes of furfural and its derivatives, which in the future can lower the cost of their production. This could increase the scale of production, which will result in the launch on the market beneficial alternative fuels for spark ignition engines, which are forward-looking replacement for conventional gasoline [2].

2 Experimental/methodology

This work is devoted to furfural hydrogenation under H_2 over hypercrosslinked polystyrene-supported 3% Ru catalysts. A Ru/HPS catalyst was synthesized by the impregnation method using Ru(OH)Cl3 as a precursor of Ru-containing nanoparticles with the following reduction with hydrogen. To stabilize ruthenium nanoparticles hypercrosslinked polystyreneof HPS MN 100 functionalized by amino groups was used. Furfural hydrogenation was carried out on six-cell reactor Multiple Reactor System (MRS) Series 5000 at H_2 a pressure of 6 MPa, at temperatures ranging from 363 to 403 K. 0.1 g Ru-containing catalyst, 2 ml of pure furfural and 48 ml hexane were added to the reactor. Hexane was used as the solvent. The hydrogenation was carried out under continuous stirring (800 rev/min). Samples obtained during the hydrogenation reaction were analyzed using GC-MS Shimadzu QP-2010. Chromatographic separation of sample occurred on a capillary column HP-1MS 30m×0.25mm×0.25mkm with efficiency 4300 theoretical plates for pentadekan.

3 Results and discussion

Figure 1 shows dependence of the concentration on time for furfural and furfuryl alcohol from the reaction time of furfural hydrogenation using 0.1 g of 3% Ru/HPS at 363-403 K, under H_2 pressure of 60 atm, 48 ml hexane as the solvent



a b

Fig. 1. Dependence of the concentration on time for a) furfural b) furfuryl alcohol from the reaction time of furfural hydrogenation using 0.1 g of 3% Ru/HPS at 363-403 K, under H_2 pressure of 6 MPa, 48 ml hexane as the solvent for 80 min

During the investigation furfuryl and tetrahydrofurfuryl alcohol was found to be the main product of hydrogenation reaction, also and the intermediate products of reaction were found. The maximum conversion obtained over hypercrosslinked polystyrene-supported 3% Ru catalysts at 383 K and 6 MPa was 99.1% with 1.4% and 60.7% selectivity to furfuryl alcohol and tetrahydrofurfuryl alcohol. Increasing conversion furfural from 79.5% to 99.1% was observed in the temperature range 363 - 403 K while the formation of furfuryl alcohol decreased from 27.9 to 0%.

Keywords: hydrodesulfurization, NiW, hierarchical mordenite

1 Introduction

Due to the stringent demand of environmental regulations, the sulfur level in fuels must be reduced to 10 ppm in many countries, thus requiring more efficient HDS catalysts. The utilization of acidic supports has been suggested to improve the catalytic performance, in particular by enabling isomerization of the alkyl substituents in refractory compounds. Zeolites with strong acidity have thus been considered, however, due to their relatively small pore size, several problems such as rapid deactivation and diffusion limitation were generally met. To remedy this disadvantage, hierarchical zeolites have attracted much attention because of the introduction of additional mesopores. In the present work, we reported on NiW catalysts supported on mordenite and hierarchical mordenite. The catalytic performance of the obtained catalysts was evaluated in HDS of dibenzothiophene (DBT) and 4,6-dimethyldibenzothiophene (4,6-DMDBT) and compared with that of an alumina supported catalyst.

2 Experimental/methodology

Hierarchical mordenite was obtained by an acid–base–acid posttreatment method [1]. NiW based catalysts were prepared by impregnation on commercial and hierarchical mordenites and were labelled NiW/HM and NiW/HM-M, respectively (WO_3 content of 15 wt%, W/Ni molar ratio of 2.75). For comparison, a NiW/Al_2O_3 catalyst was prepared from a commercial alumina (BET surface area: 220 m^2/g, pore volume obtained by water adsorption: 0.6 cm^3/g). BET, TEM and XPS were conducted to characterize the materials. The HDS of DBT and 4,6-DMDBT was performed in high-pressure fixed-bed microreactor (length: 40 cm, inner diameter: 1.25 cm) at 613 K under 4 MPa of total pressure after in situ sulfidation of the catalyst [2].

3 Results and discussion

The catalytic performance of the catalysts were first evaluated in HDS of DBT. On NiW/Al_2O_3, products resulting from direct desulfurization (DDS) and hydrogenation (HYD) are identified [3], with a HDS reaction rate of 2.19 mmol $h^{-1}g^{-1}$. Nevertheless, lower HDS reaction rates than on alumina were measured on NiW/HM and NiW/HM-M, 0.37 and 0.98 mmol $h^{-1}g^{-1}$ respectively (as shown in Fig.1), despite the fact that these solids present higher sulfidation and promotion degree of W, as calculated from XPS. This could be attributed to the rapid deactivation of zeolite supported catalysts due to strong acidity of the support. Over NiW/HM and NiW/HM-M catalysts, alkylation (ALK) and further hydrocracking occurred due to the strong acidity of mordenite, with identical selectivities.

The catalytic performance of the solids was further evaluated in the HDS of 4,6-DMDBT, a more refractory molecule. As expected, a much lower HDS activity of NiW/Al_2O_3 (0.44 mmol h^{-}

$^{1}g^{-1}$) was found compared to HDS of DBT, attributed to the effect of steric hindrance of the methyl groups [4]. In presence of acidic supports (HM and HM-M), in addition to the products observed over conventional sulfided catalysts, isomerization products (mainly 3,6-dimethyldibenzothiophene) and their desulfurized products were obtained, allowing to maintain the same HDS reaction rates than with DBT. As a result, NiW/HM-M exhibited the best HDS rate (0.9 mmol h^{-1} g^{-1}), twice that of NiW/Al_2O_3, owing to the isomerization reactions promoted by the zeolite support. Moreover, the mesoporosity in the HM-M support appeared to be beneficial as it allows to double the HDS rate, for DBT and 4,6-DMDBT, in relation with higher developed acidity (as shown by IR-pyridine adsorption), better dispersion of the active phase (as illustrated by TEM analysis), better accessibility to large molecules and possibly to better anti deactivation ability.

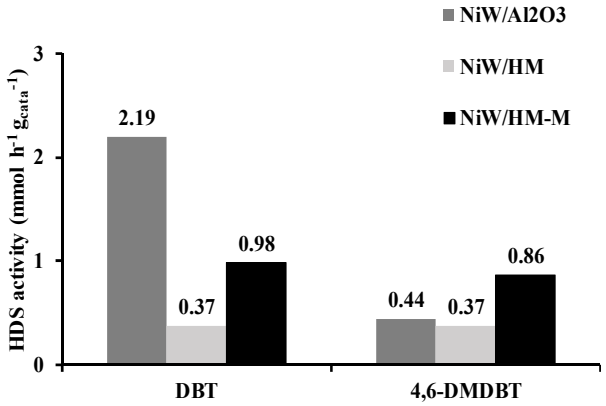

Fig 1: Activity in HDS of dibenzothiophene (DBT) and 4,6-dimethyldibenzothiophene (4,6-DMDBT) measured at 340°C under 4 MPa as total pressure, for the studied catalysts.

4 Conclusions

NiW/Al_2O_3 exhibited better HDS activity than NiW/HM and NiW/HM-M in the HDS of DBT. However, its activity was greatly inhibited in the HDS reaction of 4,6-DMDBT where NiW/HM and NiW/HM-M displayed maintained catalytic performance, probably in relation with additional reaction routes like isomerization associated to the strong acidity of the support. Furthermore, NiW/HM-M exhibited higher catalytic activity than NiW/HM in the HDS reactions of DBT and 4,6-DMDBT, showing the potential interest of hierarchical zeolites as support for deep desulfurization.

"Self-Sensitization" of Photocatalytic Activity of ZnO into Visible Region

Blashkov I.*, Basov L., Lisachenko A.

St. Petersburg State University, Department of Physics, Saint-Petersburg, Russia

* slipknoter90@rambler.ru

Keywords: photocatalysis, ZnO, intrinsic defects, "core-shell" structure, spectral self-sensitization

1 Introduction

The wide-bandgap oxide ZnO is one of the most widespread converters of solar energy into chemical and electric ones. However the threshold of the band-gap excitation ($h\nu \geq 3.3$ eV) lies in UV, so less than 5% of sunlight radiation may be used. Usually it is sensitized to visible region (containing 40% of solar energy) by molecular dyes, anions/cations doping, pretreatment in plasmas of Ar, N_2 or H_2, designing composites ZnO with narrow band semiconductors.

We have developed the original "self-sensitization" methods of the wide-bandgap photocatalysts formation using intrinsic defects [1] or designing near-surface 2D structures [2].

In this report we have studied an environmentally important reaction $CO + NO \xrightarrow{h\nu} CO_2 + 1/2\, N_2$ (1) on the "self-sensitizated" ZnO photocatalyst under the activation in the visible region.

2 Experimental/methodology

The powders of ZnO grade "OSCh 12-2 ($d \sim 100$ nm), previously refined of biographical impurities, were used. Surface defects of F-type were produced by photo-reduction of the surface at low temperature. The spectro-kinetic investigation in gas phase and the analysis of adsorbed intermediate products were performed using the mass-spectrometric method. The optical and the energy parameters of the surface were determined by optical spectroscopy and UPS. Spectral features of the photo-adsorption of H_2, CO, NO and C_2H_6 molecules were measured for to determine the nature of the active centers.

3 Results and discussion

It is shown that O_2 is photo-adsorbed on electron-donor centers, while H_2, CO and C_2H_6 are photo-adsorbed on hole centers. NO is photo-adsorbed on the centers of both types giving NO^- and NO_2^- precursor states.

The reaction (1) is really photocatalytic. The spectral activation region for the reaction (1) is shifted from the UV edge (385 nm) of ZnO to the visible light up to $\lambda > 570$ nm due to the intrinsic point defects of F-type which form a near-surface 2D structure. The mechanism of the reaction kinetics and the energy schemes of the active centers are presented.

4 Conclusions

We can expect that "self-sensitization" of $ZnO/ZnO_{1-\delta}$ based photocatalysts using intrinsic point defects and near-surface 2D-nanostructures is a feasible way to optimize the design of efficient photoactive catalysts for the use of solar energy.

Keywords: one-step hydrocracking, sunflower oil, borated alumina, borated zirconia, renewable, diesel

1 Introduction

The continuous growth of quality requirements for motor fuels and reducing hydrocarbon reserves demand participation of renewable sources based on biomass in their production. The process of production diesel fuels, based on the total hydrodeoxygenation (HDO) oils is one of the promising technologies for processing of vegetable feedstock. The resulting hydrocarbon product is characterized by increased content of C_{15}-C_{18} alkanes and the absence in the composition of sulfur compounds and aromatics. The catalysts of hydrotreating with the active phase Co(Ni)-Mo-S supported on alumina, mixed oxides (SiO_2-Al_2O_3, SiO_2-TiO_2) and zeolites are widely used in HDO. However, the cloud and pour points of the obtained diesel fuel do not reach the values stated in the current specifications. Therefore, additional hydroisomerization of fuel components over catalysts containing noble metals and acidic supports (SAPO-11, ZSM-22) are required. In addition, the stability of hydrotreating catalysts is maintained by a special introduction sulfur compounds into the reaction medium. This inclusion reduces the environmental benefits of renewable fuel production. Therefore, the development of non-sulfide hydrocracking catalysts providing one-step production of components of diesel fuels with improved low temperature properties is actual.

The main objective of this research was studying the effect of the nature oxide supports (γ-Al_2O_3, ZrO_2, B_2O_3-Al_2O_3, B_2O_3-ZrO_2) on the properties of bifunctional Pt-containing catalysts for hydrocracking of vegetable oil.

2 Experimental/methodology

The supports (γ-Al_2O_3 and ZrO_2) were prepared by calcination of pseudoboehmite and zirconia hydrate, respectively. Zirconia hydrate was obtained by precipitation from a solution of zirconium oxynitrate. The ZrO_2-Al_2O_3 support was synthesized by calcination a mixed hydroxide obtained by precipitation from a solution of zirconium and aluminum nitrate salts. Sample supports B_2O_3-Al_2O_3 and B_2O_3-ZrO_2 (20 wt.% B_2O_3) was synthesized by mixing zirconium hydroxide or pseudoboehmite with a solution of boric acid, followed by calcination. In all cases, the calcination is performed in air at a final temperature of 550 (γ-Al_2O_3, B_2O_3-Al_2O_3) or 650°C (ZrO_2, ZrO_2-Al_2O_3, B_2O_3-ZrO_2). Then, the platinum (0.5 wt. %) was introduced by impregnation of the supports with an aqueous solution of H_2PtCl_6. The obtained materials were dried at 120°C and calcined in air at 500°C. Before each experiment the catalysts were underwent to reduction treatment in hydrogen flow at 500°C. The catalysts were characterized by N_2 adsorption, XRD, TPR-H_2, chemisorption of H_2, TPD-NH_3, FTIR adsorbed CO, UV-Vis and HRTEM techniques. The catalytic tests were carried out in a continuous flow fixed bed reactor at temperature of 380°C, pressure of 4.0 MPa. The WHSV of feed was 1.0 h^{-1}. The H_2/feed ratio was 1400 (v/v). The time on stream was 20 h. The purified sunflower oil was used as the feedstock. The gaseous products of the process were determined by gas chromatograph equipped with the Porapak R column and TCD. Light gases (C_1-C_4) were analyzed by gas

chromatography using a DB-1 column and FID. Liquid hydrocarbon products were identified by GH-MS analysis. Contents of gasoline (IBP-150°C), diesel (150-350°C) and heavy gas oil (350°C-FBP) in liquid product were determined by simulation distillation.

3 Results and discussion

As can be seen from Table 1, catalysts $Pt/\gamma\text{-}Al_2O_3$ and $Pt/B_2O_3\text{-}Al_2O_3$ have the most developed porosity. Borate-containing catalysts $Pt/B_2O_3\text{-}Al_2O_3$ and $Pt/ZrO_2\text{-}B_2O_3$ are characterized by high levels of acid sites.

Table 1. Textural properties, acidity and dispersion of catalysts.

Sample	Surface area, m^2/g	Pore volume, cm^3/g	Pore size, nm	Desorption NH_3, μmol/g	Dispersion (H_2), %
$Pt/\gamma\text{-}Al_2O_3$	179	0.48	10.8	326	100
$Pt/B_2O_3\text{-}Al_2O_3$	203	0.50	9.9	498	76
Pt/ZrO_2	59	0.14	9.7	212	19
$Pt/ZrO_2\text{-}Al_2O_3$	67	0.15	9.1	187	15
$Pt/ZrO_2\text{-}B_2O_3$	150	0.16	4.4	353	7

According to the catalytic tests all systems provide complete hydrodeoxygenation vegetable oil. On the $Pt/B_2O_3\text{-}Al_2O_3$ and $Pt/ZrO_2\text{-}B_2O_3$ catalysts yield of diesel fraction reaches 81.5 wt. %. The diesel fraction include significant amounts of iso- and cycloalkanes (27.8 and 60.3 wt.% respectively, Table 2) along with the n-alkanes. That should have a positive effect on the low temperature properties of the resulting fuel components. The latter may be due to the dominance of Brønsted acid sites on the surface of borate-containing catalysts. The catalysts $Pt/\gamma\text{-}Al_2O_3$, Pt/ZrO_2, $Pt/ZrO_2\text{-}Al_2O_3$ are characterized by the Lewis type of acidity and contribute to the formation of products as almost exclusively n-alkanes (96.8 wt.% in the composition of the diesel fraction).

Table 2. Hydrocarbon composition of diesel fractions.

Compound	$Pt/\gamma\text{-}Al_2O_3$	$Pt/B_2O_3\text{-}Al_2O_3$	Pt/ZrO_2	$Pt/ZrO_2\text{-}Al_2O_3$	$Pt/ZrO_2\text{-}B_2O_3$
	Content in the diesel fraction, wt. %				
$\sum n\text{-}C_{10}\text{-}n\text{-}C_{14}$	0.7	1.0	0.9	0.9	3.7
$n\text{-}C_{15}$	5.8	3.4	7.5	7.0	3.6
$n\text{-}C_{16}$	2.1	2.7	0.9	0.9	2.9
$n\text{-}C_{17}$	66.0	41.5	77.3	77.2	21.2
$n\text{-}C_{18}$	21.1	22.7	4.4	5.0	7.5
$n\text{-}C_{19}+n\text{-}C_{20}$	1.1	0.9	2.5	2.8	0.9
The amount of n-alkanes:	96.8	72.2	93.6	93.8	39.7
The amount of iso-alkanes:	3.2	27.8	6.4	6.2	60.3

4 Conclusions

It is shown that as effective catalysts of vegetable oils hydrocracking can be used supported Pt-containing system based on both individual and borate-containing alumina and zirconia. The use of catalysts $Pt/B_2O_3\text{-}Al_2O_3$ and $Pt/ZrO_2\text{-}B_2O_3$ is more preferably due to the formation of iso- and cycloalkanes, which potentially providing good low temperature properties of diesel fuels.

Keywords: autothermal reforming, hydrogen production, bimetallic catalysts

1 Introduction

The decrease of anthropogenic load on the environment and transition to ecological energy production is one of urgent problems of modern society. Hydrogen energy and fuel cell technology are feasible alternatives for clean energy generation [1]. Autothermal reforming (ATR) of hydrocarbons is the most promising process for hydrogen production because of its high energy efficiency. While ATR reaction occurs at 800–900°C, the specific role of catalyst support is to provide high surface area and thermal stability, maintain dispersion of the metal particles and promote stability against sintering and carbon formation [2].The catalyst preparation method is also a key factor which can regulate the catalyst properties [3]. So the purposeful variation of support composition and preparation mode open possibility of control of state, dispersion and redox properties of the active metal, and consequently of the catalyst performance. This work is devoted to the study of the effect of support composition (x/Al_2O_3, x = CeO_2, ZrO_2, La_2O_3, $Ce_{0.5}Zr_{0.5}O_2$, $La_2O_3/Ce_{0.5}Zr_{0.5}O_2$) and preparation mode (co-impregnation, sequential impregnation) on the stability of NiPd bimetallic catalysts in the ATR of CH_4.

2 Experimental

The x/Al_2O_3 (x = CeO_2, ZrO_2, La_2O_3, $Ce_{0.5}Zr_{0.5}O_2$, $La_2O_3/Ce_{0.5}Zr_{0.5}O_2$) supports were prepared by impregnation of $(\gamma+\delta)$-Al_2O_3 granular support (0.25-0.5 mm) by an aqueous solution of salts (cerium nitrate $Ce(NO)_3 \cdot 6H_2O$, oxychloride of zirconium $ZrOCl_2 \cdot 8H_2O$, lanthanum nitrate $La(NO_3)_3 \cdot 6H_2O$) with following drying at 120°C and calcination under air at 850°C for 6 h. The content of support modifying additive (x) was varied at the range of 5-30 wt.%. NiPd bimetallic catalysts were prepared by Ni+Pd co-impregnation (CI) and Pd/Ni sequential impregnation (SI) methods. The nickel nitrate $Ni(NO_3)_2 \cdot 6H_2O$ and palladium nitrate $Pd(NO_3)_2$ were used as metal precursors. After drying at 120°C catalysts were calcined under air at 500°C for 4 h. The nominal contents of Ni and Pd metals in the prepared samples are 10 wt.% Ni and 0.2-0.5 wt.% Pd. ATR experiments were performed in a 14 mm i.d. quartz fixed bed reactor with a feed composition of CH_4: H_2O: O_2: He equal to 1: 1: 0.75: 2.5 under atmospheric pressure, at temperatures 650-950°C and gas flow rate 200 ml_N/min. Prior to each catalytic activity test, the catalysts were reduced in 30%H_2/He flow (100 ml_N/min) at 800°C for 2 h. Analysis of both inlet and outlet reaction mixtures was accomplished using the Stanford Research Systems QMS 300 mass-spectrometric gas analyzer by applying the preliminary peak intensity calibrations based on model gas mixtures.

3 Results and discussion

The ATR tests (time on stream 24 h) show that the prepared catalysts provide methane conversion of 90-100%, CO yield of 55-80% and H_2 yield of 55-85% at 850°C.The catalyst performance was significantly affected by support composition and method of catalyst preparation. An increase of H_2 yield is observed at the increase of the content of support modifying additive from 5-10 to 20-30 wt.% or using the Pd/Ni sequential impregnation method

instead of Ni+Pd co-impregnation method for the Ni and Pd precursors introduction into the support. The optimal support composition ($10Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$) and preparation method (Pd/Ni sequential impregnation) were selected. The optimized catalyst $NiPd/10Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$(SI) shows high activity (methane conversion of 90-100%, H_2 yield >80%) and resistance to deactivation by carbonaceous deposition during 100 h testing at 850°C in ATR of CH_4 with and without addition of H_2S (50 ppm).

In order to understand the evolution of the catalyst under reaction conditions the as-prepared and spent catalysts have been characterized by XRD, N_2 adsorption, HRTEM-EDX, DTA/TG and XPS. For as-prepared samples it was shown that average size of NiO particles increases from 6.7 to 17.5 nm in the following order of supports: La_2O_3/Al_2O_3< $La_2O_3/Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$< Al_2O_3< $Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$< CeO_2/Al_2O_3< ZrO_2/Al_2O_3. The type and content of nickel-containing phases (NiO, $NiAl_2O_4$, La_2NiO_4, Ni-La-Al-O) and Ni^{2+}cation reducibility are regulated by changing support composition by means of the change of strength of metal-support interaction. The content of Ni-containing species which are reduced in the high-temperature region (450-650°C) increases with: i) an increase of La content; ii) a decrease of Ce or Zr content in the support composition. The preparation method also modifies the catalyst reducibility. The use of the Pd/Ni sequential impregnation instead of Pd+Ni co-impregnation leads to formation of different types of Ni^{2+} species which are reduced in two temperature regions (300-400°C and 450-650°C). According to XRD and HRTEM-EDX data, resulting from 24-100 h on stream at 850°C in conditions of ATR of CH_4 reaction, the phase transformation of γ-Al_2O_3 to δ-Al_2O_3 and formation of Ni-Pd alloy particles (12-18 nm) occur, an increase of NiO particle size (from 10 to 25 nm) is observed, while $CeZrO_2$ particles retain their high dispersion (2-10 nm). The NiPd alloy/NiO ratio in the spent catalysts is affected by support composition and preparation mode. The formation of NiPd alloy is promoted by the use of co-impregnation method of preparation and is impeded by the presence of species with strong metal-support interaction (Ni-La-O, Ni-Al-O).

4 Conclusion

The directional regulation of Red-Ox properties, structure and particle size of Ni-containing active component by means of variation of support composition and preparation mode provides the development of an active and stable NiPd bimetallic catalyst for ATR of CH_4. Developed catalyst formulation 10wt.%Ni0.2wt.%Pd/10wt.%$Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$ prepared under optimized conditions shows high activity (CH_4 conversion ~100%, H_2yield > 80%), stability (time on stream 100 h), resistance to carbon formation and resistance to deactivation by sulfur. The best ATR of CH_4 performance of the optimized catalyst can be associated with peculiarity of NiPd particles structure and the optimal ratio between Ni^{2+} species with different ability for reduction.

Keywords: pillared, clays, isomerisation, Pt-catalysts, n-hexane, acid, center, (a.c.)

1 Introduction

The modern requirements to the quality of motor fuels suggest significant limitations aromatics which are ecologically dangerous components. In this connection, for the production of high-octane additives for gasoline the most promising direction is process of n-alkanes isomerization in isoparaffins and the development of new effective catalysts.

Using as a carrier of pillared layered aluminosilicate for platinum catalysts creates the opportunity for increasing of the conversion of n-alkanes, regulating of the composition and amounts of isomers at the expense of the varying acidity, dispersion of Pt particles and their distribution over the surface on the catalyst by creation of the new surface centers.

The purpose of work was the determination of the physical-chemical characteristics of the Pt-catalysts on Fe-pillared montmorillonite with varying content of platinum (0.1 and 0.35%) and their catalytic activity in the reaction of n-hexane isomerization.

2 Experimental/methodology

Methods were used: BET, XRD, TPD of ammonia, elemental analysis, electronic and IR spectroscopy. For the preparation of Pt-catalyst was used iron-pillared H-montmorillonite in Na- and Ca-forms. Pillaring was made by iron hydrocomplexes with following washing and heat treatment of the material. Platinum was introduced from H_2PtCl_6 solution by impregnation method.

The catalysts were tested in the isomerization of n-hexane at250-400^{0}C, P=1atm, molar ratio of H_2:C_6H_{14}=3.5,ω- 0.82 hour^{-1}. Analysis of the reaction products was carried out by GLC method on "3700" chromatograph with FID and the capillary column filled by squalane.

3 Results and discussion

The specific surface of iron pillared montmorillonite Fe(2.5)NaHMM and Fe(2.5)CaHMM are 166.7 and 176.6 m2 / g, accordingly. Introduction of 0.1% platinum reduces the Sss for Fe(2.5)NaHMM-contact in 1.1 times, and for Fe(2.5)CaHMM -1.2 times, with the increasing of Pt amount to 0.35% Sss of contacts is reduced in 1.6 times for Fe(2.5)NaHMM and in 1.42 times for 2 sample. It was shown that all the studied catalysts are mesoporous and mesopore maximum amount is found on the 0.35% Pt/Fe(2.5)CaHMM (90%) and 0.1% Pt/Fe(2.5)NaHMM (79.1%). Features of the porous structure of the contact lead to the concentration of platinum on the surface layers of catalyst. With the introduction of 0.35% Pt in the surface layer platinum is found 0.83% -for Fe(2.5)CaHMM and 0.97%-for Fe(2.5)NaHMM. The strength of Pt- contacts based on Fe(2.5)NaHMM is 155.5N/sm^2, and on the basis of Fe(2.5)CaHMM - 135.5 N/sm^2.

During tests of the catalysts is shown that the maximum conversion of n-hexane is 36.4%, which is observed on 0.1%Pt/Fe(2.5)NaHMM at 400^{0}C, characterized by increased amount of mesopores (79.0%). Selectivity to C_6 and C_{6+} -isomers on 0.1%Pt/Fe(2.5)NaHMM at 350 and 400^{0}C exceeds the corresponding value for the contact based on the Fe (2.5) CaHMM. Among

reaction products for catalysts of both types the insignificant quantity of C_1-C_5-products of hydrocracking and the increased content of C_{6+} isomers are noted, so that the selectivity to C_{6+} isomers is 97.8-100%. On 0.1%Pt/Fe(2.5)NaHMM disubstituted isomers of hexane and heptane in amount of 60.4% are formed. The proportion of 2,2 and 2,3dimethylbutane is 52.5% among of total amount of isomerization products. On 0.1% Pt / Fe (2.5) CaHMM proportion of 2,2 and 2,3 dimethylbutane is 66.7%, and it is 44.4%. for C_7-isomers. At the transition to the 0.35% Pt-catalysts the conversion of n-hexane increases especially at 350 and 400^0C, which is obviously connected with hydrocracking, which leads to the decreasing of selectivity to C_6 and C_{6+} isomers. The relative number of disubstituted isomers formed on 0.35%Pt-catalysts is less than on 0.1% -contacts.

Study of acid characteristics showed that total acidity of 0.35%Pt/Fe(2.5)NaHMM, which is equal to 250 mkmolNH_3/g, as the conversion of n-hexane, is more than for catalyst on the base Fe(2.5)CaHMM.The same regularity was observed on 0.1% Pt-catalysts. The acidity of Pt /Fe(2.5)NaHMM is more in 1.5 times and the activity in 1.8 times more than these values for Pt/Fe(2.5)CaHMM-contacts. Catalysts based on NaHMM markedly excel in catalysts based on CaHMM by the total amount of strong and medium a.c. (in 1.6 times). Probably for this reason, the catalysts based on NaHMM show higher activity in hydrocracking. Comparison of the data for the montmorillonite in Na- and Ca-forms, pillared iron, it can be concluded correlation between the isomerization activity of studied Pt-catalyst and total amount of a.c. and the total content of medium and strong a.c. Pt- catalysts supported on FeNaHMM have higher activity compared with the results on FeCaHMM. For identifying of acid centers type was used the method of IR spectroscopy with molecule-probe of carbon monoxide. Data on the adsorption of CO on NaHMM, Fe(2.5)NaHMM and 0.35Pt/Fe(2.5)NaHMM-contacts were compared. L.a.c. and B.a.c. with predominance L.a.c. are found on the surface of NaHMM and Fe (2.5) NaHMM. In these catalysts absorption bands of B.a.c., at vacuum after CO adsorption at 200 and 400^0C disappear. On the Pt-containing contacts after evacuation absorption bands of CO characterizing B.a.c. remain, probably due with the formation of surface water hydroxyls due to the platinum-catalyzed reaction of CO with hydrogen. It is concluded that L.a.c. and B.a.c. of different strengths in experience conditions are presented on the surface of Pt-catalyst.

Pt^0 particles with size 40-50Å are identified by TEM method on 0.1% Pt-catalysts. In addition with metal platinum particles of Pt_3Fe, αFe, FeO, and etc. are identified. With the increasing of Pt content amount of small metal particles is reduced and large Pt particles increases. The results indicate the formation of nanodispersed Pt particles on the surface of Fe-pillared MM and a strong interaction between the supported metal and carrier with formation of intermetallic compounds and oxides are observed. Because the activity the catalysts with formation of disubstituted isohexanes increases with decreasing amounts of platinum can talk about the influence of Pt particles dispersion on the direction of the isomerization process.

4 Conclusions

Conversion of n-hexane under atmospheric pressure in isomerization correlates with the total amount of strong and medium a.c. Pt-supported catalysts on FeNaHMM have more higher activity compared with the results of FeCaHMM. It has been shown that the increased acidity of Fe (2.5) NaHMM-contact leads to increased cracking and reduced selectivity by C_6-isomers. The relative number of disubstituted isomers formed on 0.35%Pt-catalysts is less than on 0.1% -contacts.The results indicate the formation of nanodispersed Pt particles on the surface of Fe-pillared MM and a strong interaction between the supported metal and carrier with formation of intermetallic compounds and oxides. It is concluded that the effect of dispersion of platinum particles on the direction of the isomerization process.

Keywords: acetylation, glycerol, phosphate, sulphate, acid, catalyst, triacetin

1 Introduction

In recent years, due to the increasing price of fossil fuel and to the environmental concern there has been a considerable interest in developing biodiesel as alternative fuel. Biodiesel is a mixture of fatty acid methyl ester (FAME) produced by the transesterification of triglycerides with methanol. One of the major problems, during the production of biodiesel, is the formation of glycerol (10% wt) as principal by-product. Different chemical transformatios of glycerol into high-value chemicals have been developed to produce propanediols, acrolein, hydroxyaceton, glyceric acid [1]. Among the different reactions, the esterification of glycerol into acetins is quite attractive due to the versatile industrial application of the final products, going from cosmetic to fuel additives [2]. Conventionally, the esterification reactions are industrially performed under batch conditions in homogeneous liquid phase catalysed by strong Brønsted acids. Efforts are being made to turn the process into "green" chemical reaction working on heterogeneous catalysts that are easier to handle and safer. Recently, some of us have reported for sulfonic acid functionalized mesoporous silicas high activity and good stability for glycerol acetylation to triacetin [3]. Metal (IV) phosphates have been successfully used as solid acid catalysts for several biomass-based components conversion to chemicals [4,5]. Proper substitution of phosphate by sulfate would increase the acidity of the catalysts.

In the present work the acetylation of glycerol over zirconium phosphates with formula $Zr_3(PO_4)_4$, α-$Zr(HPO_4)_2$ and ZrP_2O_7 was investigated. Moreover, the effect of substituting phosphate group by sulfate was also addressed.

2 Experimental

All the used catalysts were synthetized by precipitation. Zirconium phosphate with formula, $Zr_3(PO_4)_4$ and mixed zirconium phosphate-sulphate, with formula, $Zr_2(PO_4)_2SO_4$ were prepared, respectively, by adding $ZrOCl_2 \cdot 8H_2O$ aqueous solution to H_3PO_4 acid solution or to a stoichiometric mixture of H_3PO_4 and H_2SO_4 acid solutions. The obtained gel was stirred for 2 h at 80 °C until dryness, then it was dried in oven at 110 °C overnight and calcined at 500°C for 24 h. The zirconium phosphate α-$Zr(HPO_4)_2$ was prepared by adding $ZrOCl_2 \cdot 8H_2O$ aqueous solution to concentrate H_3PO_4 acid and refluxing for 48 h. The obtained gel was recovered by filtration, then, it was washed with water until pH 4.5 and dried at room temperature.

The ZrP_2O_7 was obtained by calcining at 500 °C for 24 h a portion of the α-$Zr(HPO_4)_2$ compound. The prepared samples are herein named as fresh catalysts.

Characterizations by XRD, FT-IR, NH_3-TPD were performed. Moreover, XPS analyses were carried out over the most active samples. The surface chemical composition in terms of P/Zr and S/Zr atomic ratios was monitored in the fresh and used catalysts. The glycerol acetylation reactions were performed by using a mass ratio of catalyst/glycerol equal to 5wt% and molar ratio acetic acid/glycerol corresponding to 3:1, as previously used [3]. The products

were analysed by GC-MS. Recycling experiments up to 5 cycles were performed over the most active catalysts.

3 Results and discussion

The glycerol conversion as a function of the various catalysts is displayed in Fig. 1a. Over $Zr_2(PO_4)_2SO_4$, 96% of glycerol conversion was obtained in only 1h and full conversion was reached after 3h. $Zr_3(PO_4)_4$, ZrP_2O_7 and α-$Zr(HPO_4)_2$ were less performing giving about 85-90% of glycerol conversion after 3h. The selectivity of the glycerol acetylation was oriented toward the formation of mono- and diacetin. Only in presence of $Zr_2(PO_4)_2SO_4$, after 3h of reaction, 11% of the desired triacetin was detected. The stability of the $Zr_2(PO_4)_2SO_4$, exhibiting the best catalytic performance, was investigated in recycling runs of 1h (Fig. 1b). A decreased activity was observed after the first cycle yielding about 80% of glycerol conversion in the second, third and fourth run. Further deactivation occurred in the fifth cycle, suggesting leaching of sulphate species, as confirmed by XPS analyses of the fresh and used catalyst.

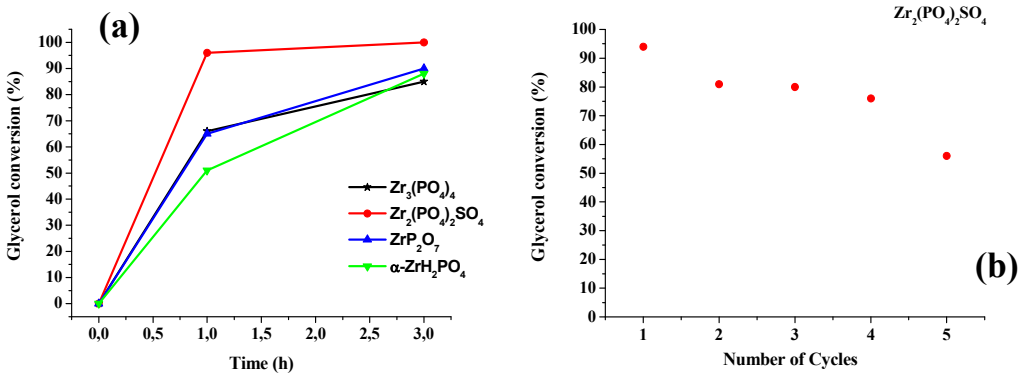

Fig. 1. (a) Conversion of glycerol over different Zr phosphates and Zr phosphate-sulphate catalysts. (b) Recycling runs over the most active catalyst, $Zr_2(PO_4)_2SO_4$.

4 Conclusions

Mixed Zr phosphate sulphate catalysts, such as $Zr_2(PO_4)_2SO_4$, appear promising for glycerol acetylation and worthy of further investigation. With this aim, glycerol acetylation over other mixed composition, $Zr_3(PO_4)_2(SO_4)_3$, $Zr_4(PO_4)_2(SO_4)_5$ and $Zr(SO_4)_2$ is in progress.

Keywords: copper, delafossite, synthesis, catalyst

1 Introduction

Cuprous oxide $CuMO_2$ with the structure of delafossite attracts the attention of researchers due to their physicochemical properties. Copper delafossites are p-type semiconductors transparent in the visible range of light having luminescent, thermoelectric and catalytic properties.

Well crystallized delafossite $CuMO_2$ could be prepared by solid state reaction at temperatures exceeding 1000°C [1]. However, the literature describes methods for obtaining at low temperatures, for example, synthesis using aluminum nitrate or hydrothermal synthesis [2,3]. Thermal treatment of joint co-precipitated oxyhydroxides was also studied in this research.

2 Results and discussion

Sintering of aluminum nitrate and copper oxide at 300°C doesn't give a delafossite structure, but it gives CuO phase and X-ray amorphous aluminum-containing phase. Analysis of radial distribution function of the electron density showed that aluminum cations have octahedral oxygen coordination in this compound. According to thermal analysis and XRD, the evolution of oxygen leads to the delafossite formation at temperatures as high as 990 °C (Figure 1). The final phase composition of the sample depends on the calcination and cooling atmosphere. Apparently, the cooling in the synthetic air leads to oxidation of Cu^{+1} and to the formation of spinel $CuAl_2O_4$ and copper oxide CuO phases (Table 1).

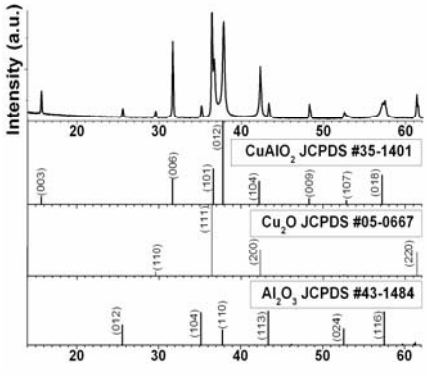

Figure 1. Diffraction pattern of the aluminum nitrate and copper oxide mixture heated at 1000°C in argon.

Table 1. Phase composition of the mixture heated to 1000 C in air and in argon.

Phase	Calcined at 1000 °C in argon		Calcined at 1000 °C in synthetic air	
	Mass fraction, %	CSD size, nm	Mass fraction, %	CSD size, nm
$CuAlO_2$	69	26	48	43

		[001]: > 100		[001]: > 100
$CuAl_2O_4$	-	-	21	45
Cu_2O	16	> 100	-	-
CuO	-	-	20	61
Al_2O_3	15	> 100	11	> 100

The copper-aluminum hydroxycarbonate obtained by coprecipitation transforms to the delafossite at 885°C. This temperature is by 100° C lower than for the samples prepared from a mixture of copper oxide and aluminum nitrate. According to thermal analysis, this process is accompanied by heat absorption and weight loss of about 1.5%.

Using the hydrothermal method of preparation, we managed to get a small amount of delafossite phase at 220°C. The best results of hydrothermal synthesis in terms of the delafossite phase yield and dispersion were obtained using Cu-Al coprecipitated compound of composition Cu:Al = 1:1 pre-calcined at 350°C. Apparently, the use of phase in which copper and aluminum ions are uniformly distributed is more preferable for delafossite phase formation under hydrothermal conditions than the use of a mixture of metal oxides and aluminum.

The significant yield of delafossite phase at a relatively low temperature (less than 420°C) has been achieved for the Co-containing sample prepared by co-precipitation method. The delafossite phase yield depends on the composition. Addition of minor amounts of aluminum improves the yield from 15% to almost 70% (Table 2).

Table 2. Phase composition of Co-containing samples.

Phase	$Cu_{0,5}Co_{0,5}$		$Cu_{0.45}Co_{0.45}Al_{0.1}$	
	Mass fraction, %	**CSD size, nm**	**Mass fraction, %**	**CSD size, nm**
$CuCoO_2$	15	22	~70	20
CuO	44	11	~18	26
CoO	37	11	-	-
Co_3O_4	4	21	~12	25

3 Conclusions

Preparation of copper oxide compounds with delafossite structure is possible at a low temperature. Dispersion suitable for the catalytic applications can be achieved. However, further research is needed to improve the phase purity of the samples.

Keywords: biodiesel, three-stage method, esterification, neutralization, transesterification

1 Introduction

Biodiesel is a mixture of methyl esters of fatty acids. It is synthesized by transesterification of vegetable oils, in presence of alkaline catalysts for fast production and industrial application. Waste cooking oils (WCO) and non-edible oils, despite their high contain level of free fatty acids (FFA) and other impurities that cannot be directly converted into biodiesel, were used because of their low price [1]. It is, therefore, required to reduce the FFAs concentration in the oil below the allowed limits prior to biodiesel manufacturing. Different approaches have been attempted: neutralisation, esterification and acid or lipase catalysis transesterification. All these contribute to the increase of the biodiesel cost [1]. The synthesis using the in-situ three-stage method based on in-situ esterification, neutralization and transesterification is possible. The present work was devoted to the optimization of the neutralization step.

2 Experimental

The feedstocks (WVO) used in this study was supplied by Kilimanjaro Environment Company (Casablanca, Morocco). The WCO was filtered and heated at 115°C before using it to remove impurities and water. The oil is characterized by its high acidity developed by heating and hydrolysis (4%). The three-stage method is based on the acid-catalysis esterification of the FFA, followed by in-situ neutralization by an excess of $Ca(OH)_2$ that served as the catalyst for the followed step, e.g. transesterification. In all the stages, water was eliminated on silica traps. Esterification and transesterification reactions were performed according to literature [1].

3 Results and discussion

The calcium hydroxide material used as neutralization base and transesterification catalyst was characterized by DRX. The untreated sample exhibits a typical diagram of calcium hydroxide (portlandite) in agreement with JCPDS (N°.01-073-5492) file. The FTIR spectrum of $Ca(OH)_2$ presents a narrow absorption band at 3642 cm^{-1} due to stretching mode of O-H. TG curve showed that the dehydroxylation of $Ca(OH)_2$ occurs between temperatures 390 and 476°C, with a mass retain of about 23.5%, very close to CaO. Prior to its use $Ca(OH)_2$ was preheated at 200°C.

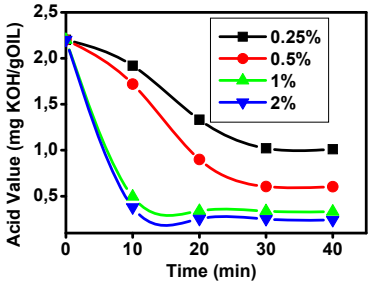

Fig. 1. Acid value variation versus time at different $Ca(OH)_2$ concentration

Preliminary studies showed that butter esterification can be completed at 60°C after 60 min using a methanol/oil ratio equal to 18:1. The achieved conversion corresponds to a residual acidity of 0.44% which is equivalent to the acidity used in the best transesterification. After the esterification, calcium hydroxide was added to the reaction mixture. Fig.1 shows that the addition of $Ca(OH)_2$ decreases the acidity of the reaction mixture denoting a neutralization of the acid catalyst. Addition of a stoichiometric amount of the base compared to the initial amount of H_2SO_4 reduces slightly the acidity.

After the neutralization, the mixture was centrifuged and the two phases were recovered. DRX characterization of the solid phase showed the formation of calcium sulfate dehydrate, e.g. $Ca(SO_4),2H_2O$ (Fig. 2) confirming an in-situ neutralization of the acid catalyst.

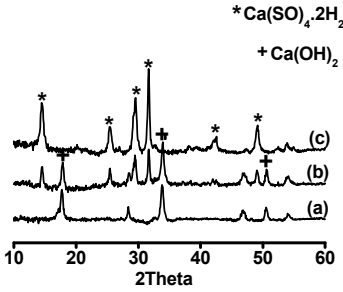

Fig. 2. DRX diagrams of $Ca(OH)_2$ (a), Excess of $Ca(OH)_2$(b) and Stoichiometric amount of $Ca(OH)_2$(c)

The transesterification was also performed immediately after the neutralization. The results show that the conversion was complete and reaches around 96 % in the three-stage method. The produced biodiesel responds reasonably to the European Standards (Table 1).

Table 1: Physicochemical properties of synthesized biodiesel

Batches		Three stages method	Classical method	Standards
Yield	**4** t.%	95.8	79	_
Ester content	**5** t.%	98	95.5	≥ 96.5
Viscosity (40°C)	**6** st	3.5	4.7	3.5-5.5
Density (15°C)	g/cm^3	0.885	0.880	0.88-0.9
Water content	ppm	348	368	500x

4 Conclusions

The optimal conditions for the transesterification reaction depend on the quality of the used cooking oil. The ^{1}H-NMR, ^{13}C-NMR, FT-IR and GC analyses of the final product confirmed that it is possible to produce biodiesel obeying European standards by the in-situ three-stage method.

Keywords: ^{13}C labeled experiments, Ni/Zr O_2, Pt/Zr O_2, DRIFTS, circulation system, dry reforming

1 Introduction

Climate change and depletion of hydrocarbon resources of the Earth are the main causes of the nowadays increased research on catalytic dry reforming (DRM: $CO_2+CH_4 \leftrightarrow 2\ CO+2\ H_2$). In our laboratory several aspects of dry reforming have been already investigated over Ni-based catalysts prepared by different methods and supported on different oxides[1,2]. In the present study the same amount of Na as catalyst promoter was used to get ZrO_2-supported Ni and Pt catalysts, applying a simple preparation method that could be feasible at larger (industrial) scale. Structural differences between the samples were investigated and the catalytic behavior was evaluated in plug flow reactor with high excess of methane and in closed loop circulation system at sub atmospheric pressure with labeled $^{13}CO_2$ reactant to be able to spoor the fate of different carbon species.

2 Experimental/methodology

ZrO_2 calcined at 600°C (denoted as Zr6) or 800°C (denoted as Zr8) was used as support for the preparation of 1%Ni/ZrO_2, 3%Ni/ZrO_2 and 1% Pt/ZrO_2 catalysts. The impregnation was done with large excess of water and with the addition of $NaHCO_3$. Dried samples were calcined in air and reduced in H_2 at 600 °C before further use. Structural investigations were carried out by TEM, HRTEM, XRD, XPS and DRIFTS methods (CO chemisorption).

Temperature programmed dry reforming experiments were done i) at atmospheric pressure in plug flow reactor and an in situ DRIFTS cell or ii) under sub atmospheric pressure (~50 mbar) in a closed loop circulation system using labelled $^{13}CO_2$. TPD in this circulation system and TPO of the retained species were used to further reveal the differences between the samples.

3 Results and discussion

The calcined and reduced fresh catalysts contained nanoparticles in the range of 2-20 nm, the Pt/ZrO_2 sample had the highest metal dispersion. The presence of Na was suggested to induce the population of unique bridged CO sites during CO chemisorption DRIFTS measurements on all the samples and to cause binding energy shift to lower values in the case of the highly dispersed Pt/ZrO_2 (XPS).

Low temperature DRIFTS measurements (shown in Figure 1 a) in the presence of dry reforming mixture showed that the carbonates/formates decomposed or could not form in a large amount on Pt/ZrO_2, while on Ni samples more and fairly stable adsorbed carbonates were detected.

On Ni samples coke formation took place during DRM reaction, as measured by the

subsequent TPO. However, most part of this carbon must reside on the support, and leave the Ni sites free, because Zr6Ni3imp despite of this coke was fairly stable and active catalyst (flow tests). CO_2 dissociation on Ni is suggested to provide the main source of active oxygen species at higher temperatures.

In contrast to Ni samples, no deposited carbon was formed on Pt/ZrO_2. The significant water gas shift activity seen during the plug flow tests and the TPD experiments after dry reforming reaction is supposed to keep the surface carbon species hydrogenated and easy to be removed in the case of Pt/ZrO_2.

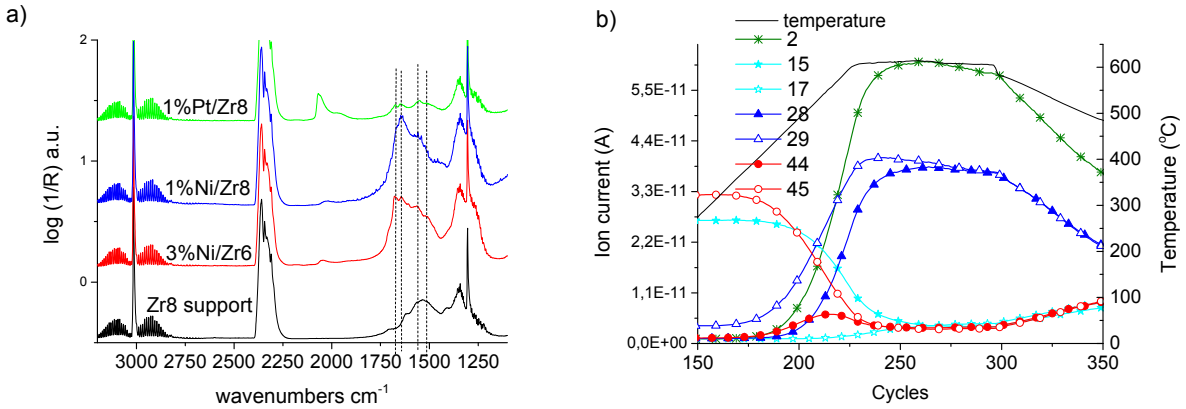

Fig. 1. a) Comparison of DRIFTS spectra of the samples obtained at 400°C in the presence of 70%CH_4:30%CO_2 mixture. b) Dry reforming reaction with 25 mbar CH_4 + 25mbar $^{13}CO_2$ in circulation system on 3%Ni/Zr8. Conditions: temperature ramp up to 600°C with 10°C/min, then 30 min isothermal part, x axis reflects time (1 MS cycle~25.8 sec).

4 Conclusions

Considering all our results, an overall mechanism for the start of reaction could be suggested that holds for Ni and Pt catalysts as well. Figure 1 b reflects, that first CO_2 is activated as $^{13}CO_{2(gas)} \leftrightarrow {}^{13}CO_{ads} + O_{ads}$ and the $^{13}CO_{ads}$ immediately desorbs. At 350-400°C, $^{12}CH_4$ dissociation happens and the surface C get oxidized by abundant active O species and desorbs as $^{12}CO_2$ together with the recombined H_2 molecules. Next, ^{12}CO appears in the gas phase because of the incomplete oxidation of surface carbon due to less available surface oxygen species and because of the $^{12}CO_2 \leftrightarrow {}^{12}CO+O$ reversible transformation on the catalyst surface. Methane dissociation is considered reversible, because methane can form from $^{13}CO + H_2$ or $^{13}CO_2 + H_2$ via surface methanation reaction that proceeds through C_{ads} intermediate species. According to our isotope labeled measurements, common reaction intermediates originating from methane and carbon dioxide do exist at 600 °C.

Mathematical Model of Catalytic Hydrodewaxing of Distillates

Belinskaya N.S.*, Ivanchina E.D., Ivashkina E.N., Nazarova G.Yu.

National Research Tomsk Polytechnic University, Tomsk, Russia

* belinskaya@tpu.ru

Keywords: catalytic hydrodewaxing, diesel fuel, mathematical model, polyfunctional catalyst

1 Introduction

One of the varieties of light hydrocracking is hydrodewaxing of distillates. It represents light hydrocracking (breakage) of n-paraffin hydrocarbons in order to produce diesel fuel with improved low-temperature properties. The purpose of the process is producing of winter arctic diesel fuel with very low freezing point (from -18 to -68 °C). A polyfunctional zeolite-containing catalyst is used in this process [1]. The work is devoted to mathematical model of the process development.

2 Methodology

While developing of the catalytic hydrodewaxing model thermodynamic analysis of reactions was made via quantum-chemical calculations of thermodynamic characteristics of reactions under technological conditions that correspond industrial unit operation. Then hydrocarbons conversion scheme was created. It includes primary reactions of long-chain n-paraffins cracking and subsequent isomerization of cracked n-paraffins through the stage of olefin and iso-olefin formation on acid sites of polyfunctional catalyst. The side reactions of hydrogenation of monoaromatic and polyaromatic compounds, cyclization of iso-paraffins are also included in the conversion scheme.

Willing to hydrocarbon conversion scheme kinetic model was developed. It represents a system of differential equations of concentrations changing under contact time:

$$\begin{cases}
\frac{dC_{N-paraffins\ C_{10}-C_{27}}}{d\tau} = -W_1 \\
\frac{dC_{N-paraffins\ C_5-C_9}}{d\tau} = 2\cdot W_1 - W_2 + W_{-2} \\
\frac{dC_{I-paraffins}}{d\tau} = W_3 - W_{-3} - W_4 + W_{-4} \\
\frac{dC_{Olefins}}{d\tau} = W_2 - W_{-2} - W_3 + W_{-3} \\
\frac{dC_{Naphthenes}}{d\tau} = W_4 - W_{-4} - W_5 + W_{-5} \\
\frac{dC_{Monoarom}}{d\tau} = W_5 - W_{-5} + 2\cdot W_6 - 2\cdot W_{-6} \\
\frac{dC_{Polyarom}}{d\tau} = -W_6 + W_{-6} \\
\frac{dC_{Hydrogen}}{d\tau} = -W_1 + W_2 - W_{-2} - W_3 + W_{-3} + W_4 - W_{-4} - 3\cdot W_5 + 3\cdot W_{-5} - W_6 + W_{-6}
\end{cases}$$

Contact time is calculated via volume of catalyst (V_{cat}) and sum of feed and hydrogen rich gas flow rate (G_R and G_{HG} respectively):

$$\tau = \frac{V_{kat}}{G_R + G_{HG}}.$$

Kinetic values of the model (preexponential factor in Arrhenius equation for each reaction) were found via solution of reverse kinetic problem using a large selection of full-scale experimental data. Rate constants of the straightforward reactions were found via Arrhenius equation and account

1.241, 1.795, 3.108 for hydrocracking of long-chain n-paraffins, dehydrogenation of short-chain n-paraffins and hydrogenation of olefins respectively. Rate constants for cyclization of iso-paraffins, hydrogenation of monoaromatic compounds, hydrogenation of polyaromatic compounds are 0.014, 0.128, 0.128 respectively.

Verification of model to the full-scale process showed a high degree of calculations accuracy in comparison to experimental values. Absolute error of calculations did not exceed 3 % wt.

3 Results and discussion

In the process of hydrocracking it is crucial to maintain the excess of hydrogen in circulating gas as fresh hydrogen, injected simultaneously with the feed, is intensively consumed in chemical reactions of hydrocracking. The hydrogen circulation rate is as higher as heavier the feed is and higher conversion degree is as well as lighter obtained products are. The hydrogen consumption rate significantly influences the exploitation expenses as well [1]. For these reasons optimal hydrogen containing gas maintenance depending on the feed composition is vital in order to achieve resource efficiency of the plant.

Using developed mathematical model hydrogen to feed molar ratio on the conversion of long-chain n-paraffins and yield of i-paraffins was investigated.

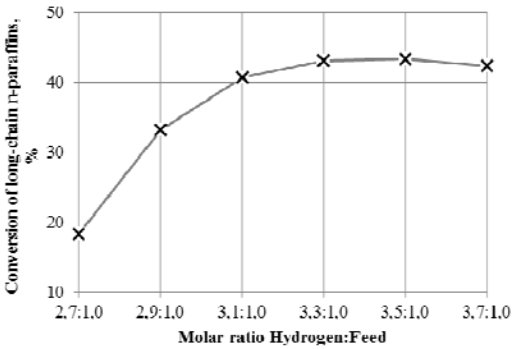

Fig. 1. Conversion of long-chain n-paraffins depending on molar ratio Hydrogen:Feed

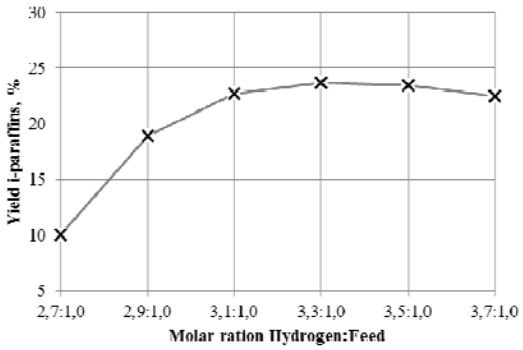

Fig. 2. Yield of i-paraffins depending on molar ratio Hydrogen:Feed

According to the fig. 1 and fig. 2 conversion of long-chain n-paraffins and yield of i-paraffins increase steadily with Hydrogen:Feed ratio increasing until 3,3:1,0 and reach 43 % and 24 % respectively for the taken feed composition. Further increasing the ratio is worthless as it leads to decreasing in long-chain n-paraffins conversion and i-paraffins yield.

4 Conclusions

The presented research showed that mathematical model is an effective instrument for analysis and optimization of complicated multifactorial re-refinery process of hydrodewaxing. Application of the model allows increasing resource efficiency of the high quality diesel fuel production on 15-20 %.

Keywords: nitrous oxide, alkenes, selective oxidation, ketones

1 Introduction

Nowadays nitrous oxide (N_2O) is considered as effective donor of oxygen. Thus recently it was discovered that nitrous oxide can lead the non-catalytic liquid-phase oxidation of alkenes into carbonyl compounds – aldehydes and ketones. These reactions run at 150-250°C with high selectivity, often close to 100% [1]. The investigation of the wide range of such reactions demonstrated that carbonyl compounds can be synthesized using different types of alkenes include linear, cyclic, heterocyclic and derivatives.

In the present work the influence of cis-trans isomerization of heptane-3 on reactivity of C=C bond of alkenes towards N_2O as well as the contribution of the reaction route with the break of the initial double bounds were studied. This knowledge is important for the understanding the oxidation reaction by nitrous oxide of double bonds of butadiene rubbers with different degrees of stereo regularity.

2 Experimental/methodology

The reaction was carried out in stainless steel Parr reactor with capacity of 100 cm^3. The composition of products was investigated by gas chromatography and NMR spectroscopy.

3 Results and discussion

On the base of obtained data the scheme of heptane-3 oxidation by N_2O was proposed. It was shown that both cis- and trans-heptane isomers perform very similar reactivity. For example the cis-isomer conversion at 240°C after 6 hours was 21.4%. In the case of trans-isomer under the same conditions conversion was 19.5%. At the same time for trans-hepten-3 the contribution of the route with C-C bound break (F_{br}) is approximately three times higher comparing with cis-heptane-3. So under such oxidation conditions trans-isomer performs higher reactivity towards bound break comparing with cis-isomer. The origin of this difference is under discussion.

It should be mentioned that conclusion on the portion of C-C bound breaks for different isomers made on the base of presented experiments well agrees with our previous studies. Thus for the oxidation of buten-2 and penten-2 F_{br} performed the intermediate value (F_{br} = 8%) [2], evidently this can be explained by the fact that these alkenes consist of the isomer mixtures. The portion of the route with C-C bound break found for cis-hepten-3 is close to F_{br} = 5% obtained for the oxidation of stereo regular cis-butadiene-1,4 rubber by N_2O [3]. At the same time the portion of the bound break for trans-heptane-3 is in good agreement with F_{br} = 15% observed for C=C bound oxidation of butadiene-nitrile rubber [4], which contains trans-butadiene-1,4

units mostly.

4 Conclusions

The presented study reveals the common regularities of the oxidation of compounds with C=C bounds by nitrous oxide. The observed difference in contribution of the reaction route with C-C bound break for the olefins confirms the results obtained for rubbers previously.

Keywords: hydrotreating, hydrocracking, oil sludge, micro/mesoporous materials, sulfided catalysts

1 Introduction

Incorporation of oil sludge (OS) in refining will help to solve some urgent environmental and economic problems such as energy recovery and reduction of the volume and quantity of waste. OS is the waste of oil production and sometimes refining; it consists of heavy hydrocarbons mixture (essentially, crude oil) and water [1]. Thermohydrocatalytic treatment due to particular feature of OS composition is considered to be the most reasonable way to use OS. Here we report the new synthesis of sulfided catalysts based on the micro/mesoporous systems, phys.-chemical properties of these catalysts and their catalytic activity in OS hydrotreating.

2 Experimental

In this work, an original approach for preparing NiW/SBA-15/ZSM-5 and NiW/SBA-15/zeolite-β hybrid support is presented. The adopted preparation strategy was based on the effective confinement of the suflided catalyst within the pores of an SBA-15/zeolite carrier (d_{pore} = 7.0 nm). In the course of study two different ways of synthesis micro/mesoporous aluminosilicates were applied: a) zeolitization of ZSM-5 and β in SBA-15 walls b) double templating synthesis [2]. New NiW catalysts were obtained by one-step incipient-wetness impregnation method and after that they were dried at 110 ^{o}C, calcined at 550 ^{o}C and presulfided by sulfur-toluene solution, 50 atm H_2, 400^{o}C. The supports and catalysts were characterized by various techniques including XRD, nitrogen adsorption, TEM, ^{27}Al and ^{29}Si MAS NMR, and TPD NH_3. The reactions were carried out in a steel autoclave at 50 atm. H_2 and 350-420^{o}C.

3 Results and Discussion

The results from the TEM and XRD analyses confirm incorporation of zeolites into the SBA-15 structure. Moreover, ^{27}Al MAS NMR measurements indicate that the framework aluminum species in SBA-15/zeolite is practically the same as in zeolite structure. The catalytic study shows that both SBA-15/Zeolite-β and SBA-15/ZSM-5 materials are good supports for NiW catalysts in the hydrotreating of OS. It was demonstrated that oil sludge hydrotreating gets light and middle distillate hydrocarbons and sulfur becomes less about 10 times. The experiments carrying out at 400^{o}C and higher reveal that there were a lot of gas products especially in case of NiW/SBA-15/ZSM-5 catalyst. Furthermore, it was found out that these catalysts showed higher activity than a reference NiW/SBA-15 catalyst.

4 Conclusions

In this work, NiW sulfided catalysts based on micro-mesoporous composite materials SBA-15/zeoilte-β and SBA-15/ZSM-5 were successfully synthesized. The characterization results show that the composite material possess the same mesoporous structure as SBA-15 and contain Beta (ZSM-5) zeolite crystals simultaneously. The high activity of SBA-15/zeolite supported

catalyst in oil sludge hydrotreating might be attributed to the combination of open mesoporous structure and the large amounts of acid sites.

Keywords: fluidized bed, chemical reactor, numerical simulation, structural elements

1 Introduction

Fluidized bed reactors are widely used in the petrochemical industry, in particular for the isobutane dehydrogenation process with fine particles of the chromia-alumina catalyst. An injection of hot catalyst particles is needed for sustenance the temperature of the reaction. The main objective is effective heating of the fluidized bed region with the highest concentration of catalyst. In the large reactors the structural elements (lattice) are used for breaking gas bubbles and active mixing of gas and catalyst. In present paper the motion of solid catalyst particles with a size of 20-200 microns in isobutane dehydrogenation reactor model was investigated. Geometrically reactor is5.1 m in internal diameter and 17.4 m in height, partitioned by ten distributive lattice of angle-type with an area of free section of 30%. A vertical pipe is placed in the center part of reactor for the supplying of heated catalyst. Calculations of hydrodynamic and heat transfer processes in the reactor were carried out by numerical methods using computers with special attention to the flow near the walls in reactor.

2 Formulation of the problem

Currently, one of the ways to determine the properties of large-scale fluidized beds is numerical simulation. In a study of fluidization an Eulerian-Eulerian approach was applied, when carrier phase (gas, liquid) and discrete (solid) phase are continuous. Using kinetic theory of gases, equations (for each discrete phase) which are describing kinetic energy changes of granules in consequence of collisions was added for account of features in a fluidized bed movement.

Presented results of calculations are carried out for mono disperse catalyst (one phase of particles with 90 μm in diameter) and for poly disperse catalyst (two phases of particles with 90 μm and 30 μm in diameter). A steady fast downward flow of catalyst grains along walls of reactor and slow upward movement in the central zone was observed in calculations. This motion is providing the total intensive circulation of catalyst and gas. Any structural elements (e.g. lattice) in reactors can have a significant impact on all circulating field. Parametric calculations for different distances between lattice and reactor walls are performed in this investigation. Namely, in the calculations distance parameters as 9 cm, 5 cm and 3.6 cm were used. The main aim is to analyze catalyst and gas circulation in reactor.

3 Result of calculations

The analysis results of calculations for three cases that were described above of different distance between lattice and walls are shown in figure 1. The arrows on the lattice define the main directions for average upward and downward flows of circulating catalyst and gas in reactor. Reactor about 5 meters in diameter in cases with minor differences in structural elements of apparatus has a significant differences on the overall circulation field as it can be

seen from the figure. Catalyst rises in the central zone, and falls down in the areas closer to the external wall and in the thin layer around the central tube in case with distance 9 cm. Catalyst descends in the central zone and in a thin layer near the external wall and rises upwards in the areas closer to the outer wall in case with distance 3.6 cm. Finally, catalyst rises in almost all the reactor zones and descends in thin layers around the central tube and the external wall, but with higher velocity.

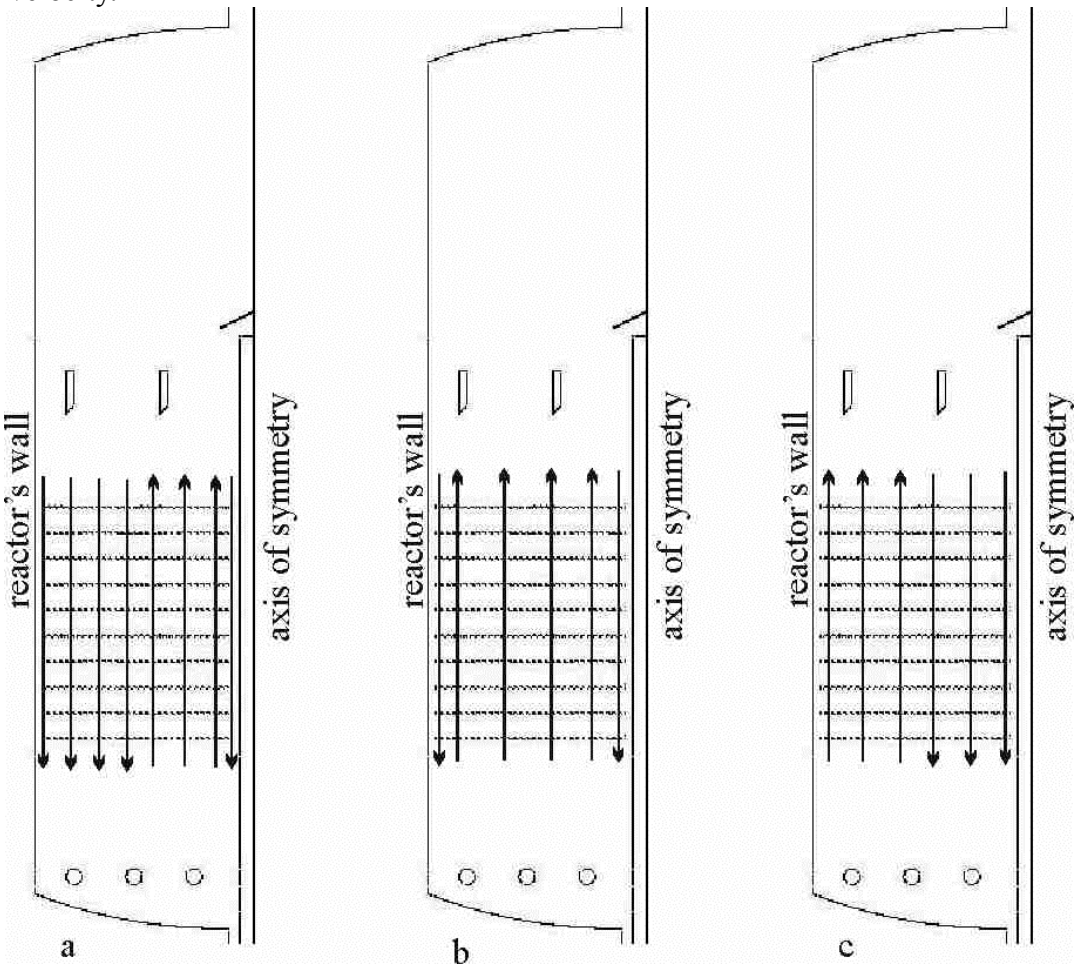

Fig. 1. Scheme of reactor and directions for average upward and downward flows of circulating catalyst and gas for different cases of distance between lattice and walls: a – 9 cm, b – 5 cm, c – 3.6 cm.

4 Conclusion

Any minor changes in the structural elements geometry can have a significant influence for hydrodynamics of the fluidized bed. Application of numerical simulation allows to predict the behavior of bed with using approximations. The researching results can be of interest for industrial applications where it is important to have a proper circulation bed.

Keywords: paraffins, oxidative dehydrogenation, olefins, hydrotalcite, materials

1 Introduction

Layered double hydroxides (LDHs) known as hydrotalcite-like layered metal hydroxo salts, are extensively explored as precursors of various catalysts. Interest in LDHs is provided by the fact that two, three or more cations may be introduced in the brucite-like layers, besides various anions (e. g. decavanadate, paramolybdate, etc) in the interlayer space [1]. However the information on the application of such materials as multi-component catalysts for oxidative dehydrogenation (ODH) of light alkanes is still scanty. We have performed an extensive investigation of the synthesis of complex hydrotalcite-like hydroxo salts and their application as precursors of catalysts. In the present work the catalysts containing Sm and Eu were prepared using complex hydrotalcite-like layered hydroxo salts (LDHs) as precursors and tested in ODH of light alkanes (ethane, propane, isobutane) in the presence oxygen-nitrogen mixtures and CO_2.

2 Experimental

Catalysts were prepared, using complex hydrotalcite-like layered hydroxo salts (LDHs) as precursors by coprecipitation at 65°C and constant pH according to experimental procedures, described in detail earlier [1-3]. ODH of alkanes was carried out in a fix-bed quartz reactor (1.0 g of the catalyst) with on-line GC analysis. The reaction was studied varying the experimental conditions (400-650°C, atmospheric pressure, LHSV 1.0-1.5 h^{-1}). The catalyst precursor was calcinated at 500°C. The structure of the prepared precursors and calcinated materials was investigated by XRD and BET. The thermally treated samples were characterized with respect to their textural properties. The stability tests were carried out in prolonged runs of 25 and 100 hours under optimum conditions.

3 Results and discussion

Synthesized LDHs materials showed well-crystallized hydrotalcite structure. Thermal decomposition converted the precursors into mixed metal oxides characterized by developed (74 m^2/g) surface area and pore size of 200-300Å.

The optimum reaction conditions for synthesis of alkenes have been determined. Results of tests showed that ethane ODH proceeded at low temperature over catalysts containing Sm (450^0C). Ethene is formed with high selectivity (86-90%) over this catalysts but its yield is low 13.5 – 16.1%). There are data of propane and isobutane ODH over Sm-Al-Mg-O in Tables 1 and 2. The results of stability test of the Sm-Al-Mg-O catalyst for a feed with CO_2+O_2 were similar to those without O_2 addition in the feed. Thus, it seems that there is no point in using oxygen to improve the stability of the catalyst in propane and isobutane dehydrogenation with CO_2.

Table 1. Data of propane ODH over Sm-Al-Mg-O. Reaction mixture: C_3H_8:CO_2=1:1

Temperature, °C	C_3H_8 conversion, %	C_3H_6 yield, %	C_3H_6 selectivity, %
450	24.1	17.7	72.2
600	30.5	21.5	69.3

Table 2. Data of isobutane ODH over Sm-Al-Mg-O. Reaction mixture: i-C_4H_{10}:CO_2=1:1

Temperature, °C	C_4H_{10} conversion, %	(i-C_4H_8+C_3H_6) yield, %	(i-C_4H_8+C_3H_6) selectivity, %
450	23.0	20.9	90.8
600	57.0	43.0	75.6

Eu-V-Mg-O catalyst displayed a good stability during 100 hours on stream. Conversion of propane decreased gradually during the first three 3 hours on stream and became stable without any tendency to decline for following 100 hours at the average level of 20.4%. The selectivity to total alkenes remained stable during the time on stream at the average level of 76%. The propene/ethane ratio in the reaction mixtures remained constant being equal to 3/2. Conversion of isobutane and selectivity to isobutene at the presence of CO_2 and O_2 were 36.1 and 85.0 %, respectively, at 450°C over catalyst containing Eu. At 650°C conversion of isobutane and selectivity to isobutene were 65.1 and 63.0 %, respectively. Obtained data show that introduction of Sm and Eu results in an increase of olefins yield and its selectivity.

4 Conclusions

The results of complex investigation of the process of ODH of light alkane are presented. The new hydroxosalts which have a layered structure of hydrotalcite type with Sm and Eu were synthesized. These hydroxosalts were used as precursors for oxidative dehydrogenation of ethane, propane and isobutane. A strong dependence of the yield and selectivity of alkanes loading and the conditions of heat treatment were observed. The optimum reaction conditions for formation of alkenes have been determined. It was shown that introduction of Sm and Eu results in an increase of olefins yield and its selectivity.

Novel α,α-Phosphinoaminoacids: Synthesis, Properties and Catalytic Activity in the Ethylene Oligomerization Process

Fomina O.S.[1,2*], Yakhvarov D.G.[1], Sinyashin O.G.[1], Heinicke J.W.[2]

1 - A.E. Arbuzov Institute of Organic and Physical Chemistry, Kazan Scientific Center, Russian Academy of Sciences, Kazan, Russia

2 - Institute of Biochemistry Ernst-Moritz-Arndt University of Greifswald, Greifswald, Germany

* myaolechka@yandex.ru

Keywords: α,α-phosphinoaminoacids, catalytic activity, oligomerization

1 Introduction

Synthetic amino acids are of interest in various fields of chemistry, biochemistry and pharmacy.[1] The first epresentatives with a phosphanyl group were obtained by condensation of natural amino acids with secondary phosphanes and formaldehyde, usually forming bis(phosphanylmethyl) amino acids, and studied with respect to their use as ligands in rhodium-catalysed hydrogenation reactions and in complexes for radio-diagnostics.[2] The use of primary phosphanes extended the range of N-phosphanylmethyl amino acids to various P,N-heterocyclic types. The incorporation of P-alkyl instead of Pphenyl groups led to an increase in the sensitivity of Nalkyl-α-phosphanylglycines. To obtain more stable α-phosphanyl amino acids we systematically varied the nitrogen substituents of the (diphenylphosphanyl)glycines and report here on the novel N-aryl derivatives 1, their synthesis, structure and properties, and the first examples of their transitionmetal complexes and their use in homogeneous catalysis.

2 Experimental/methodology

All manipulations with air-sensitive compounds were conducted under nitrogen using Schlenk techniques. Solvents were dried by standard methods and freshly distilled before use.

I. Novel α,α-phosphinoaminoacids were all prepared by A three-component one-pot reaction of diphenylphosphine, primary amine and glyoxylic acid hydrate in diethyl ether or methanol [1,2] (Fig. 1).

II. Oligo/Polymerization of Ethylene: The various phosphanylglycines and $Ni(COD)_2$ (each ca. 100 μmol) were dissolved in THF or toluene (10 mL), cooled to 0 °C (10 min) and mixed. The resulting yellow-brown solution was stirred at room temperature for 5 min and transferred through a Teflon® tube to the argonfilled autoclave. After weighing, the autoclave was pressurized with ethylene (30–50 bar), the amount of ethylene was determined and the autoclave was placed in the silicon bath and heated overnight (15 h) at 100_5 °C. After cooling to room temperature unconverted ethylene was allowed to escape through a cooling trap (–40 °C; only trace amounts of butenes were observed). The volatiles were flash-distilled at 80 °C/4.0 mbar from the solvent product mixture. The residual waxy oligomer or polymer was treated for 1 d with methanol/hydrochloric acid (1:1), thoroughly washed with methanol and finally dried in vacuo.

3 Results and discussion

A three-component one-pot reaction of diphenylphosphine, primary amine and glyoxylic acid hydrate in diethyl ether or methanol allowed an easy access to N-monosubstituted diphenylphosphinoglycines. The reaction of nickel (0) complexes with N-monosubstituted diphenylphosphinoglycines leads to the formation of a catalytically active form of the ethylene oligomerisation catalyst via oxidative addition to O-H or O-C bond of the used phosphorus

ligand. The linear olefins with terminal methyl and vinyl groups are the main products of the catalytic ethylene oligomerisation process. The highest conversion of C_2H_4 into linear α-olefins was observed with *N*-C_6H_3-2,5-$(COOMe)_2$ phosphinoglycinate ligand.[3-5]

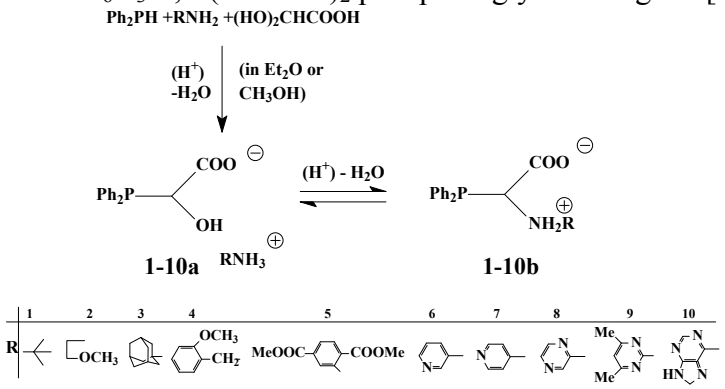

Fig. 1. Preparation of α,α-phosphinoaminoacids

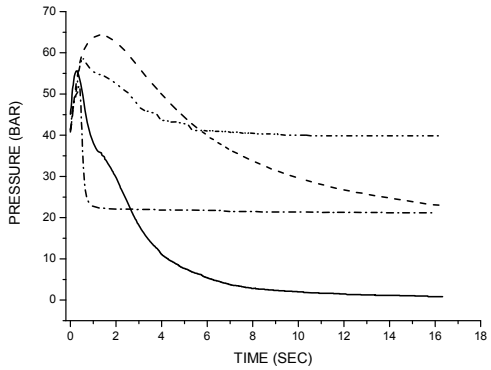

Fig. 2. Pressure time plots for consumption of ethylene (pstart 40–50 bar) in batcholigomerization tests of precatalyst complexes, formed from 4(dot dash line), 5(dotted dotted point line) , 8 (dotted line) and asolution of $Ni(COD)_2$ (each ca. 100 lmol) in THF; bath temperature 100^0C, and oligomerization tests of precatalyst complexes, formed from 4(full line) and a solution of $Ni(COD)_2$ (each ca. 100 lmol) in toluene; bath temperature 70^0C

4 Conclusions

N-Aryl-α-phosphanylglycines, novel α-phosphanyl amino acids with reduced basicity at the nitrogen atom, are easily accessible by one-pot three-component reactions of primary arylamines, diphenylphosphane and glyoxylic acid hydrate in diethyl ether at room temperature. The reaction is restricted to *N*-monosubstituted amines and was found to involve intermediate arylammonium (diphenylphosphanyl)glycolates, which reversibly condense to the slightly more stable phosphanylglycines. Highly active catalysts for oligomerization of ethylene are formed in situ from THF solutions of the phosphanylglycines and Ni(cod)2. The selectivity is the same as with the less easily accessible but hydrolytically more stable (diphenylphosphanyl) acetic acid ligand and hints at catalyst stabilization by a PO– nickel chelate backbone.

Keywords: biomass, pyrolysis, synthetic oil, hydroisomerization, catalyst, cold flow upgraded, motor fuels

1 Introduction

The expansion of the feedstock and the increasing of the production capacity for high quality jet fuel and diesel fuel with upgraded cold flow properties are one of the priority directions for Russian oil refining industry progress.

The production of fuels in accordance with modern environmental and operational requirements determines the need for new flexible and versatile technologies development to replace fossil fuels with alternative renewable energy sources, in particular vegetable feedstock due to wide availability, accessibility and environmental safety. We considered two processes among the modern technologies for the production of synthetic liquid fuels from plant biomass (BTL): thermochemical conversion without oxygen access (pyrolysis) and gasification to synthesis gas which is a feedstock for the Fischer-Tropsch synthesis [1, 2].

2 Experimental/methodology

At Gubkin Russian State University of Oil and Gas were carried out the investigations slow pyrolysis process of sawdust (500°C, contact time – 10-30 sec). Obtained liquid pyrolysis products contained a high water concentration, a lot of oxygenated compounds and high iodine number. Because of such characteristics pyrolysis products were unusable for use as a motor fuels component. If the feed of the process was the mixture of sawdust and black oil (the fraction boiling >350°C), pyrolysis ran with higher intensity and there was a greater liquid products yield with quality superior to products of sawdust pyrolysis. Experimentally it has been defined the best ratio between sawdust and black oil equal 1 : 3 for vegetable and oil feedstock co-processing. This ratio was used for pyrolysis to obtain the motor fuel components. Due to the high content of sulfur, nitrogen and oxygen containing compounds and aromatic hydrocarbons the pyrolysis middle fractions were subjected to hydroconversion in mixture with the straight-run diesel distillate with subsequent improvement of cold flow properties by isodewaxing.

At All-Russia Research Institute of Oil Refining (VNII NP, JSC) the samples of synthetic oil were produced by Fischer-Tropsch synthesis (low temperature, Co-catalyst). The feedstock for Fischer-Tropsch process was synthesis gas of the plant biomass steam-oxygen gasification (1200°C, 0.5 MPa). The synthetic oil boils in the kerosene and gas oil range, contains almost no aromatic and oxygenated compounds and is characterized by the absence of sulfur and nitrogen compounds.

The mixture of the synthetic oil and the hydrotreated diesel fraction was processed by isodewaxing for obtaining jet fuel and diesel fuel satisfying the requirements for use in arctic

climatic zone conditions. For this process the catalyst was developed by specialists of VNII NP, JSC.

3 Results and discussion

Hydroconversion (MPa, 350°C, 1.0 h^{-1}) of mixtures of pyrolysis middle distillate fractions and straight-run diesel distillate ran with maximum hydrogenation depth conversion of heteroatomic compounds if feedstock content up to 20% bio-component. The cold flow properties according to Russian State Standard 55475-2013 (GOST R 55475-2013) are achieved by the isodewaxing process (table 1).

Table 1. The results of the co-processing of liquid pyrolysis products and petroleum distillates.

Quality index	Value of quality index		
	Feedstock	Hydroconversion product	Isodewaxing product
Density at 15°C, kg/m^3	856	848	853
Fractional composition			
initial boiling point	180	165	140
end boiling point	360	358	357
Filterability temperature limit, °C	minus 5	minus 8	minus 32
Sulfur content, ppm	1200	16	18
Cetane number	52	50	47

Isodewaxing process of the mixture of synthetic oil obtained by the biomass gasification and hydrotreated diesel fraction resulted in yield of products with were separated on gasoline, kerosene and diesel fractions. Kerosene and diesel fractions were the main products of isodewaxing.

Isodewaxing stable product can be used as a diesel fuel for arctic conditions and meets the requirements for class 4 of EN 590:2009.

The fraction boiling in the range 135-280°C evolved from isodewaxing products on key quality indicators pass standard for aviation fuel brand JET-A1.

4 Conclusions

1. The studies shown that as a result of co-processing of pyrolysis liquid products of plant biomass and oil feedstock by processes of the hydroconversion and isodewaxing can be produced the winter diesel fuel with filterability temperature limit equal to minus 32 according to standard GOST R 55475-2013.

2. Processing of synthetic oil in a mixture with petroleum diesel distillate by isodewaxing process allows obtaining jet fuel brand JET-A1 and diesel fuel for arctic conditions of EN 590:2009 "Automotive fuels – Diesel – Requirements and test methods".

1 Introduction

The study of the chemical processes in organized media containing metallomicelles based on complexes of metals with surfactants attracts the attention of researchers due to their potentiality for the significant enhancing of the catalytic activity of systems. This is important for the creation of new materials, the decomposition of toxic substances and toxicants, as well as from the viewpoint of biomimetic aspects [1]. An important characteristic of the complexes of metals with surfactants, which determines their catalytic activity, is the ability to aggregate in solution. We have studied micelle forming, adsorption and solubilization of aqueous solutions of the complexes of 1-hexadecyl-4-aza-1-azoniabicyclo[2.2.2]octane bromide (HB-16) with nitrates of transition metals (Cu^{2+}, La^{3+}) by methods of tensiometry, conductometry, spectrophotometry (solubilization of water-insoluble dye Orange OT).

2 Experimental/methodology

Complexes 2HB-16·× $Cu(NO_3)_2$ and 2HB-16 × $La(NO_3)_3$ were obtained by the reaction of HB-16 with $Cu(NO_3)_2 \cdot 3H_2O$ and $La(NO_3)_3 \cdot 6H_2O$, respectively, in methanol. The surface tension was determined by the ring detachment method (Du-Nui). Conductivity data of solutions were obtained on CDM-2d device. Spectrophotometric measurements were carried out on a Specord 250 Plus spectrophotometer.

3 Results and discussion

The values of critical micelle concentration (CMC), adsorption characteristics at the water-air interface (the surface excess (Γ_{max}), the surface area per molecule (A_{min}), the standard free energy of interfacial adsorption at the air/saturated monolayer interface ($\Delta G_{ад}$) and standard free energy of micellization per mole of monomer unit ($\Delta G_{м}$)), the solubilizing power of aggregates were determined. It was shown that the value of CMC of the complexes by 2-3 times lower than CMC of the original HB-16 (Table 1) and its cyclic (hexadecylpyridinium bromide) (6.8 10^{-4} M, tens. [3]) and acyclic (hexadecyltrimethylammonium bromide, CTAB) (8.0 10^{-4} M, tens. [4]) analogues. The adsorption characteristics of the complexes and HB-16 are also very different. Higher area of the cross section of complexes indicates that the lower density of the surface layer of the amphiphiles occurs at the water-air interface.

Table 1. CMC of complexes in water, 25 ^{0}C

Substance	CMC × 10^4, M		
	Tensiometry	Conductometry	Orange OT solubilization
2HB-16 x $Cu(NO_3)_2$	**3.8**	2.9	3.2
2HB-16 x $La(NO_3)_3$	**3.3**	3.3	3.00
HB-16 [a]	**10.0**	10.0; 110 [b]	-

a **Data of [2];** ***b*** **CMC_2 .**

It has been established (spectrophotometry) that the solubilizing power (S) of the micellar aggregates of the complexes and the cationic surfactants with respect to the hydrophobic substrate (Orange OT) is varies at the sequence CTAB < HB-16 < [2HB-16 × $Cu(NO_3)_2$] < [2HB-16 × $La(NO_3)_3$] (Table 2), i.e. the formation by the cationic surfactant (HB-16) of the complex with copper nitrate and lanthanum nitrate facilitates its solubilization capacity. In the investigated concentration range of the complexes of copper and lanthanum the increase of the Orange OT solubility in respect of its solubility at CMC reaches 670 and 730 times, respectively. Moreover, the value S of the complexes is by 1.3-2.5 times higher than that of the original HB-16, and substantially higher (up to 3-6.5 times) than S of the acyclic analogue CTAB.

Table 2. Solubilizing power of the complexes and surfactants in water, 25 ^{0}C

Substance	S × 10^3	$S_{complex\ (surf)}$ / S_{HB-16}	$S_{complex\ (surf)}$ / S_{CTAB}
2HB-16 × $La(NO_3)_3$	**103**	**2.5**	**6.5**
2HB-16 × $Cu(NO_3)_2$	**53.2**	**1.3**	**3.3**
HB-16	**42.2**	**1.0**	**2.7**
CTAB	**15.9** [a]	**0.38**	**1.0**

a **Data of [5].**

4 Conclusions

The BH-16 complexes with copper nitrate and lanthanum nitrate are surfactants with high the aggregating capacity and the solubilizing action with respect to the hydrophobic substrate. Importantly, aggregation and solubilization capacity are main factors contributing to the catalysis of bimolecular reactions in organized solutions. It has been shown that addition of metal ions (e.g. lanthanum ions) can accelerate the cleavage of ester bonds by six orders of magnitude.

Development of a General Heat Transport Modelfor Open-Cell Metal Foams

Aghaei P., Visconti C.G., Groppi G., Tronconi E.*

Politecnico di Milano, Department of Energy, Laboratory of Catalysis and Catalytic Processes, Milano, Italy

* enrico.tronconi@polimi.it

Keywords: open-cell metal foams, catalysts, carrier, tubular, reactor, heat transfer

1 Introduction

Open-cell metal foams are particularly interesting as catalyst supports in reactors with fast exo/endo-thermic reactions due to their high voidage, and thus a low pressure drop, in combination with their excellent heat transfer properties. The main goal of this work is to continue the previous works [1,2] and develop a general simulation model that is capable of describing the heat transfer properties of different open-cell metal foams with different structural properties at different operational conditions and with different gases.

2 Experimental/methodology

For this purpose, 180 steady-state heat transfer experiments using N_2 and He as flowing gasses at 300 ˚C and 500 ˚C were carried out over several different foams, FeCrAl alloy, NiCrAl alloy, aluminum, copper, and cobalt, all having a high porosity between 89 and 98% and with cell diameters varying from 0.58 to 5.09 mm. The geometrical properties of the metal foams were studied using optical microscopy and the total and hydraulic porosities were measured by a gravimetric technique. The heat transfer data were collected at three radial positions in the cylindrically shaped foams and at 11 different axial coordinates along the foam bed length, from 0 to 100 mm. First, the effective wall heat transfer parameters in the inlet zone just before the foams ($1/Bi_{w,in}$) were estimated to characterize the flow behaviour in this section. These results were then used to develop a 2D pseudo-homogeneous model based on heat transport literature correlations.

3 Results and discussion

The radial effective conductivity is composed of the sum of three contributions, i.e. conduction, convection, and radiation. The contribution by thermal conduction can be well described by the empirical correlation from Calmidi et al. [3], which considers the heat conducted through both the solid and the fluid phase. The contribution by the thermal dispersion in the foams is properly described using the model proposed by Hunt et al. [4] accounting that the dispersive contribution is directly proportional to the local flow velocity. The radiative contribution is described using the modified diffusion approximation in the Rosseland equation proposed by Glicksman et al. [5]. The wall heat transfer coefficient is estimated considering its dependency on the gas properties and also the thin gap between inner surface of the heating tube and outer surface of the sample foam [6], and additionally a contribution by radiation. All the fitting parameters in the correlation are optimized and their effects on the general fit are investigated. The simulation model based on the presented correlations showed a very satisfactory fit for all different foams and flow types tested within the range of the operational conditions covered. Among 11340 single temperature measurements, i.e. 12 foams, 15 different experimental conditions, 3 radial and 21 axial measurement points the foam bed, 91% points have temperature difference between the experimental and simulated temperature in the range of 0 to 5 °C, 8% points have the temperature difference between 5 to 10 ˚C and only 1% of the

single temperature measurement deviates more than 10 ˚C from simulations.

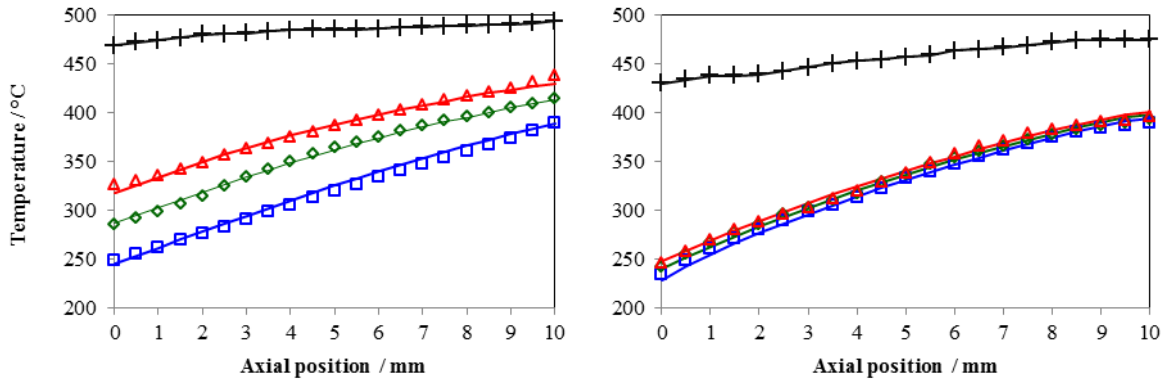

Fig. 1. Axial temperature profiles for a) NiCrAl alloy foam at 500 °C, N_2 flow rate of 35 Nl min^{-1}, cell diameter of 0.58 mm and b) Aluminium foam at 500 °C, N_2 flow rate of 35 Nl min^{-1}, cell diameter of 3.59 mm. The following abbreviations and legend are used: experimental temperature measurement at center, 0.5, 2/3 radius and heating tube wall, Exp(0) □, Exp(0.5) ◊, Exp(2/3) Δ, and Wall ┼. Fit results at centerline, 0.5, 2/3 radius, Sim(0) ▬ , Sim(0.5) ▬, and Sim(2/3) ▬.

4 Conclusions

The open-cell metal foams used in this study show a promising future as catalyst supports due to their high surface area with a small pressure drop in combination with a high effective radial thermal conductivity, varying from 0.5 W m^{-1} K^{-1} for FeCrAl and NiCrAl alloys up to 5 W m^{-1} K^{-1} for copper and aluminum foams, which can improves the heat management in catalytic reactors, resulting in higher productivity and selectivity with lower cost. By using the test results on a large number of different metal foams with various compositions, geometrical properties and porosities, at various temperatures, gas types, and gas flow rates , a general correlation was developed successfully for the effective thermal conductivity. This correlation contains a contribution by stagnant thermal conductivity accounting for conduction through both the solid and the fluid, a contribution by dispersion, and a contribution by radiation. The correlation requires as input the following foam properties: porosity, pore size, cell size, thermal conductivity of the foam solid material, and the gap size at the wall. For all foams tested the ratio of the stagnant solid conductivity of the foam and the conductivity of the dense solid material was close to one third of the relative volumetric density of the foam [1].

Keywords: heavy oil, steam cracking, semibatch process

1 Introduction

The gradual depletion of light and middle crude oils with simultaneous increase of hydrocarbons consumption needs the development and upgrade of technologies on mining, transportation and processing of heavy hydrocarbon feedstock (HHCF), such as heavy oils and natural bitumens. Presently, the share of HHCF processing of total petroleum refinery processes is very low due to problems in HHCF mining, transportation and conversion. The main problems of HHCF processing are connected with high viscosity, low content of light hydrocarbons fractions, high content of tars, asphaltens, S and other heteroatoms and transition metals, mainly V and Ni. The most common approaches for HHCF processing based on two strategies: reducing carbon content by cocking and hydrogen saturation. The hydrogen saturation is usually carried out by hydrogenation and hydrocracking in the presence of Ni- and/or Mo-containing catalysts at 400 – 500 °C and high pressures of H_2 up to 200 bar and higher [1].

As an alternative source of hydrogen for HHCF cracking and hydrogenation, water can be used. Temperatures of the HHCF steam cracking are usually 420 – 500 °C, employed catalysts are Ni-based, promoted by K or Na [2] or FeO_x-based [3]. This work is devoted to investigation of process of steam cracking of high-sulfuric heavy oil (HO) from Tatarstan (Russia) in semi-flowing regime by water.

2 Experimental/methodology

For the investigation the process of steam cracking of the HO, the installation presented in Figure 1 was used. HO (200 g) and part of water (50 g) were loaded into the batch reactor with

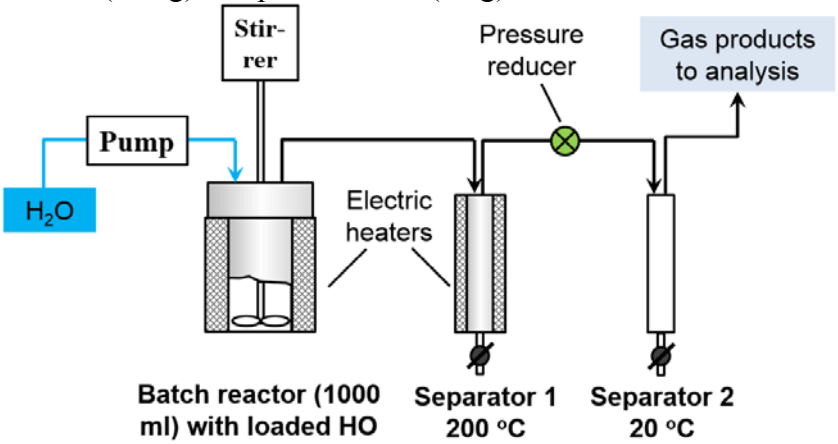

Fig. 1. The installation used for investigation the steam cracking of heavy oil (Tatarstan, Russia)

catalyst and started heating up to needed temperature (425 and 450 °C) with the rate 5 °C/min and continuous stirring 1000 rpm. When needed temperature was achieved, the water pumping (80 ml/h) was switched on. Time of the process was 2.5 h, the pressure was 20 – 25 bar. The

main part of liquid products and was being collected in the heated separator. In the case of catalytic steam cracking, the experiment was carried out with 10 % Fe_2O_3/γ-Al_2O_3 catalyst obtained by impregnation Fe from solution of $(NH_4)_3[Fe(C_2O_4)_3]$ onto γ-Al_2O_3 with following drying and calcination at 700 °C for 2 h. The analysis of fraction composition of the liquid products was carried out on a semi-automatic apparatus for distillation of petroleum products accordingly with ASTM 1160 standard. Gaseous products were studied by gas chromatography.

3 Results and discussion

Since the catalytic steam cracking is enough complex process including such subprocesses as just thermocracking (TC), steam cracking (SC) and catalytic steam cracking (CSC), the corresponding experiments on elicitation of the subprocesses have been carried out separately. In the Table 1, yields of the main products and fraction composition of liquid products are presented.

Table 1. Fraction composition of the initial heavy oil (HO) and yields of the main products of the HO thermocracking (TC), steam cracking (SC) and catalytic steam cracking (CSC).

Products	HO	TC, 425 °C	SC, 425 °C	CSC, 450 °C
	Yield, wt. %			
Liquid fractions ($T_{boil.}$ interval):	100	60.2	75.2	70.0
IBP – 200 °C	0	20.5	13.0	18.5
200 – 350 °C	20	31.1	39.9	37.3
350 – 500 °C	32	6.0	20.0	11.9
> 500 °C	48	2.6	2.3	2.3
Coke	-	25.5	15.4	18.5
Gas phase + losses:	-	14.3	9.4	11.5

In the case of TC the lowest yield of liquid products and the highest ones of coke, gaseous products and the lightest fraction were obtained. Water introducing (SC) has led to significant increase of liquid products (by 15 wt. %) and to the same total decrease of yields of coke (by 10 %) and gas (by 5 wt. %). Meanwhile, the liquid products contained lower content of fraction IBP – 200 °C and higher content of more heavy fractions. Introducing the catalyst (CSC) and increasing the process temperature from 425 to 450 °C has led to some decrease of the yield of liquid products and to increase of coke and gases yields (by ~ 5 wt % in total). The yield of gasoline (IBP – 200 °C) fraction increased by 5.5 %, the yields of more heavy fractions decreased. In the case of TC and SC, gaseous products contained low contents of H_2 (4 – 6 %) and high content of C_1-C_4 hydrocarbons. Gaseous products of CSC contained significantly more H_2 (44 %). Also in the case of SC and CSC there were traces of CO_2 (up to 2.5 %) and C_2H_4 (up to 4.0 %). H to C atomic ratio in the initial HO is 1.70, in the liquid products of TC and SC it decreased to 1.60, which seems to indicate on losses of hydrogen mainly in form of C_1-C_4 hydrocarbons. Liquid products of CSC had H to C ratio 1.78, indicating on occurring of hydrogen saturation processes in the presence of catalyst.

Mechanochemical Synthesis of Molybdenum Carbide: New Approach for the Hydrodesulfurization Catalysts Preparation

Vasilevich A.V.*, Baklanova O.N., Lavrenov A.V., Likholobov V.A.

Institute of Hydrocarbons Processing of Siberian Branch Russian Academy of Sciences, Omsk, Russia

Keywords: molybdenum carbide, mechanochemical synthesis, hydrodesulfurization, dibenzothiophene

1 Introduction

In recent years, petroleum refining industry has been facing significant challenges because of the continuously decreasing allowable amount of emissions, such as SO_x, NO_x and aromatics from the combustion of fuels. With the currently used technology, the quality of fuels prescribed by the new environmental regulations can be attained by the significant modifications of refining operations [1].

Transition metal carbides are considered as the new promising catalysts and have been widely investigated in recent years because of their unique electronic structure and high performance [2]. Molybdenum carbides, with their resemblance in electronic structure to noble metals [3], have similar catalytic properties to noble metal catalysts in various organic chemical reactions [4]. It makes molybdenum carbides to be a promising substitute for noble metal catalysts in the future. These catalysts show good catalytic activity and selectivity in hydrogenation, hydrodesulfurization and hydrodenitrogenation in petroleum refining.

Molybdenum carbides were first obtained in a classical way of metallurgical process at high temperatures and the obtained material was of rather high particle sizes and low specific surface area [5]. The main method for synthesizing such molybdenum carbides currently is temperature-programmed reaction method via carbonization of molybdenum trioxide with gas hydrocarbon, such as methane, ethane, butane and their gas mixtures. In this work of molybdenum carbides were prepared using the mechanochemical synthesis. The structure and catalyst activity of the molybdenum carbides were also studied.

2 Experimental

Two series of samples were synthesized through mechanochemical synthesis both under air and inert atmosphere. Molybdenum (VI) oxide, zinc or aluminum and carbon black powders mixtures with varying molar ratio were ball milled using a AGO-2 type planetary high energy ball mill with stainless steel vials and balls under air atmosphere. The rotation speed of the mill was 1000 rpm and the ball-to-powder mass ratio was about 40:1. The second series of samples was prepared using the standard incipient wetness method. Molybdenum was impregnated at 10 wt% on carbon black using a aqueous solution ammonium heptamolybdate tetrahydrate (Aldrich, 99.98%) then the sample was dried at 120°C. Obtained sample was performed in a planetary ball mill under argon atmosphere. Samples were heat treated at 800°C for half an hour in an argon atmosphere.

3 Results and discussion

The obtained samples were characterized by means of XRD-method using a D8 Advance Bruker (40 kV and 40 mA) diffractometer with CuKα radiation (λ = 0.154 nm). The morphologies of the samples were observed by transmission electron microscopy (JEM-2100).

Fig. 1 shows the XRD patterns of samples, obtained by mechanochemical synthesis in an inert and air atmosphere. Phase Mo_2C hexagonal has sufficiently high crystallinity. In addition

to the phase Mo_2C on XRD patterns contains phases such as rhombic Al_2O_3, hexagonal FeMoO and hexagonal Fe_3C.

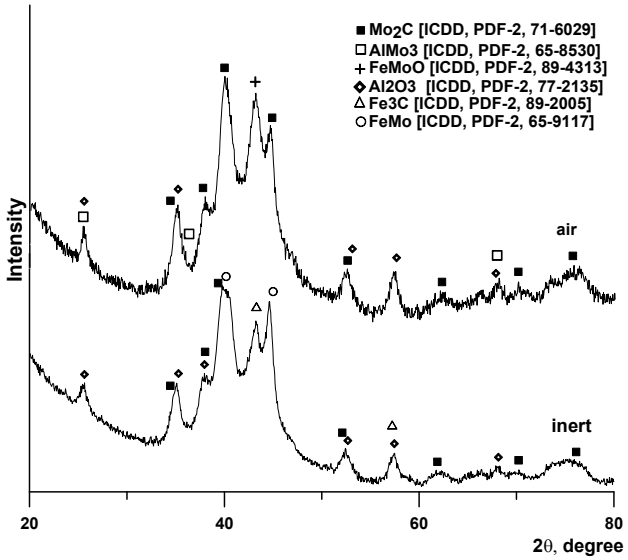

Fig. 1. XRD patterns of samples, obtained by mechanochemical synthesis in an inert and air atmosphere.

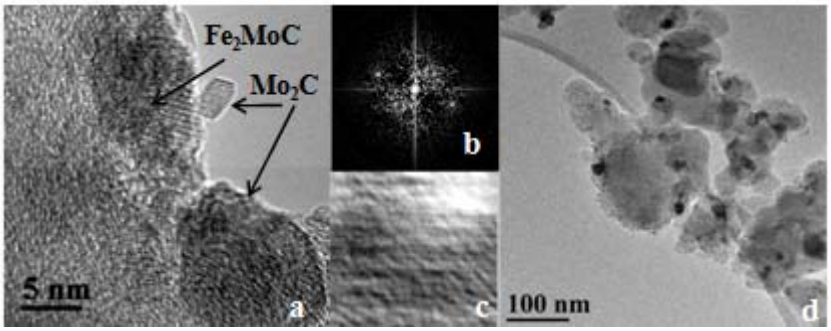

Fig. 2. (a-d) Electron-microscopic images of the samples prepared by mechanochemical synthesis and calcinations in an inert atmosphere and (b) the electron diffraction pattern and (c) image of the crystal lattice of Mo_2C obtained from a region marked with an arrow.

The model feedstock for testing of samples in the hydrodesulfurization was a heptane solution of 1 wt% and 4.7 wt% dibenzothiophene containing. The model reaction was performed at 300-320^{o}C, under a total pressure of 3.5 MPa, WHSV 2 h^{-1} and the molar ratio of hydrogen to the feedstock is 600.

4 Conclusions

Conducting testing of catalysts in the hydrodesulfurization of DBT model reactions exhibit high activity at 320^{o}C - 97.7% of DBT conversion. Analysis of the composition of the reaction products showed selectivity of the catalyst: 88.3 wt% in the composition of the reaction products accounted for cycloalkanes.

Keywords: catalyst, aquathermolysis, heavy oil, viscosity reduction

1 Introduction

Catalyst systems are important in chemical synthesis and technology of novel compounds, various hydrocarbon conversions and derivatives thereof, and in obtaining intermediate basic chemical raw materials. Consequently, the catalysts can be conventionally subdivided into catalysts for oil refining, catalysts for petrochemicals, gas chemistry, and organic synthesis, etc. Based on the analysis of current Russian and international research, we can define a new group of catalysts - catalysts for upgrading heavy oil under reservoir conditions [1-3].

2 Experimental/methodology

Thus, we synthesized and studied heavy oil upgrading catalysts - carboxylates of nickel and cobalt, which are organic salts of these transition metals. The obtained compounds were mixed with the heavy oil solution of tetralin as hydrogen donor. Since minerals of the oil-reservoir can influence the process of aquathermolysis [4], the experiments were carried out in the presence of kaolinite. Catalytic aquathermolysis treatment was executed in a 1 liter autoclave for 5 hours at the initial air pressure of 0,1 MPa at 250; 300 and 350°C. The product was separated to asphaltenes, hydrocarbons (HC), benzene resins (BR) and alcohol-benzene resins (ABR). To study the structural-group composition of petroleum products we calculated spectral coefficients [4]. The values of upgraded heavy oil viscosity were measured on the inclined plane rheometer at 20°C [5]. We also conducted gas chromatography/mass spectrometry (GC-MS) analysis of oil components from the initial boiling point to 125ºC.

3 Results and discussion

The results of the composition analysis of the original oil and catalytic aquathermolysis products shows significant redistribution of oil components towards increased oil content and

Table 1. Chemical composition of the original oil and the products of aquathermolysis.

The temperature of the experiment, °C	Viscosity, mPa*sec	Density at 20°C, kg/m^3	Component composition, wt %				
			HC	BR	ABR	Σ Resin	Asph
-	3390,0	960,0	55,27	25,27	13,36	38,63	6,00
250	1961,2	958,6	59,88	22,05	11,48	33,53	6,64
300	310,2	953,6	71,56	13,29	8,77	22,06	6,38
350	793,3	-	61,90	22,51	10,82	33,33	4,76

reduced resin content. Maximum redistribution of oils and resins was observed at a temperature of 300°C, due to degradation reactions of macromolecular oil components. These changes were also reflected in the decreased value of the dynamic viscosity from 3390,0 to 310,2 mPa*s and the

density from 960,0 to 953,6 kg/m^3 at 20ºC. It should be noted that this experiment showed a slight increase in asphaltene content. This is apparently due to the oxidative dehydrogenation of oils and resins in the presence of air oxygen during the catalytic aquathermolysis resulting in aromatization of hydrocarbons, and spectral coefficients testify to it. In a series of benzene, alcohol-benzene resins and asphaltenes oxydation increased respectively by 6,00; 4,81; 0,66 times and aromaticity by 1,25; 1,32; 1,48 times (Table 2). The lower temperature in the experiment (250°C) did not make it possible to achieve significant changes in the heavy oil components. If the temperature of aquathermolysis process rose to 350°C, a slight increase in the content of oil and a slight decrease in the resin content (compared with the original oil), as well as a significant reducing of asphaltenes content was observed. It could be connected with intensive hydrogenolysis and C-C bonds cracking [6]. The viscosity of the product is higher than that of the product received during the experiment conducted at 300°C. Along with a high resin content it may indicate intensified condensed reactions in an oxygen environment.

Table 2. The results of an FT-IR spectral analysis of the initial oil and the products of aquathermolysis.

Spectral indices*	Initial oil			Products after aquathermolysis, °C								
				250			300			350		
	BR	ABR	Asph	BR	ABR	Asph	BR	ABR	Asph	BR	ABR	Asph
C_1	1,62	1,87	2,07	1,26	3,53	2,81	2,03	2,47	3,07	3,65	4,35	5,80
C_2	0,06	0,16	0,05	0,04	0,43	0,25	0,24	0,77	0,33	0,04	0,44	0,26
C_3	0,53	0,61	0,74	0,55	0,64	0,76	0,62	0,67	0,78	0,57	0,70	0,75
C_4	3,36	2,45	2,06	3,49	2,11	1,82	2,50	2,39	1,70	2,89	1,77	1,30
C_5	0,16	0,53	0,29	0,15	0,49	0,35	0,30	0,42	0,34	0,17	0,60	0,37

*C_1 = D1600 / D720 (aromaticity); C_2 = D1710 / D1465 (oxidation); C_3 = D1380 / D1465 (branching); C_4 = (D720 + D1380) / D1600 (aliphaticity); C_5 = D1030 / D1465 (sulfurization).

Fraction yields from the initial boiling point to 125°C of the initial oil and of the products obtained during the experiments at 250; 300 and 350°C correlated as 1:4,3:15,0:11,6. Their analysis by GC-MS revealed that after conversion oils were enriched (compared with samples before reaction) with aliphatic hydrocarbons of isomeric structure (C4-C8) containing mono-, bis-, trismethyl-, ethyl- substituents and methyl-, ethyl- substituents of naphthenic hydrocarbons (cyclopentane, cyclohexane). A small number of aldehydes and aliphatic ethers also were found.

4 Conclusions

Thus, the role of catalysts is to intensify the reactions of hydrogen redistribution, which can involve not only the hydrogen donor but also naphthenoaromatic oil compounds, fostering the reactions of hydrogenation and hydrogenolysis of resin-asphaltene substances, and saturation of free radicals to prevent their recombination with the formation of new light components. Aquathermolysis of heavy products, which impair the stability and rheological properties of oil at a relatively high temperature, is possible. In this regard, it is important to choose the temperature of implementation of heavy oil in-situ catalytic aqauathermolysis to achieve the optimum degree of viscosity reduction at the lowest possible consumption of steam and contribution of condensed reactions.

Keywords: chromium-magnesium, catalysts preparation, hydrofluorination, pentafluoroethane

1 Introduction

A wide range of solid catalysts is used for fluorination reactions: oxides, oxofluorides, and fluorides of chromium [1]. In recent decades, considerable efforts have been focused on the synthesis of chladones having zero ozone depletion potential. One of the most promising in this regard is the pentafluoroethane (Freon 125). It is well-known that the activity and selectivity of catalysts strongly depend not only on the catalysts composition, but on the method of precursor preparation as well.

In this work, we studied the effect of the Cr-Mg precursor preparation techniques on physicochemical and catalytic properties of the catalysts for the gas-phase hydrofluorination of perchloroethylene to pentafluoroethane.

2 Experimental

The catalyst samples (precursors) were prepared by using the four different techniques: wet mixing solid support. MgF_2 with $CrCl_3$ solution (sample 1) co-precipitation of metal hydrous oxides $Cr(OH)_3$ and $Mg(OH)_2$ (sample 2), mixing solid carrier MgF_2 with Cr_2O_3 slurry (sample 3) and precipitation of $Cr(OH)_3$ on solid carrier MgO (sample 4). Then, the samples were dried, heat treated in nitrogen flow at 330°C and activated by hydrogen fluoride.

Catalytic hydrofluorination of tetrachloroethylene (TCE) to pentafluoroethane was carried out in a flow reactor with a fixed catalyst bed at 330–370°C, 0.4 MPa, reactant molar ratios of HF: C_2Cl_4 = 11:1, and a contact time of 1–3 s. The activity was estimated in terms of the rate constant $k = -\ln(1 - X)/\tau$, where X is TCE conversion at the contact time τ [2].

3 Results and discussion

Most commonly used method for the Cr-Mg precursor synthesis is wet mixing of chromium chloride and magnesium fluoride [1]. As shown in the table, the sample 1, obtained by this way contains 6.1% chromium, the BET specific surface area is equal to 60 m^2/g and the reaction rate constant of the tetrachloroethylene hydrofluorination at 370°C is equal to 0.46 s^{-1}. We have found that obtaining of Cr-Mg precursors by this method with higher chromium content is difficult because the obtained pastes have poor rheological properties.

Table 1. Effect of the Cr-Mg precursor preparation techniques on the chromium content, the BET specific surface area (S_{sp}), total pore volume (V_{pore}), mean pore diameter (D_{pore}) and catalyst activity (k at 370^0C).

Sample №	Method of preparation	Cr,% (wt.)	S_{sp}, m^2/g		V_{pore}, cm^3/g	D_{pore}, Å	k_{370}, s^{-1}
			before reaction	after reaction			
1	mixing $CrCl_3$+MgF_2	6.1	60	33	0.3	400	0.46
2	co-precipitation $Cr(OH)_3$+$Mg(OH)_2$	56.1	230	3.8	0.08	70	0.04
3	mixing Cr_2O_3+MgF_2	28.9	130	35	0.4	350	0.32
4	precipitation $Cr(OH)_3$ on MgO	30.1	170	66	0.27	200	0.19

It is known that co-precipitation allows to vary the content of active component in a wide range. However, for investigated sample 2 co-precipitation of magnesium and chromium hydroxides was impossible due to a large difference in pH values for formation of hydroxides Cr (~ 5-7) and Mg (> 9). As a result, the precursor has poor textural characteristics: small volume and radius of pores, consequently, the catalyst has the low activity. The low concentration of Mg-containing support and unsatisfactory porous structure of the precursor, apparently leads to a dramatical decrease of the specific surface (from 230 m^2/g up to 3.8 m^2/g) under the reaction conditions.

Other used methods for the precursor preparation are by a mixing of solid carrier MgF_2 with a Cr_2O_3 slurry (sample 3) and by precipitation of $Cr(OH)_3$ on solid carrier MgO (sample 4), although it led to an increase in the chromium content, but did not increase the catalysts activity.

Conclusions

The effect of the chromium-magnesium precursor preparation techniques on physicochemical (the BET surface area, the total pore volume, the mean pore diameter) and catalysts activity in the gas-phase hydrofluorination of perchloroethylene to pentafluoroethane was studied. It was obtained, that more active catalyst was prepared by wet mixing of the solid carrier MgF_2 with a solution of $CrCl_3$. The precursor contained 6.1% chromium, and the BET specific surface area was equal to 60 m^2/g.

Kinetic regularities have been studied for the most active catalyst. Based on the experimental data, the pathway of perchloroethylene fluorination with HF over a 6.1% chromium–magnesium oxide catalyst was identified. The process involves several consecutive reactions for the formation of main fluorination products and parallel reactions for the formation of by-products.

Keywords: aquathermolysis, precursor of the catalyst, heavy oil, SARA-analysis, viscosity

1 Introduction

Gradually deteriorating structure of the world's hydrocarbon reserves. Research is focused on development of deposits of heavy oils. Reserves of heavy oil are comparable to reserves of traditional hydrocarbons [1]. The main obstacle in the extraction of heavy oils is their abnormally high viscosity due to the content of a significant amount of resinous-asphaltene substances. To extract heavy oil apply steam carrying thermal methods that provide viscosity reduction in the reservoir and partial conversion of heavy components as a result of aquathermolysis [2]. To increase the efficiency considering the possibility of using nanoscale or molecular catalysts, which injected into the reservoir. The search for new effective catalysts obtained by using available raw materials, is an important task for improving the energy efficiency of thermal methods of heavy oil production.

2 Experimental/methodology

Laboratory simulation of aquathermolysis on a sample of the heavy oil Ashalchinskoye field (Republic of Tatarstan) out on a laboratory autoclave (Parr Instruments, USA) with stirring was carried. In the reactor was loading of 70 g of oil and 30 g water. Precursor of the catalyst as a solution in petroleum ether on the basis 1.0 wt.% of oil was injected. Experimental conditions: temperature 250 °C, initial pressure 3 MPa, duration of the experiment 6 hours.

Hydrocarbon type content - saturated hydrocarbons, aromatics, resins and asphaltenes (SARA-analysis) based on the ASTM D4124-09 and state standards, Russian federation 32269-2013 by liquid adsorption chromatography on the aluminium oxide was determine.

The elemental analysis was performed on the analyzer PerkinElmer 2400 Series II (USA). Measurement of dynamic viscosity was carried out using a rotational viscometer FUNGILAB Alpha L.

3 Results and discussion

Aquathermolysis accompanied not only by changing the viscosity of the reservoir oil, but also a change in its composition. Commonly used molecular or colloidal catalysts are formed *in situ* from a precursor representing an organometallic compound or complex. With good solubility of the precursor of the catalyst, a hydrophobic portion of the petroleum fluid that prevents their agglomeration stabilizes the catalyst particles. The effectiveness of the catalytic process is enhanced by the association of molecules or particles of a polar (hydrophilic) catalyst with more hydrophilic asphaltenes molecules due to the considerable content of oxygen, sulfur and nitrogen functional groups, as well as associated metals such as nickel and vanadium [3]. As a result, the asphaltene fraction can be enriched with low molecular weight components, which provides an irreversible decrease in the viscosity of crude oil.

In this work the catalyst precursor has been synthesized by reacting under heating (90 to 95°C) catalyst bases - iron oxide (III) and ligand-form component - alkyl benzene sulphonic acid in a molar ratio of 1: 6.

Oil samples after aquathermolysis using different concentrations of the synthesized catalyst were examined. Found that when the content of the catalyst 1 wt.% of saturated hydrocarbons increased in 1.62 times, the amount of aromatics, resins and asphaltenes decreases in 1.12, 1.65, 1.21 times, respectively, compared with the crude oil. According to the SARA analysis determined that the asphaltene stability index (ASI) increases with increasing conversion of raw feedstock by tumors of saturated hydrocarbons. Carrying out elemental analysis of petroleum systems showed that significantly reduced sulfur content and the ratio of C/N. The viscosity of the product experience is also reduced. It is also found that the synthesized catalyst promotes the hydrogenation and hydrogenolysis reactions of the resinous-asphaltene compounds to form the light ends, hydrocarbons and non-hydrocarbon gases.

4 Conclusions

Synthesized a new catalyst for an intensification of steam carrying thermal method of heavy oil production, using available domestic raw materials. Organometallic catalyst is a complex (the precursor), based on iron oxide, soluble in polar and non-polar liquids.

Application of this catalyst showed high efficacy in the hydrogenolysis and hydrogenation of resinous-asphaltene compounds heavy oil. The catalyst promotes the formation of light fractions, thus reducing the viscosity of heavy oil.

Performance of Modified Nickel Catalysts in a Catalytic Membrane Reactor for Partial Oxidation of Methane

Ushakov A.E., Kozhevnikov V.L., Patrakeev M.V., Leonidov I.A., Markov A.A.*

Institute of Solid State Chemistry, Ural Branch of RAS, Ekaterinburg, Russia

Keywords: synthesis gas, modified nickel catalysts, membrane, reactor, partial oxidation

1 Introduction

Natural gas is broadly used as a feedstock in the production of liquid hydrocarbons via synthesis gas (syngas) as an intermediate step [2]. The industrial reforming of natural gas to syngas is dominated by catalytic steam reforming [3], which requires a large excess of the gas supply for heating. The catalytic partial oxidation (CPO) allows improvement of the reforming efficiency due to the using of the heat evolved in the CPO reaction. Further advancement in the overall performance of the gas to liquid process can be achieved by combining CPO with oxygen separation from air in a membrane reactor [4]. The long term stability and selectivity toward products of partial oxidation, i.e. CO and H_2, greatly depend on the catalyst used at the permeate side in the membrane reactor. Therefore, the aim of this work was to study the behavior of Ni based catalysts in the membrane reactor for partial oxidation of methane.

It was observed that simple Ni/Al_2O_3 catalysts degrade rather quickly because of the soot formation. In order to suppress this undesirable reaction we modified the catalysts by adding M_2O_3 oxides, where M = Mn and Fe.

2 Experimental/methodology

The preparation of the catalysts was based on co-impregnation of industrial γ-Al_2O_3 support with solutions of Ni, Mn and Fe nitrates. The BET surface area was determined by N_2 adsorption at -196°C with the help of a Micromeritics Gemini VII device. Prior to measurements the samples were pre-treated in vacuum at 300°C for 5 h. The catalytic tests were carried out in a fixed-bed flow reactor operated at atmospheric pressure. The outer shell of the reactor was made of a quartz tube. The ferrous oxygen separating membrane [4] was set inside the quartz casing in between alumina tubes that served also as in- and outlet air ducts. The membrane sizes were 1, 10 and 30 mm for wall thickness, diameter and length, respectively. The space between the membrane and the casing was filled with the catalyst. The methane conversion X_{CH_4} and selectivity S_{CO} for CO were calculated as:

$$X_{CH_4} = \frac{CH_4^{in} - CH_4^{out}}{CH_4^{in}} \times 100\% \qquad (1)$$

$$S_{CO} = \frac{CO^{out}}{CO^{out} + CO_2^{out}} \times 100\% \qquad (2)$$

3 Results and discussion

The atmospheric pressure experiments were carried out at 850-950°C for over 300 h. It should be noted that a rapid increase in the selectivity for CO was observed for both catalysts immediately after the start-up. Further increase in the methane flow was accompanied with a

decrease in the selectivity, which was more expressed for Ni/Fe_2O_3 /γ-Al_2O_3 catalyst. The selectivity attained 96 - 98% for both Fe and Mn modified catalysts (Fig.1) at methane flow values 40 – 45 ml/min whereupon a steady state was achieved (Fig.2).The methane conversion over modified catalysts was about 99 %. The after test inspections of the catalysts did not reveal any significant formation of soot or/and coke.

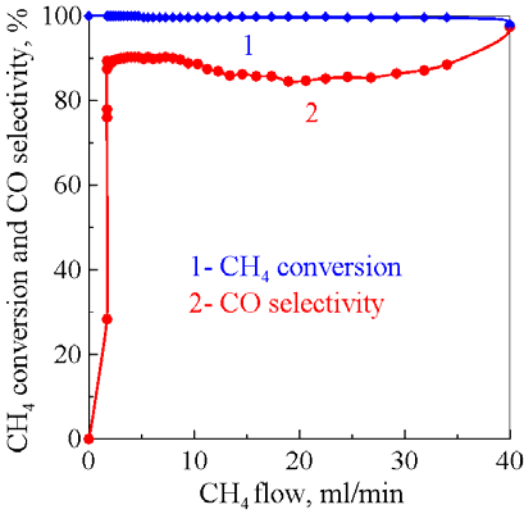

Fig. 1. CH_4 conversion and selectivity for CO at partial oxidation methane over Ni/Fe_2O_3 /γ-Al_2O_3 catalyst.

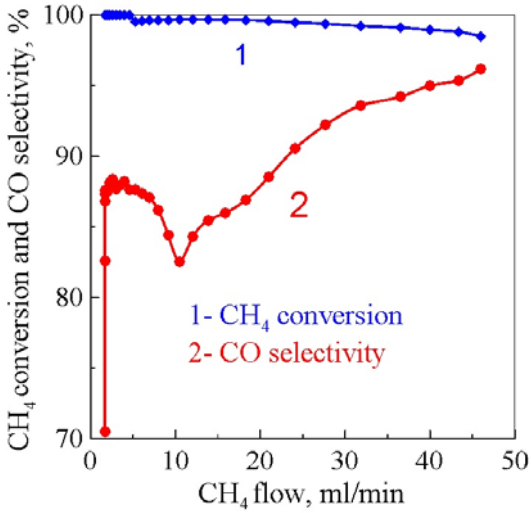

Fig. 2. CH_4 conversion and selectivity for CO at partial oxidation methane over Ni/Mn_2O_3/γ-Al_2O_3 catalyst.

4 Conclusions

The results of this work lead to the following conclusions: modified nickel catalysts were shown to exhibit high activity and stability in a catalytic membrane reactor for partial oxidation of methane.

Alkylphenols to Phenol and Olefins by Zeolite Catalysts: a Shape-selective Process to Valorize Raw and Fossilized Lignocellulose

Verboekend D.*, Liao Y., Schutyser W., Sels B.F.

KU Leuven, Leuven, Belgium

* Danny.Verboekend@biw.kuleuven.be

Keywords: lignin, coal, alkylphenol, dealkylation, shape-selective, zeolite

5 Introduction

The large-scale consumption of fossil fuels today will eventually lead to the depletion of the world's (cheap) oil reserves. Accordingly, an alternative source of everyday base-chemicals for the production of polymers, pharmaceuticals, and other specialty chemicals needs to be explored. Of the different types of base chemicals, aromatics represent an important building block for the (fine-)chemical industry in the manufacture of plastics, rubbers, and other synthetic fibers [1]. Ultimately, these aromatics should be derived from a sustainable source, such as plant-like materials (lignocellulose). The main constituents of raw lignocellulose are cellulose, hemi-cellulose, and lignin. Particularly the valorization of lignin is of high relevance as it is the only of the three types which comprises a substantial amount of aromatics (*ca.* 50 wt.%) [2]. Currently, a wide academic interest focusses on the extracting aromatic monomers from lignin, using a wide variety of catalyst of varying efficiency. However, the final product is often an alkylated phenol [3]. On the middle-long term the shortage of oil is likely to be (partially) compensated by the increased valorization of solid fossilized lignocellulosic resources, such as peat, lignite, and coals. Particularly on coal, the technology to isolate aromatics has been already developed decades ago [4]. Related processes primarily yield syngas, but often also up to 10 wt.% of residue (coal tar), which is rich in ethyl- and propylphenols. Although some specific applications of alkylated phenols may exist, the valorization of the substantial streams of alkylphenols is a must to fuel tomorrow's chemical industry. In this contribution we identify unmodified acidic ZSM-5 zeolites as shape-selective catalysts to convert a variety of alkylphenols selectively to phenols and olefins.

6 Experimental

Dealkylation experiments were performed in a custom-built plug-flow fixed-bed reactor equipped with 4 parallel quartz reactors. Each quartz reactor was filled with 30 mg of zeolite catalysts (H-ZSM-5, CBV 8014, Zeolyst, sieve fraction: 0.125-0.250 mm). The alkylphenol (Sigma-Aldrich, >98%) was brought to the gas phase using a nitrogen flow passed through a saturator. The same was done separately with a saturator filled with water. Afterwards, the flows were mixed and passed through the reactors. Effluent gasses where characterized using an in-line gas chromatograph equipped with a HP1 column and a FID detector.

7 Results and discussion

The most abundant alkylphenol to be derived from lignin and coal is 4-*n*-propylphenol. Initial results showed that with time on stream the catalyst deactivates rather fast (**Figure 1**). The addition of water to the feed was studied to test the catalyst ability to coop with wet streams of alkylphenols, which may originate from the streams of raw lignocellulose [5] or from the gasification of fossilized lignocellulose [4]. Unexpectedly, a full recovery of the initial

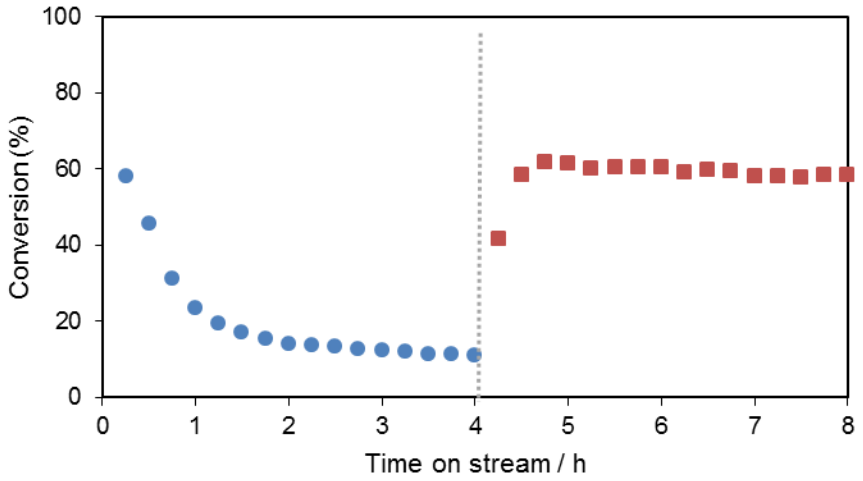

Fig. 1. Conversion of 4-*n*-propylphenol (4PP) as a function of time over a H-ZSM-5 catalyst without (0-4 h, circles) and with co-feeding water (4-8 h, squares). The selectivity was >95% at all times. The co-feeding of water completely restored the activity of the catalyst. Conditions: p = 1 bar, T = 310°C, WHSV 3.3 h^{-1}, partial pressures (0-4 h): p_{4PP} (0.02 bar) and p_{N2} (0.98 bar), partial pressures (4-8 h), p_{4PP} (0.02 bar), p_{H2O} (0.12 bar), and p_{N2} (0.86 bar).

activation occurred, hereby revealing a crucial role of the co-feeding of steam. This performance strongly differs from the dealkylation of alkylbenzenes [6], as the latter reaction requires the zeolite to be modified with metal functions or rare-earth cations, and the co-feeding of H_2 to prevent coking and maintain a stable performance. In this contribution we highlight the nature of the role water plays in the dealkylation of alkylphenols is reaction, and extrapolate it to other reactions. In addition, the influence of the length, branching, and position of the alkyl moiety is studied and related to the composition (Si/Al ratios ranging from 2.5 to 200), pore-size (0.4-0.8 nm), and pore connectivity (1D-3D) of the zeolite. Accordingly, light is shed on the exact nature of the active site, its location, abundance, and strength.

8 Conclusions

The dealkylation of alkylphenols represents a key conversion in the valorization of raw and fossilized lignocellulose. Unmodified H-ZSM-5 is a highly active catalysts and clearly displays shape-selectivity behaviour in this type of conversions. Finally, the co-feeding of water plays a crucial role in maintaining catalytic activity.

Study of Catalytic Activity of Impregnated VMgO Catalystsin the Oxidative Dehydrogenation of Ethane

Slyemi S., Barama A.*, Messaoudi H.

Laboratoire des Matériaux Catalytiques et Catalyse en Chimie Organique, USTHB, Faculté de Chimie, Alger, Algérie

* a_barama@yahoo.fr

Keywords: VMgO, $Mg_3V_2O_8$, ethane, oxidative dehydrogenation

1 Introduction

The V-Mg-O mixed oxides are known to be active and selective catalysts in the oxidative dehydrogenation of short alkanes. These good performances of VMgO catalysts are attributed to the two factors: the surface basicity which facilitates the alkene desorption and the absence of V=O species which decrease the oxidative properties of the surface [1]. Three Mg vanadate phases ($Mg_3V_2O_8$, α-$Mg_2V_2O_7$ and MgV_2O_6) can be formed in these oxides depending on several parameters, e.g., the vanadium composition, the preparation method and the calcination temperature. However, the phase responsible for the ODH selectivity in the V-Mg-O system is still a topic of debate. Most of the studies report that $Mg_3(VO_4)_2$ is the active phase and the isolated tetrahedral species (VO_4) present in this phase are responsible of the activation of the C-H bond of the hydrocarbon **[2]**. Recently, other researchers found that the biphasic V-Mg-O exhibited better catalytic performances than the pure phases **[3]**. In other words, the coexistence of $Mg_3V_2O_8$ with other phases such as MgO and α-$Mg_2V_2O_7$ could generate interactions between the different phases that improve the catalytic behavior of these mixed oxides. The formation of V_2O_5 crystallites with V=O double bond in which the V^{5+} is in octahedral coordination in these oxides favors the complete oxidation and the production of oxygenate compounds **[2]**.

2 Experimental/methodology

Two series of V-Mg-O catalysts (Mg/V=4.5) were prepared by impregnation of $Mg(OH)_2$ or commercial MgO (Merck, 97%) **,** using an aqueous hot and basic (pH=11) solution of ammonium metavanadate NH_4VO_3 (Merck, 99%). The obtained solids have been calcined at 550 and 650°C for 6 hours (5°C/mn).

3 Results and discussion

The XRD and the FTIR analysis show for all the samples, the formation of a mixture of crystalline phases: $Mg_3(VO_4)_2$, α-$Mg_2V_2O_7$ and MgO. The $Mg_3V_2O_8$ is the major phase and the α-$Mg_2V_2O_7$ is detected as traces. The MgV_2O_6 and the V_2O_5 are not observed in our catalysts. The TPR profiles, show for each of the two samples prepared by $Mg(OH)_2$ and commercial MgO, one peak of reduction observed respectively at 750 and 715°C. These two maximum peaks reduction observed at relatively high temperatures because of the high vanadium composition in our catalysts (50% of V_2O_5), indicate one step of vanadium reduction which correspond to the passage from tetrahedral coordination (V^{5+} belonging to $Mg_3V_2O_8$ phase) to a cubic spinel phase MgV_2O_4 containing V^{3+}. H_2-HT-XRD analysis effectuated for all the catalysts, show, that the lines of $Mg_3V_2O_8$ phase which is already formed at ambient temperature remained up to 625°C. Above this temperature, we note: the disappearance of $Mg_3V_2O_8$ peaks and the appearance of a cubic spinel type phase MgV_2O_4. This reduced structure of our solids is conserved after cooling the sample to the ambient temperature.

The reduction of $Mg_3V_2O_8$ phase to MgV_2O_4 indicates a change in the oxidation state of the vanadium from V^{5+} to V^{3+}. This reduction was confirmed by many researches [ref] that reported the formation of a reduced cubic phase (MgV_2O_4) containing only V^{3+} upon treatment of $Mg_3V_2O_8$ under reducing conditions.

The reactivity of the V-Mg-O samples tested in the oxidative dehydrogenation of ethane (Tr=450°C and C_2H_6/O_2=2) for 4 hours show good catalytic performances with selectivity to ethylene of 99%. These good catalytic performances are attributed to the predominance of Mg orthovanadate and to its coexistence with Mg pyrovanadate and MgO. For more precision, there may exist a cooperation between the two phases $Mg_3(VO_4)_2$ and MgO present on the catalyst surface. The higher basicity induced by the presence of MgO on the catalyst surface facilitates desorption of alkenes thus prohibiting side reactions. The significance of the role of the acid-base character of catalysts in hydrocarbon partial oxidation reactions has been pointed out in the literature. It is confirmed by this study that coexistence of $Mg_3(VO_4)_2$, MgO and α-$Mg_2V_2O_7$ is beneficial for the increased production of ethylene. It has been also established that the catalyst, prepared by commercial MgO, is less active than the solid prepared by $Mg(OH)_2$ (ethane conversion 57% against 73%). This fact allows us to say that the higher the proportion of $Mg_3V_2O_8$ detected by XRD, the higher is the conversion of ethane. The obtained results confirmed the important role of (VO_4) units present in Mg orthovanadate phase which are responsible of the activation of the C-H bond. The high activity and selectivity to ethylene obtained with the catalyst prepared via $Mg(OH)_2$ is probably due to the presence with a great proportion of isolated tetrahedral (VO_4) species on the catalyst surface.

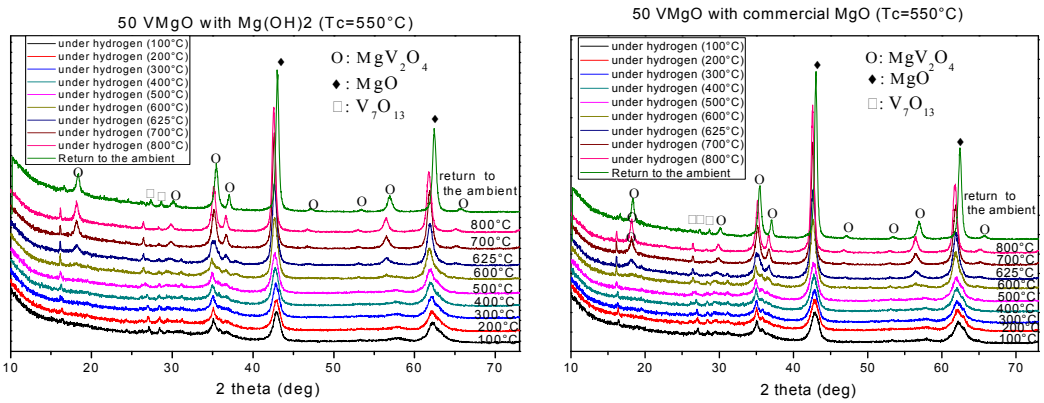

Figure: XRD patterns during reduction under hydrogen of the V-Mg-O catalysts.

4 Conclusions

The mixed oxides V-Mg-O (%V_2O_5=50%) prepared using a simple impregnation method, exhibit good catalytic performances in the ODH of ethane. The high activity and selectivity to ethylene are attributed to the high proportion of tetrahedral (VO_4) units present in Mg orthovanadate phase and to the coexistence of this phase with α-$Mg_2V_2O_7$ and MgO. These results are also due to the absence of V_2O_5 phase (confirmed by XRD and FTIR) which favors the formation of combustion products (COx). The best catalytic activity is obtained with the catalyst prepared by impregnation of $Mg(OH)_2$.

Keywords: amorphous, silica-alumina, hydroconversion, hydrocracking, parafines, wax

1 Introduction

The growing interest in mining in cold and arctic climate is a growing need for waxy motor fuels. Traditionally, winter diesel fuel and jet fuel produced from petroleum feedstocks. However, worsening environmental problems caused by rapid technological progress has led to the need to involve the raw material that does not contain nitrogen compounds, sulfur, aromatic compounds and heavy metals. Thus, natural gas processing technology "gas to liquid" produces mostly *n*-alkanes normal structure of a wide range of composition - from light gases to heavy paraffins vacuum fraction. Long-chain *n*-alkanes processing to produce components of diesel and aviation fuels is carried out by their hydroconversion processes accompanied by hydrocracking and hydroisomerization. Bifunctional catalysts traditionally used for these processes are systems which contain a carrier, characterized by acidic properties and metal, performing hydrogenation function. Varying acidic properties of catalysts allows controlling the product distribution [1].

Zeolite catalysts tend to produce lighter products gasoline fractions [2] while the output of middle distillates is possible to increase through the use of catalyst supports with moderate acidity, which is the amorphous silica-alumina [3] and silica-alumina phosphates [4]. Moreover the developed porous structure and a large pore diameter media promotes the formation of branched alkanes inside the pores and provides a light diffusion long-chain initial alkane molecules and the conversion products. The use of platinum as the hydrogenation component is due both to the high specific activity of the metal (in comparison, for example, nickel) and the absence of catalyst poisons (like a sulfur) impurities in the feed [5].

Thus, it was investigated the behavior of Pt-containing catalysts based on amorphous silica in the hydroconversion process of the model feed containing C_{20}-C_{31} *n*-alkanes to obtain kerosene and diesel fractions having improved cold flow properties.

2 Experimental/methodology

Amorphous silica-alumina with SiO_2/Al_2O_3=10 molar ratio was synthesized in water and propanol-2 solution at room temperature using tetraethyl orthosilicate (TEOS) a as silica and alumina tri-*sec*-butoxide as an alumina sources respectively. Hexadecylamine was used as a surfactant. The prepared support was formed with Al_2O_3 (Sasol Pural SB-1) and denoted as ASA(10)-Al_2O_3. Pt was impregnated on ASA(10)-Al_2O_3 *via* the incipient-wetness method using H_2PtCl_6 aqueous solution. The Pt loading was adjusted to 0.5, 1 and 2 wt.%. The impregnated solid was dried at 100 °C overnight and reduced in H_2 flow at 350 °C for 3 h. The resulting catalysts were denoted as (X)-ASA(10)-Al_2O_3, where X is Pt content in wt.%. The samples were characterized using complex of analytical methods.

Catalytic experiments were made in a continuous flow reactor. The process parameters were varied: temperature (T) = 310-360 °C, pressure p(H_2) = 50-60 atm and liquid hour space

velocity (LHSV) = 0.5-1 h^{-1}. The composition of the feed and products was determined by gas chromatography. The cold filter plugging point (CFPP) of products was determined by ASTM D6371.

3 Results and discussion

It was shown some trends in hydroconversion of C_{20}-C_{31} *n*-alkanes with Pt-ASA(10)-Al_2O_3: increasing the reaction temperature leads to decreasing the middle distillates yield, the pressure H_2 in the range 50-60 atm doesn't make influence at products distribution and LHSV increasing resulted in conversion level decreasing. The best catalytic results were achieved by catalyst having 1 wt. % platinum content. So, the Figure 1 clearly presented the composition of the feed *(a)* and of the product *(b)* received using the sample 1%Pt-ASA(10)-Al_2O_3 at 320°C, LHSV = 0.5 h^{-1} and p(H_2) = 50 atm.

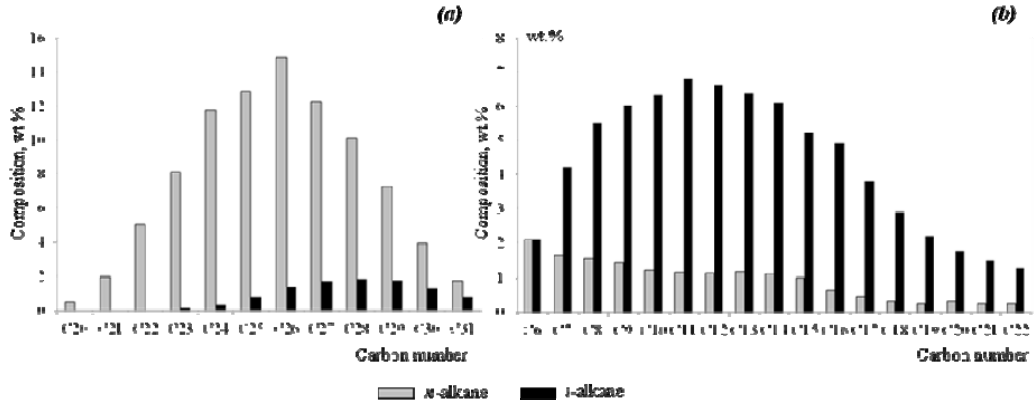

Fig. 1. Composition of the feed *(a)* and gasoline-kerosene-diesel fraction of hydroconversion product *(b)*

The cold filter plugging point determined for the diesel fraction of the product was minus 34 °C, which is a good index for the winter fuel additives.

4 Conclusions

The synthesized Pt/amorphous silica-alumina catalyst provides the formation of branched alkanes of diesel fraction from C_{20}-C_{31} *n*-alkanes that is a key factor of good cold flow fuel properties. At high conversion level up to 90% it is possible to produce up to 50 wt.% of diesel fraction.

Keywords: Pt, CoPt nanoparticles, mixed oxides, intrinsic and effective acidity, 5-hydroxymethylfurfural

1 Introduction

The catalytic potential of metal nanoparticles (MNPs) in catalysis is well known and MNPs have been exploited in many reactions of importance for various fields [1]. Bimetallic nanoparticles can provide improved selectivity to desired products in given reactions; so the selection of given formulations (nature and relative amounts of the metal species) offers optimized systems in catalysis.

Supporting MNPs on inorganic materials gives the possibility to use these systems as effective heterogeneous catalysts, in particular maintaining the MNPs dispersion during reaction, even when severe reaction conditions have to be applied. The surface properties of the support are key factors for the optimal dispersion of the MNPs and for their stable anchorage on the surface. Among the surface properties, acidity is one of the most important. Acidity is an *intrinsic* surface property of any given material, but it can be modified by adding a second oxide component. Moreover, the acidic properties of a given material can be also modulated by means of the environment, namely the reaction solvent. Therefore, it is important to consider the actual acidity showed by the materials under the reaction conditions (*effective* acidity) [2].

Our recent advances in the catalytic application of monometallic and bimetallic nanoparticles supported on several silica mixed oxides of different acidity are here presented. Pt and Co NPs and bimetallic PtCo NPs have been synthesized and then deposited (1 wt.%) on silica modified with 5 wt.% of Al, Nb, Ti, and Zr. The obtained samples have been fully characterized by several surface techniques in order to study the textural properties (N_2 adsorption/desorption), metal dispersion, (TEM and HRTEM), and acidity properties, measured by base titrations in different liquids in order to provide measurements of both *intrinsic* and *effective* acidity [2].

The prepared samples have been used in the reaction of 5-hydroxymethylfurfural (HMF) with butan-2-ol, under H_2 pressure. From this reaction, several valuable chemicals are known to be formed [3,4], like 2,5-dimethylfuran (DMF), 2,5 dihydroymethylfuran (DHMF), 5-methyl furfural (5MF), 5-methylfuranether (5MFE), 5-hydroxymethylfuran-2-ether (HMFE), 2,5-bis(sec-butoxymethyl)furan diether (HMFDE). On the studied samples, the product of a certain reaction path and its selective formation showed to be correlated to the effective acidity of the oxide support, as measured in methanol, which provides an environment similar to the reaction one.

2 Experimental/methodology

Commercial silica (Grace) was modified at the surface with 5 wt.% of Al (Al/SiO_2), Nb (Nb/SiO_2), Ti, (Ti/SiO_2), and Zr (Zr/SiO_2) by controlled precipitation of aluminum isopropoxide, niobium ethoxide, titanium butoxide, and zirconium propoxide, respectively. The acidity of the oxide supports was determined by liquid-solid titration with phenylethylamine (PEA) basic probe dissolved in cyclohexane and methanol for the determination of the *intrinsic* and *effective* acidities, respectively [2]. Co, Pt, and PtCo NPs were deposited (1 wt.%) on the oxide supports. TEM images

of the supports with Pt, Co, and CoPt NPs have been collected with a Zeiss EM 902 electron microscope at 80 kV and HRTEM images with a Jeol JEM2100F microscope at 200 kV.

The catalytic activity was studied in an autoclave magnetically stirred (1250 rpm) at 180°C for 4-6 hours; the substrate (1.2 mmol HMF) and solvent (15 mL butan-2-ol) were loaded to the reduced catalyst sample (150 °C, 4 bars of H_2). After filtration, the reaction mixture was analyzed by gas chromatography (GC) equipped with a thermal conductivity detector (TCD).

3 Results and discussion

The synthesized mixed oxide supports possessed high surface area values (from 474 m^2/g of silica down to 352 m^2/g of Al/SiO_2, 283 m^2/g of Nb/SiO_2 and 254 m^2/g of Zr/SiO_2 and Ti/SiO_2) and good pore volume (ca. 1 cm^3/g). Silica was poorly acidic and it lost quite all its acidity in methanol. The mixed oxide supports are all more acidic than silica and they maintained lively acid sites in methanol; the following ranking of *effective* acidity in methanol was obtained (in terms of acid site density, μequiv/m^2): Al/SiO_2 >> Ti/SiO_2 ≅ Nb/SiO_2 > Zr/SiO_2 >> SiO_2.

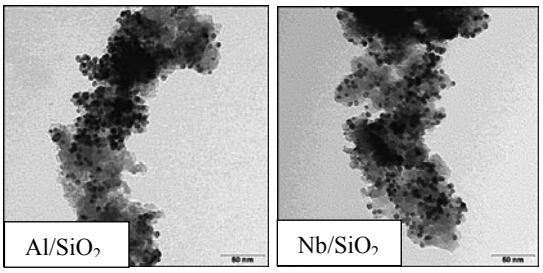

Fig. 1. TEM images of supported PtCo NPs.

Pt, Co, and PtCo NPs were deposited on the supports (1 wt.%) mainly as spherical particles of ca. 7-8 nm of size, regularly distributed, as observed from TEM images (see Figure 1, as example). The surface area values and porosity of the metal loaded samples were maintained without any remarkable differences with the relevant support.

The reaction of HMF in butan-2-ol under H_2 gave different results as a function of the *effective* acidity of the support, mediated by the nature of the metal, Pt or Co, or CoPt. The activity of the catalysts was affected by the support acidity. The bare oxidic supports had a non-negligible activity; solely SiO_2, with a very poor acidity, was completely inactive. Increasing the acidity of the support, the selectivity to ethers (HMFE and HMFDE) increased, but using the most acidic support (Al/SiO_2), high amounts of unknown products were also formed. The best compromise can be reached using Nb/SiO_2, which showed an intermediate *effective* acidity in methanol. By adding Pt, Co and PtCo nanoparticles, the activity of the catalysts generally increased, but the Co based ones appeared normally more active than the Pt counterparts. The most active catalyst (Co-Nb/SiO_2) was also the most selective toward HMFDE (77%) (Figure 2).

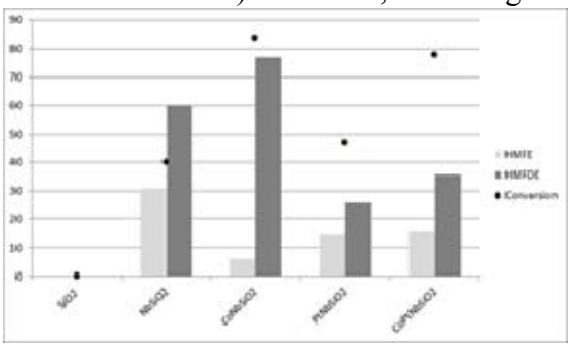

Fig. 2. Evolution of the ethers formation on MNPs on Nb/SiO_2 support.

4 Conclusions

It has been found that the support chosen for MNPs may direct the selectivity of the transformation of HMF into valuable products. Mild *effective* acidity of the support, like in the case of Nb/SiO_2, seems more suitable for enhancing the catalytic action of MNPs and depressing the production of unknown by-products.

Highly Stable and Selective Propane Dehydrogenation Catalyst

Tschentscher R.*, Akporiaye D.

SINTEF Materials & Chemistry, Oslo, Norway

* roman.tschentscher@sintef.no

Keywords: propane dehydrogenation, hydrotalcite, coking, sintering, platinum, promoters

1 Introduction

The shale gas boom has created a demand for alternative routes of propylene production, among which propane dehydrogenation is the most promising. This paper discusses the development of chromium-free catalysts with high selectivity, stability against coke formation and sintering as part of the FP7-Framework project CARENA. The work is based on earlier research on hydrotalcite-based catalyst supports.

2 Experimental

In-house made hydrotalcite-based oxide supports were used. For high dispersion the active metal phase consisting of platinum, tin and promoters was deposited by a combination of ion-exchange and precipitation. The catalysts were tested at rather severe conditions of 600 °C, without steam addition in order to rapidly screen catalysts. The optimal catalyst was tested in a wide range of conditions varying steam content, temperature and pressure. The fresh and spent catalyst was characterized by SEM, TEM, XRD, TPD and NMR.

3 Results & Discussion

Based on the screening tests a catalyst with the composition $PtZnSn/MgAlO_x$ could be identified. For propane dehydrogenation under industrial conditions the highest selectivity reported so far could be achieved (<99.5 % at 20% conversion and atmospheric pressure). Based on the high sticking coefficient of ethylene, it is expected that this byproduct has a significant role in catalyst coking by formation of oligomeric ring structures. Alloying with Zn and Sn does, thereby, reduce the size of Pt ensembles. Further, Zn poisons the acidic cracking sites. Two species of "coke" could be revealed by switching NO STEAM to STEAM during the experiment. Upon steam addition strongly adsorbed oligomeric species desorb due to competitive adsorption and hydroxylation of the support. The remaining difference in activity can be attributed to formation of high molecular weight char which can only be removed by oxidative treatment. The nature of coke is studied by NMR. Addition of steam strongly minimizes the degradation by coking. Interestingly, an increase of the steam amount above 10 vol% does not significantly change the catalyst performance. This can strongly improve the process economics compared to industrial steam concentrations of up to 60 vol%. A stable catalyst operation for several weeks can be achieved by using temperatures below 520 °C. Acceptable conversions at those temperatures could be achieved by the use of membranes removing either hydrogen or, preferably, propylene.

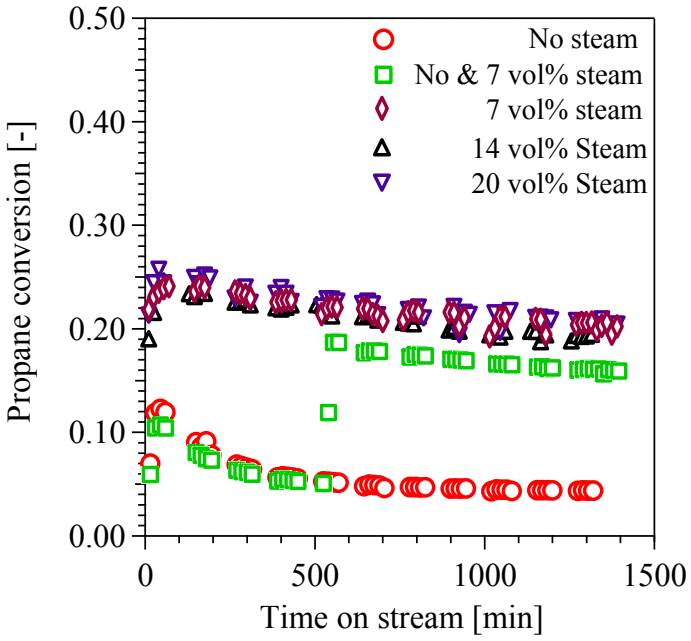

Fig. 1: Propane conversion @ 540 °C depending on steam load for 1 bar total pressure.

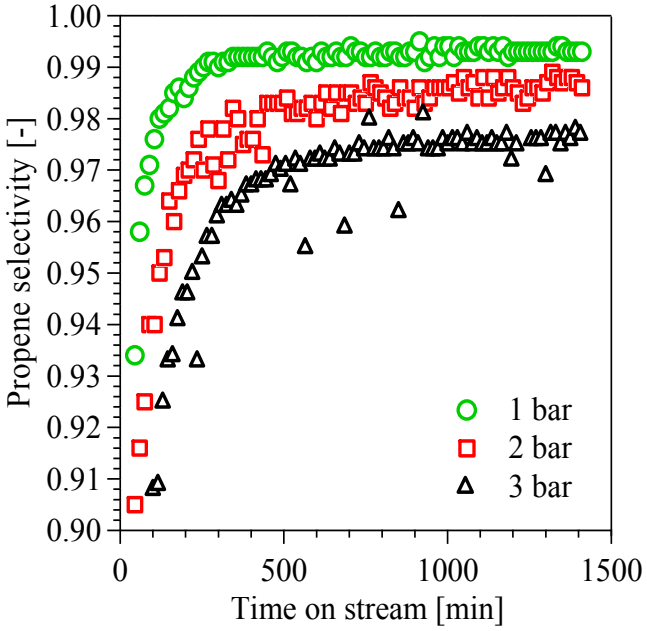

Fig. 2: Selectivity depending on pressure for 15 vol% steam.

Keywords: oil, asphaltenes, phase-dispersed structure, iron oxide, hydrothermally-catalytic processes

1 Introduction

Currently become widespread technologies aimed at mining and processing of heavy oil feedstock to produce a so-called "synthetic oil" with reduced viscosity [1]. Of interest are the processes in the environment of water vapor in the presence of sufficient available iron oxide catalysts, providing conversion of heavy petroleum residues into lighter boiling hydrocarbons [2, 3]. Elevated levels of high molecular weight components, metals and heteroelements in the heavy hydrocarbon feedstock substantially affects the processes of its production, transportation and processing. These problems are related to specific properties of asphaltenes. Asphaltenes in the oil disperse systems are in the form of supramolecular structures, which are molecules associates whose sizes vary depending on the composition and nature of oil and impact of external factors, such as temperature and pressure [4]. Therefore, in the aspects of development of deposits of heavy heavy oil and natural bitumen is important to have information about changing the composition and properties of asphaltenes in a variety of natural and anthropogenic processes.

2 Experimental/methodology

The objects of the study served as a heavy oil Ashalchinskoye field from the Permian system of Tatarstan and its conversion products. Also, its conversion products in an environment of water vapor in the presence of natural iron catalyst - hematite was obtained. Experiments were performed in an autoclave at temperatures of 210, 250 and 300 °C at various ratios of water in the reaction system. Asphaltenes from the feed oil and the products precipitated in experiments 40-fold amount of petroleum ether with Tboil 40-700° C. Deasphaltenesates were separated by liquid adsorption chromatography on silicagel ASK into components: oils and two groups of the resins: alcohol-benzene and benzene.

Asphaltenes investigated using complex physical and chemical methods: elemental and X-ray fluorescence analysis, matrix-assisted laser desorption / ionization (MALDI), ESR and IR spectroscopy. Determination of structural and dimensional parameters asphaltenes performed using X-ray powder diffraction techniques [5] and small angle x-ray scatter [6].

3 Results and discussion

The features of the processes of degradation of high-molecular components of heavy oil with a new formation of light fractions in the model of hydrothermal-catalyst system in water vapor in the presence of a catalyst - iron oxide at temperatures of 210, 250, 300°C, which lead to a change in its component, hydrocarbon, fractional and structural-group composition. The general tendency in changes in the structural and dimensional characteristics of the

supramolecular structures of asphaltenes is to increase their aromaticity factor and the distance between layers and the aromatic chain-like polymethylene moieties in their associates, as the temperature increases and experiments reduce the water content in the reaction system. This reduces size and associates itself reduces the number of aromatic layers. By small-angle X-ray scattering shows that associates the original asphaltene (before the experiment) are characterized by a heterogeneous structure, but differ in varying degrees, ordered by their location (on paracrystalline type) inside the clusters. The transition from the initial sample of asphaltenes to their transformed structure is accompanied by a shift of the maximum peak in the dispersion curves in the region of small angles up to s = 0.15 Å-1 and an increase in the interplanar spacing values to 41.2Å, due to the removal of mutual association with each other as a result of the rupture and the degradation of aliphatic chains, aromatic fringing island system. Hydrothermally catalytic treatment of heavy oil at higher temperatures (300°C) leads to a break in most of the asphaltenes of such aliphatic chains and destruction of the particles in the arrangement of correlation associates indicates that the increase in the degree of microheterogeneity at close dimensional characteristics of the particles themselves. Changes in the phase-dispersed supramolecular structure of asphaltenes accompaned by a sequence of transitions in their class in toluene insoluble substances such as carbo-carboidov further coke-like products that fall out of the dispersion medium in the form of a solid. The result of leakage is the destruction of the destructive processes supramolecular structures due to their degradation preferred alcohol-benzene resins, associated with asphaltenes, and vanadium complexes, separation of peripheral alkyl fragments, which leads to carbonisation of their structure, molecular weight decrease and increase the concentration of free radicals. Asphaltenes the conversion of heavy oil products are only those molecules and aggregates whose size is not too large to provide solubility in toluene.

4 Conclusions

Thus, it is shown the effect of temperature and water content on the formation and stability of the disperse phase in the structure of asphaltenes in the hydrothermally-catalytic processes in the presence of a catalyst - iron oxide.

Keywords: furfural, propylfurfuryl, ether, acetal, octane number, hydrogenation

1 Introduction

Devising new methods for production of biofuels and fine chemicals from biomass is the main trend of the development of modern chemical industry. Such compounds are produced either by biotechnology routes (ethanol, butanol, etc.) or by chemical methods, hydrolysis, pyrolysis and others.

Furfural is the main industrial product of pentose carbohydrates hydrolysis, however development of biofuels of the furfural platform has started to be discussed only recently [1,2]. Blending research octane numbers (BRON) of ethyl-, propyl-, and butylfurfuryl ethers (110, 113 and 97, correspondingly) were determined [2,3]. 2-methylfuran was successfully tested in the mixtures with gasoline in car engines [4].

Hydrogen consumption is one of the main characteristics for furfural and other oxygenated products hydrogenation into biofuels. Alkylfurfuryl ethers are very attractive from this viewpoint (consumption of one mole of hydrogen per mole of the product). A possible way to produce such ethers is t catalytic hydrogenation of furfural dialkylacetals.

The main goal of this paper is to study furfural catalytic hydrogenation in alcohol solutions.

2 Experimental/methodology

Mesoporous carbon Sibunit-supported copper-ruthenium and platinum- (3-8 wt%) catalysts of 40-70 μm fraction were prepared by the incipient wetness impregnation method. At the end of the impregnation procedure, all catalysts were dried in an oven overnight at 100°C. The metal-containing catalysts were activated (reduced) with hydrogen *in-situ* in the reactor. Reactions were carried out in a batch reactor of 150 ml volume at 100 – 200 °C and hydrogen pressure of 1 MPa. 19.1 g of the alcohol, 0.53 g of furfural, and 0.2 – 0.4 g of the catalyst were charged in the reactor and heated during 6 hours. The products were analyzed by GLC and GC-MS (VG-7070 GC/MS and Agilent 5973N EI/PCI).

3 Results and discussion

Catalytic hydrogenation of furfural in alcohol media is accompanied by the equilibrium limited acetal formation, with furfural conversion into the corresponding acetals attaining 55-66 % (Table 1). This equilibrium leads to further hydrogenation of dipropyl- and dibutylacetals into the corresponding furfuryl ethers, which yield attains 19 %. It should be noted, that at low furfural conversions (appr. 20 %) in the presence of CuRu/C-catalyst selectivity on butylfurfuryl ether exceeds 50 % (Table 1). A similar possibility of t5-butoxymethylfurfuryl dibutyl acetal hydrogenation into the corresponding ether, 2,5-dibutoxy-methylfuran, was recently demonstrated [5,6].

Table 1. The influence of the catalyst and alcohol on the products content (mol % based on initial furfural) in furfural hydrogenation. Conditions: furfural 0.53 g, alcohol 19.2 g, catalyst 0.400 g, 110°C, 6 hours, 1 MPa H_2.

Catalyst	Alcohol	Furfural/ Furfuryl acetal	Furfuryl ether	2-Methyl-Furfural	Furfuryl alcohol
8%CuRu/C*	Butanol	43/54**	-	-	-
8%CuRu/C*	Butanol	66/13	9.3	-	11.1
8%CuRu/C	Propanol	27/54	9.5	-	8.3
3%Pt/C	Propanol	-	16.3	29.4	8.7
3%Pt+3%Ni/C	Propanol	-	18,9	27.2	30.3
3%Pt+3%Re/C	Propanol	-	15,9	34.4	20.5

*0.2 g of the catalyst. **Nitrogen atmosphere.

The yield of furfuryl alcohol in the process is 8 – 30 %. This product is not the intermediate, which upon alkylation with propanol or butanol generated alkylfurfuryl ethers. Separate experiments showed that furfuryl alcohol does not practically alkylate propanol under these conditions, and the yield of propylfurfuryl ether did not exceed 5 %. Probably, the difficulties of direct alkylation of furfuryl alcohol result from its conversion into levulinic acid and tar.

The other main product of furfural catalytic hydrogenation is 2-methylfuran, which maximum yield exceeds 30 %.

4 Conclusions

The obtained results show that furfural hydrogenation in alcohol media is accompanied by formation of acetals. Both products, furfural and furfuryl acetals, are hydrogenated, and the acetals give the corresponding ethers. In such way catalytic hydrogenation of furfuryl acetals is an alternative and promising method to produce corresponding furfuryl ethers. The products produced in the studied process, namely butylfurfuryl ether, propylfurfuryl ether, 2-methylfuran, and furfuryl alcohol offer high anti-knocking activity (BRON above 100), and they may be applied as components of biofuels.

Effect of Support in NiO-Based Oxygen Transfer Materials for Sorption Enhanced Chemical Looping Methane Reforming: Characterization and Reactivity Studies

Keywords: NiO-based, OTMs, support, sorption enhanced, chemical looping methane reforming

1 Introduction

Sorption enhanced chemical looping steam methane reforming is an alternative method for efficient production of pure hydrogen, combining chemical looping reforming (CLR) with in-situ CO_2 capture [1]. In this process scheme, the reformer contains, in addition to the sorbent, an oxygen transfer material (OTM) that is reduced by methane into metallic form and serves as reforming catalyst. The reforming reaction proceeds under near autothermal conditions due to the highly exothermic sorbent carbonation. In a second step the saturated sorbent is regenerated, with energy supplied by exothermic OTM re-oxidation [2]. In order for the process to be viable, it is necessary to utilize OTMs which can be easily reduced and re-oxidized without losing their stability in consecutive redox cycles [3]. In this study, the effect of support (alumina, silica, zirconia, titania) on the reduction/oxidation activity and stability of NiO-based OTMs was investigated in multiple redox cycles in a TGA unit, and under both conventional and the CLR conditions at low temperature in a fixed-bed flow unit.

2 Experimental

Four NiO-based OTMs with 40wt% NiO loading were synthesized by wet impregnation using commercial supports: (SiO_2, TiO_2, Al_2O_3, ZrO_2). The materials were characterized by BET, XRD, TPR (Micromeritics Ins., AutoChem II 2920) and XPS (Kratos Analytical, Axis Ultra DLD). Reduction in methane at 650°C followed by air oxidation at 800°C was studied in the TGA (TA SDT Q600). Conventional reforming activity of the reduced OTMs was tested at 650°C in a bench scale fixed bed flow unit with a steam/methane (S/C) ratio of 3 and GHSV=$10^5 h^{-1}$. In the second step, NiO/ZrO_2, and NiO/Al_2O_3, which exhibited satisfactory reforming activity and stability, were tested under CLR conditions (in the absence of CO_2 sorbent). The materials were initially exposed to CH_4/steam in their oxidized state at 650°C for 1h (S/C=3). At the end of reforming stage, metallic Ni was reoxidized with air at 850°C for 15min and the cycle was then repeated.

3 Results and discussion

BET results showed that the surface area of the final OTM is greatly affected by the support source, with NiO/Al_2O_3 possessing the highest surface area (117.4 m^2/g) followed by NiO/SiO_2 (56.2 m^2/g), NiO/ZrO_2 (22.9 m^2/g) and NiO/TiO_2 (16.4 m^2/g). XRD confirmed the presence of NiO phase in all OTMs, together with the identifications of mixed $NiAl_2O_4$ and $NiTiO_3$ in Al_2O_3- and TiO_2- supported OTMs, indicating a strong interaction between NiO with the corresponding supports. TPR results showed that all OTMs had a high degree of reduction (around 80%) at temperatures lower than 650°C except NiO/Al_2O_3 where a high temperature TPR peak (~751°C) was attributed to reduction of $NiAl_2O_4$, and the degree of reduction up to 650°C was ~24%.

During reduction in CH_4 in TGA experiments, a sharp weight loss was initially observed due to reduction of NiO to metallic Ni, followed by weight gain due to carbon deposition resulting from CH_4 decomposition. Highest carbon formation was observed for Al_2O_3- followed by SiO_2, ZrO_2 and TiO_2-supported OTMs. NiO/ZrO_2 and NiO/SiO_2 exhibited very high reduction degrees (>94%) while NiO/Al_2O_3 and NiO/TiO_2 showed relatively lower reducibility mainly due to the strong metal-support interaction, as detected with XRD. In terms of products, low amounts of CO_2 and H_2O from CH_4 total oxidation by NiO were first detected, followed by higher concentrations of CO and H_2 from CH_4 partial oxidation and CH_4 decomposition reaction for all four OTMs. Switching to air resulted in removal of deposited carbon, as evidenced by weight decrease and CO_2 formation. After coke removal, weight increases and reaches its initial value for all four OTMs, signifying complete re-oxidation of NiO.

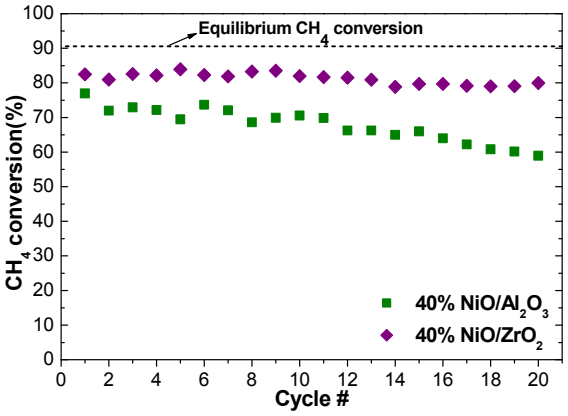

Fig. 1. Methane conversion in chemical looping reforming experiments for NiO/ZrO_2 and NiO/Al_2O_3

Experiments under conventional reforming conditions (with pre-reduced OTMs and steam in the feed) showed a satisfactory performance of NiO/Al_2O_3 and NiO/ZrO_2 at 650°C, with less than 8% deactivation after 10 h on stream. On the other hand, NiO/SiO_2 and NiO/TiO_2 were found to be inactive, with initial CH_4 conversion less than 12%. Characterization of used samples with TPO was performed to identify whether inactivity of the two latter OTMs was due to coke deposition. Carbon deposition was found to be very low and in the same range over all four supports, ruling out coke as the primary cause of deactivation. Preliminary XPS results of the used samples showed a significant amount of nickel in oxidized form over the two inactive catalysts. Further characterization is under way to confirm whether metallic Ni is easily reoxidized by steam during reforming conditions over titania and silica.

The two promising materials were then tested under CLR conditions, in the absence of CO_2 sorbent, for 20 consecutive redox cycles. Methane conversion as a function of cycles is shown in Figure 1. NiO/ZrO_2 exhibited good activity with initial CH_4 conversion around 80% and less than 2% deactivation after 20 redox cycles, corresponding to 20 hours exposure to CH_4/steam. On the contrary, NiO/Al_2O_3 even though exhibited a similar initial CH_4 conversion of 79%, deactivated quickly, leading to a CH_4 conversion of 59% in the 20th cycle. This loss of activity can be attributed to the lower hydrothermal stability of alumina compared to zirconia under steam reforming conditions.

4 Conclusions

The preliminary tests indicated that NiO/ZrO_2 is a promising OTM for sorption-enhanced chemical looping reforming, with high reforming activity and low deactivation during 20 redox cycles. The material is currently being tested with the addition of a stable synthesized CaO-ZrO_2 CO_2 sorbent to assess its full potential for the combined process.

Keywords: aqueous phase reforming, sustainable, fuel production, hydrogen, carbon-supported catalysts

1 Introduction

Fuel consumption is increasing nowadays, demanding a replacement for fossil fuels. New technologies should be developed to use renewables as an energy resource. Aqueous phase reforming (APR) allows conversion of alcohols and polyols obtained from biomass to hydrogen and hydrocarbons. This process is more energy-efficient for hydrogen production compared to steam reforming, since it is performed in the liquid phase and at lower temperatures (190-250°C) [1,2].

Traditional catalysts used for oil refining are not successful for conversion of biomass, because of low hydrothermal stability and fast deactivation [3]. Thus, new catalysts should be developed. Carbon support was shown to be exceptionally stable at the APR conditions [4,5]. Different noble and transition metals were tested in the APR process [6,7]. However, catalysts were mainly supported on γ-Al_2O_3, while the reaction pathways strongly depend on the type of the support [8,9]. Thus, additional metal screening is needed for carbon-supported catalysts.

2 Experimental

Activated carbon (AC), mesoporous carbon Sibunit and carbon nano-fibers (CNF) were used as supports for preparation of two sets of catalysts, one used for metal screening and the second for catalyst optimisation. The first set of monometallic Pt, Ni, Re, Ru and bimetallic Pt-Ni, Pt-Co, Pt-Re, Pt-Ru catalysts on Sibunit was prepared via incipient wetness impregnation with Cl-containing metal precursors. The second set was prepared via impregnation of Pt colloidal nano-particles and using the micro-emulsion method with AC, CNF and Sibunit. The catalysts were tested in the APR of xylitol in a continuous set-up at 225°C and 29.7 bar. Aqueous 10 wt % solution of xylitol was fed with a flow ranging from 0.1 to 1 ml/min. Gas-phase products were analyzed online by a micro-GC (Agilent Micro-GC 3000A). Liquid-phase products were analysed via HPLC (Agilent 1100) equipped with an Aminex HPX-87H column. Carbon balance was additionally monitored via total organic carbon analysis of liquid samples, being close to 90-95%.

3 Results and discussion

Metal screening was based on such parameters as activity and selectivity to hydrogen and alkanes. All monometallic catalysts showed significantly lower activity (Ni) or deactivated very fast (Ru, Re) compared to Pt. Activity of bimetallic Pt-Ni, Pt-Co and Pt-Ru catalysts was practically en par with the monometallic one. Pt-Re catalyst was two times more active than

others. However, addition of Re or Ru to Pt shifted the reaction pathways to formation of the alkanes. Thus, the selectivity to hydrogen was rather low with Pt-Re and Pt-Ru catalysts, compared to Pt, Pt-Co, Pt-Ni. Alkanes from C1 to C7 were produced, with the ratio between different alkanes dependent on the metal (Fig.1).

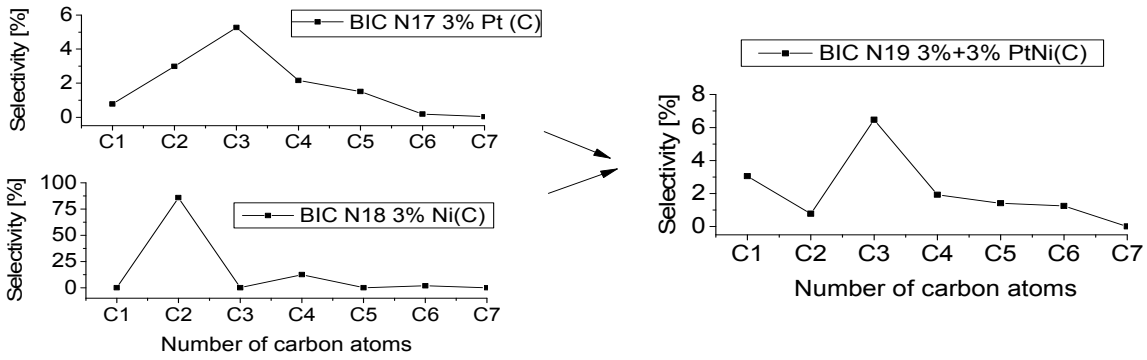

Fig. 1. Comparison of alkane distribution in APR of xylitol on Pt/C, Ni/C and bimetallic Pt-Ni/C catalysts at 225°C.

Catalysts prepared via colloidal impregnation or micro-emulsion method showed surprisingly low activity, probably due to an excess of a polymer covering catalytic sites, which leads also to leaching of Pt during long-term experiments (3-7 days).

4 Conclusions

Metal screening was performed for APR of xylitol on carbon-supported catalysts. Pt-Re was shown to be the most active and the most selective to alkanes, while monometallic Pt had the optimum combination of activity and selectivity to hydrogen among other catalysts. Alkane distribution was shown to be strongly dependent on the metal, which unravelled new insights into the reaction pathways. Stability issues were shown to be critical for the Pt catalysts prepared via impregnation of colloidal nano-particles and micro-emulsion technique.

Co-Conversion of Fatty Acids and Hydrocarbons in the Conditions of Catalytic Cracking

Lipin P.V.*, Potapenko O.V., Sorokina T.P., Doronin V.P.

Institute of Hydrocarbons Processing of Siberian Branch Russian Academy of Sciences, Omsk, Russia

* lipin@ihcp.ru

Keywords: fatty acid hydrocarbon, olefin, cracking, conversion, catalyst

1 Introduction

Effective way to identify patterns of transformation real bio raw material is study the behavior of the individual compounds under catalytic cracking. Conversion various model compounds of bio-oil in conditions of cracking investigated in the works [1-3]. The authors described the direction of transformations oxygenate hydrocarbons, belonging to different classes, the distribution of the group composition of products, as well as the influence of the conditions of cracking on yield products.

The present work was aimed at studying the transformation of model oxygenate compounds (fatty acids) and various hydrocarbons under catalytic cracking.

2 Experimental/methodology

In the work as model compounds were used oleic acid, stearic acid and hydrocarbons: cyclohexane, methylcyclohexane, decalin and tetralin. The model raw material consisted of pure hydrocarbons, or mixtures of fatty acids and hydrocarbons with a ratio components of 5/95 and 25/75 respectively.

The conversions of model mixtures were investigated on a commercial equilibrium cracking catalyst. The catalyst comprised the HREY form of Y zeolite and a matrix containing amorphous aluminosilicate, aluminum hydroxide and bentonite clay [4].

Catalytic testing was performed at a lab-scale unit with a fixed-bed catalyst in the temperature of 450ºC at a catalyst-to-oil mass ratio equal to 4.

3 Results and discussion

The study of transformation oleic acid with various hydrocarbons under cracking demonstrates that the fatty acid may have a promoting effect on the conversion of hydrocarbons, and can contribute to the suppression of cracking. At low concentration (5.0 wt.%) oleic acid in mixture change of conversion of cyclohexane, methylcyclohexane and decalin substantially not observed. However, at high concentration (25.0 wt.%) oleic acid in the mixture braking effect of cracking of hydrocarbon is observed. The growth of tetralin conversion occurs regardless of the content of oleic acid for a model mixture of tetralin-oleic acid.

The promoting effect of oleic acid is connected with deoxygenation reactions and formation high molecular olefins with one or two double bonds. Olefins readily form carbocations with acid sites of the catalyst, and further carbocations interact with corresponding hydrocarbons. However, high molecular olefins are rapidly adsorbed on the catalyst surface at transformation of model mixtures with cyclohexane and methylcyclohexane. As a result, this leads to the suppression of cracking of hydrocarbons at high content oleic acid in model mixture. The proof of this fact is high content of aromatic hydrocarbons in the liquid products and growth coke on the catalyst, as olefins with two or more double bonds in the cracking conditions to undergo cyclization followed by aromatization.

In the case of the conversion of a model mixture of tetralin-oleic acid enhanced the

competitive sorption between tetralin and high molecular olefins, thus there is no suppression of cracking of tetralin.

Researching transformation various hydrocarbon with stearic acid indicates that no promotional effect of acid depends on its content in model mixture. The greatest increase of conversion cyclohexane, methylcyclohexane and decalin is observed when content of acid in the model mixture of 5.0 wt.%. For model mixture tetralin-stearic acid the greatest conversion of tetralin observes at content of acid 25.0 wt. %. As in the case of oleic acid, the promoting effect of stearic acid explains deoxygenation reactions of acid and formation paraffins and olefins containing one double bond.

In the work also presents data on the patterns of joint transformations of fatty acids and the real feedstock – hydrotreated vacuum gas oil.

4 Conclusions

The study co-conversion oleic acid with various hydrocarbons demonstrates that the unsaturated fatty acid may provide both a promoting effect on the cracking of hydrocarbons and to suppress their transformation. At a high content (25 wt.%) of acid in the model mixture define that formed high molecular olefins with two double bonds rapidly adsorbed on acid sites, thus prevent adsorption of hydrocarbons on the catalyst surface. This eventually leads to the suppression of cracking of hydrocarbons.

Researches of transformation of model mixtures type hydrocarbon-stearic acid indicate that the mechanism promoting action of fatty acid on cracking of hydrocarbons is similar as in the case of oleic acid. However, at high content (25 wt.%) of stearic acid in model mixtures sharp reduction conversion of hydrocarbon not observed.

Comparison of the distribution products of cracking indicates that products of the model mixtures with stearic acid contain gases with high content of olefins, high yield of liquid products, with simultaneous reduction of the coke on the catalyst.

Keywords: macroporosity, alumina, sepiolite, heavy oils, hydrodesulfurization, hydrodemetallization

1 Introduction

Despite the evolution of alternative ways for motor oil production getting close attention for last decades crude oil production and upgrading still remains the one of the paramount practical importance on a global scale. Declining the quality of the feed oil causes enormous difficulties during the refinement due to the high content of sulfur, nitrogen, metals, asphaltens and high-boiling fractions. In heavy oil refining special attention must be given to these factors, therefore, the catalysts with the optimized texture and tuned acidic properties are required. In this paper in order to elucidate the role of these parameters we have investigated a set of CoMoNi hydrotreating catalysts: a pair of alumina-supported ones possessing a different texture with similar surface properties as well as sepiolite-supported ones having different phase composition.

2 Experimental

For the preparation of mesoporous alumina pseudobemite (Ltd. Promyshlennye katalizatory, Russia) was mixed with acidified water to produce a paste, then extruded into cylindric pellets and thermally treated. Macroporous alumina support Al_2O_3-T was prepared by the same technique with the use of polystyrene (PS) microbeads (diameter ~ 250 nm) as templates. Natural sepiolite-like mineral (Ltd. Anekst, Russia) was treated with orthophosphoric acid to adjust surface properties, extruded and calcined as well.

CoMo(Ni) supported catalysts were obtained by the incipient wetness impregnation with citric complex of Mo, Co and Ni, as described in paper [1]. For the proper control the catalysts were studied by XRD, XFS, SEM, TEM, mercury porosimetry and N_2 low-temperature adsorption methods.

Crude Tatar Oil having extremely high viscosity (360 sSt at 25°C) and sulfur content (3.4 wt.%) has been chosen as a heavy feedstock for hydrotreating experiments. Catalytic tests were carried out using a lab scale Berty reactor as described in paper [1]. Hydroprocessing parametres were as follows: T = 420 °C, P = 15 MPa, feed to H_2 volume ratio 1000, liquid hourly space velocity LHSV 1 h^{-1}, catalyst residence time under constant conditions – not less than 120 h.

3 Results and discussion

For the proper control of the texture parameters in a wide range of pore sizes all the supports and catalysts were investigated by nitrogen adsorption and Hg porosimetry (Fig.1 a). The alumina sample produced with the use of PS template showed a bimodal pore size distribution with the maximums at 12 and 113 nm referred to meso- and macropores respectively, while the reference sample represented only the mesoporous structure. According to Hg porosimetry data, introducing the PS template allowed the pore volume to increase by 2.5

times from 0.34 to 0.84 cm^3/g and the specific surface area by 20% from 168 to 194 m^2/g, with BET characteristics being almost unchanged. The sepiolite-based supports had the relatively low specific surface area in the range of 34-22 m^2/g and the high pore volume of 0.59-0.63 cm^3/g. A broaden pore size distribution in the range of 20-400 nm was observed (Fig. 1a). Enlarging the phosphorus content led to the declining of the specific surface area and the significant increasing of the pore volume.

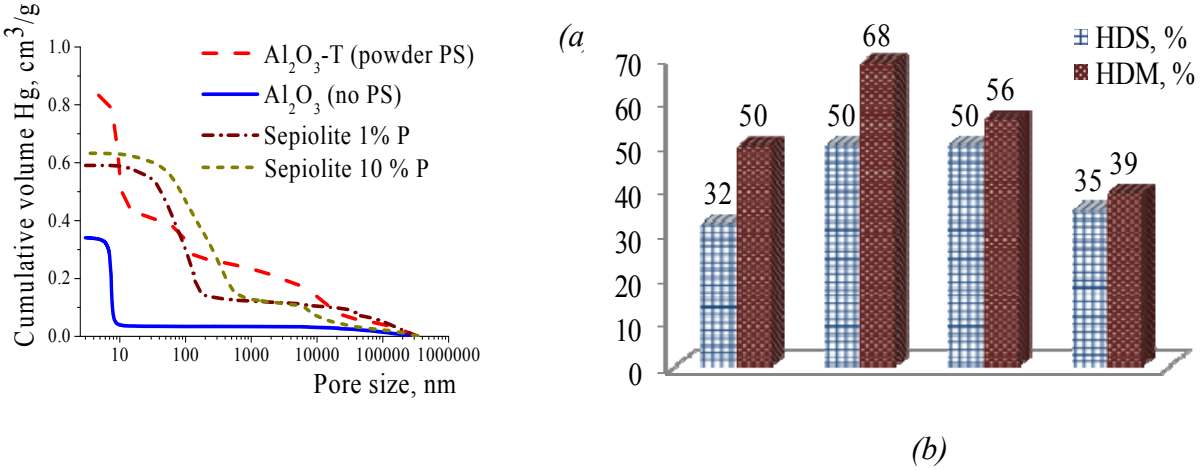

Fig. 1. (a) Mercury porosimetry data for the supports used and (b) HDS and HDM activity of the catalysts in tatar oil hydrotreating.

According to XRD data both alumina samples represented by a mixture of γ- and δ-modifications while the sepiolite-like samples had a complex multiphase composition comprised of MgO (40 wt.%) and calcium/magnesium silicates (60 wt.%) in case of Sepiolite1%P and calcium/magnesium phosphates (90 wt.%) in case of Sepiolite10%P.

The catalytic activity of the samples in tatar oil hydrotreating is evidently shown on Fig.1 b. Macro/mesoporous CoMoNi/Al_2O_3-T and CoMoNi/Sepiolite1%P performed the highest HDS and HDM efficiency among other samples, assuming the optimized texture properties make a significant contribution to the apparent activity. However, surface properties must be necessarily taken into consideration too: CoMoNi/Sep10%P despite its macroporous texture performed an unexpectedly low HDM activity (39 %) that can be accounted for the lower affinity of V-containing compounds to the phosphate surface (Fig. 1 b).

4 Conclusions

The optimized macro/mesoporous texture of the alumina support was shown to significantly affect HDS and HDM activity of the catalyst in heavy oil hydrotreating. The sepiolite-supported catalysts were found to be prospective as well due to their similar catalytic activity and basic surface properties being favourable for an enhanced catalyst lifetime. We suppose these investigations to aid in working out an effective catalyst with a high stability and an increased conversion of high molecular substrates under the heavy oil hydrotreating conditions.

The Role of Carrier's Carbonization Degree on the HDO Conversion of the Oleic Acid over the CoMo/C/Al_2O_3 Catalysts

Varakin A., Salnikov V., Nikulshin P.*

Samara State Technical University, Samara, Russia

* p.a.nikulshin@gmail.com

Keywords: hydrodeoxygenation, oleic acid, heteropolyanion, carbon-covered, alumina, CoMoS

1 Introduction

The oleic acid as a model compound for a component of plant oil is the most using to modeling the hydrodeoxygenation (HDO) of renewable feedstocks. The conversion of this bio-feedstock into hydrocarbons usually carried out on hydrotreating (HDT) catalysts like supported Co(Ni)MoS sulfides. The type of support has a significant impact on the morphology and composition of the active phase, and as a result on its activity and stability. The most commonly used support for HDT catalysts is alumina due to its high surface area, thermal stability, physical strength, and recoverability. But despite of all this advantages, acid and base sites on the surface of alumina may influence on properties and form of precursors, impede the sulfidation of metal oxide, and induce the rapid deactivation of the catalysts by coke formation in HDT process. The using of carbon supports with low acidity allows to achieve the well dispersed active sulfide phase and higher activity in HDT than alumina supported ones. However, carbon supports has some disadvantages that limiting their use in industry such as low thermal stability and fragility.

The interesting way to combine advantages of alumina and carbon supports is the use of carbon coated alumina [1,2]. This modification allows to decrease the interaction between the active sulphide phase and support surface, and as a result increasing the amount of so-called CoMoS-II phase (or NiMoS-II) and catalytic performance. The objective of the work was investigation of the role of Al_2O_3 carbonization on the HDO conversion of the oleic acid over the CoMoS/C//Al_2O_3 catalysts.

2 Experimental

Carbon coated carriers C_x/γ-Al_2O_3 (x = 0, 2 or 6 wt. %) were prepared by the pyrolysis of ethylene glycol and citric acid mixtures on γ-Al_2O_3 at 600 °C in N_2 flow. Carbon content was varied by changing the content of organic compounds and controlled by the DTA-TGA method.

The catalysts were prepared by conventional incipient wetness impregnation method on C_x/γ-Al_2O_3 with an appropriate aqueous solution of 12-molybdophosphoric heteropolyacid and cobalt citrate in order to obtain about 13.0 wt. % of molybdenum and 4.0 wt. % of cobalt. After impregnation the solids were dried at 80, 100, 120 °C for 2 h. Before each catalytic experiment, the catalysts were sulfided *in situ* by a mixture of dimethyldisulphide in toluene (sulfur content 6% wt.) at hydrogen pressure of 3.0 MPa and 340 °C for 24 h.

The textural characteristics of the catalysts were determined using N_2 adsorption at 77 K on a Quantochrome Autosorb-1. The HRTEM images of the active phase species were obtained on a Tecnai G2 20 electron microscope. The sulphided catalyst samples were analysed by XPS using a Kratos Axis Ultra DLD spectrometer.

Catalytic tests were performed in a bench-scale flow reactor in oleic acid (5 wt. % in toluene) HDO at 260 °C, H_2 pressure of 3.0 MPa, LHVS of 80 h^{-1}, and H_2/feed of 500 nL/L.

3 Results and discussion

The results of catalytic tests in oleic acid HDO are given in Table 1.

Table 1. Catalytic properties of $CoMo/C_x/Al_2O_3$ catalysts in oleic acid HDO

Catalyst	Conversion (%)		Rate constants × 10^4 (s^{-1})		TOF_{HDO} × 10^3 (s^{-1})	$E_A^{\#}$ (kJ·mol^{-1})
	x_{OA}	x_{HDO}	k_{OA}	k_{HDO}		
$CoMo/Al_2O_3$	41	33	10.1	7.8	7.2	65
$CoMo/C_2/Al_2O_3$	57	53	16.2	14.6	8.4	66
$CoMo/C_6/Al_2O_3$	43	41	10.8	10.1	5.7	64

Activity of the catalysts is essentially dependent on the carbon content in the support. The higher carbon content led to the higher stacking number of the CoMoS slabs. Dependence of the slab length on carbon content passed through the minimum at 2 wt. % of carbon. The $CoMo/C_2/Al_2O_3$ catalyst was the most active and has the higher C_{18}/C_{17} selectivity in all range of tested temperature (Fig. 1). Black bold curves on Fig. 2 correspond to the apparent dependence of k_{HDO} on Co content in CoMoS phase C_{CoMoS} and average particle length values; dotted lines correspond to possible correlations of k_{HDO} on C_{CoMoS} or on l.

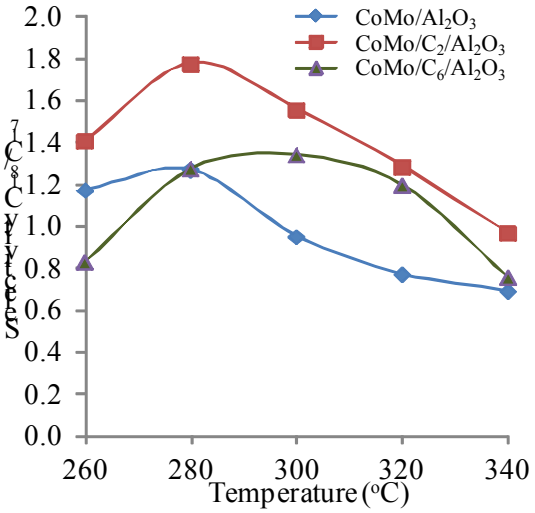

Fig. 1. The influence of process temperature on C_{18}/C_{17} ratio in oleic acid HDO

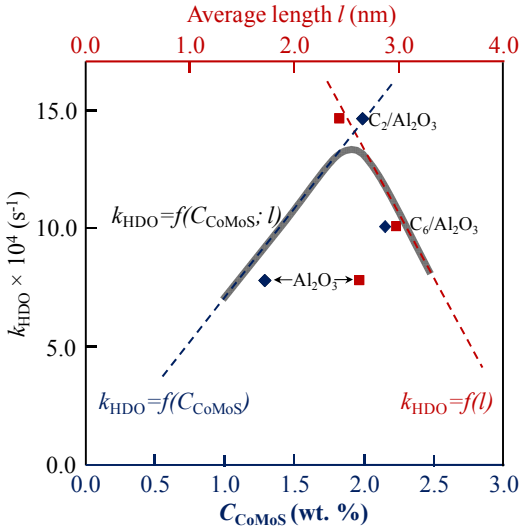

Fig. 2. Rate constants k_{HDO} correlated with cobalt content in CoMoS phase C_{CoMoS} (♦) and its average length l (■).

As a result, the $CoMo/C_2/Al_2O_3$ catalyst has optimal values of cobalt content in CoMoS phase particles and average particle length values for the highest rate constant.

4 Conclusions

The results showed that changing the carbon content it is possible to vary a stacking number/linear size ratio of the active phase particles and, thereby, to control HDO of oleic acid and C_{18}/C_{17} selectivity. $CoMo/C_2/Al_2O_3$ catalyst had optimal characteristics of active phase and highest activity and stability.

The Influence of Membrane Reactor Parameters on Efficiency of Hydrocarbons Dehydrogenation Process

Shelepova E.[1*], Vedyagin A.[1], Mishakov I.[1,2], Noskov A.[1,2]

1 - Boreskov Institute of Catalysis, Department of catalytic process engineering, Novosibirsk, Russia

* shev@catalysis.ru

Keywords: hydrocarbons dehydrogenation, catalytic membrane reactor, mathematical, modelling

1 Introduction

Dehydrogenation of saturated hydrocarbons is known to be the key route to yield the monomers despite on having the strong endothermic and equilibrium limitations. The oxidative dehydrogenation (ODH) is free of latter restrictions but characterized with low product selectivity. The use of the catalytic membrane reactor (CMR) with additional hydrogen oxidation permits one to combine the advantages of conventional dehydrogenation and oxidative dehydrogenation processes. In this case the endothermic and exothermic processes are supposed to take place within the different compartments of the membrane reactor (so called thermodynamically "conjugated" reactions). The impact of membrane reactor parameters on performance of dehydrogenation processes has been theoretically investigated and compared with the tubular reactor.

2 Experimental/methodology

In our research the dehydrogenation processes of ethane, propane and ethylbenzene were considered.

Ethane dehydrogenation reaction $C_2H_6 \leftrightarrow C_2H_4 + H_2$ appears to be the most strictly limited by the thermodynamics. In addition, an intensive coke formation taking place over the catalyst's surface at high temperature is worth to be noted as the main disadvantage of this process.

As in latter case, the process of propane dehydrogenation also has the similar endothermic and equilibrium limitations. This process is characterized by side products occurrence.

$$C_3H_8 \leftrightarrow C_3H_6 + H_2$$
$$C_3H_8 \leftrightarrow C_2H_4 + CH_4$$
$$C_2H_4 + H_2 \leftrightarrow C_2H_6$$

Ethylbenzene dehydrogenation is characterized by even higher number of side products, especially in case of gas mixture diluted by water vapors:

$$C_6H_5CH_2CH_3 \leftrightarrow C_6H_5CHCH_2 + H_2$$
$$C_6H_5CH_2CH_3 \rightarrow C_6H_6 + C_2H_4$$
$$C_6H_5CH_2CH_3 + H_2 \rightarrow C_6H_5CH_3 + CH_4$$
$$C_2H_4 + 2H_2O \rightarrow 2CO + 4H_2$$
$$CH_4 + H_2O \rightarrow CO + 3H_2$$
$$CO + H_2O \rightarrow CO_2 + H_2$$

The efficiency of the above mentioned dehydrogenation processes has been analyzed for the case of membrane reactor including the conjugation with hydrogen oxidation reaction.

The theoretical study was implemented by means of mathematical modeling. The membrane reactor consists of two concentric tubes, where the interior ceramic tube with catalyst bed is placed in the exterior one. The membrane is deposited as a continuous layer on the outer surface of ceramic tube. The dehydrogenation reaction is carried out over the catalyst in the tube side. Hydrogen permeates from the tube compartment of the reactor through the membrane inside the

shell compartment to be further oxidized with dioxygen. The two-dimensional type of non-isothermal stationary mathematical model of the catalytic membrane reactor for the "conjugated" dehydrogenation process has been developed. The balance equations represent a system of differential equations in partial derivatives, which were treated numerically by the method of lines and the appropriate method for ODE solving.

The dehydrogenation process was simulated at different dilutions of gas mixtures. The inlet concentration of ethane and propane in the inert gas was 10% while that of ethylbenzene was selected as 30%.

To achieve reasonable values of hydrocarbons conversion in tubular reactor one should keep the reaction temperature as high as 700°C (Fig.1). Within the high temperature region the contribution of side reaction leading to undesired products increases significantly. Selective hydrogen removal in the membrane reactor results in shifting the reaction equilibrium thus enhancing the products selectivity at lower temperatures.

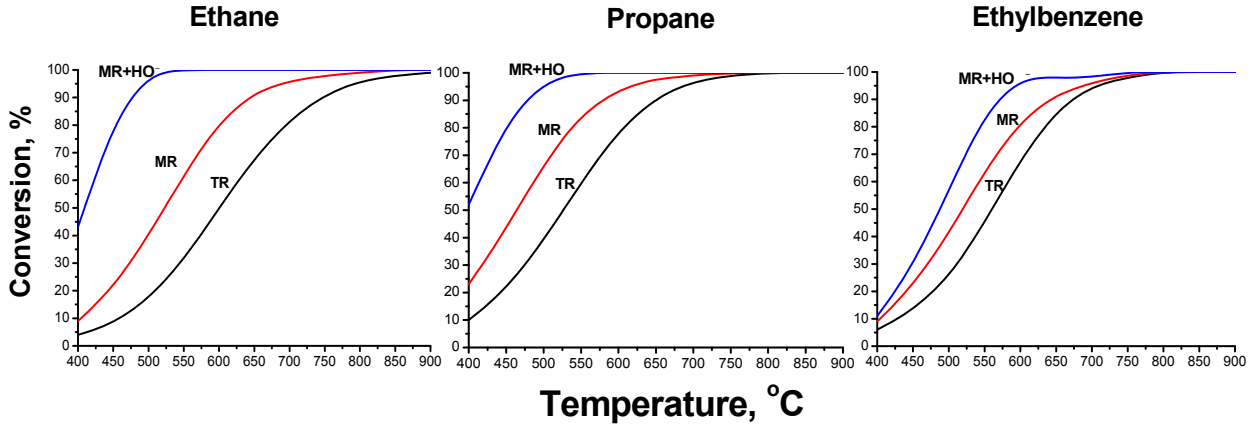

Fig. 1. Temperature dependences for ethane, propane and ethylbenzene conversions in membrane reactor (MR), tubular reactor (TR) and membrane reactor combined with hydrogen oxidation (MR+HO).

The use of the membrane reactor combined with hydrogen oxidation was found to be the most effective way to produce olefins via dehydrogenation process. Carrying out the dehydrogenation process in conjugated membrane reactor enables attainment of very high hydrocarbon conversions (98-100%) at considerably lower temperatures (500°C for ethane, 550°C for propane, and 600°C for ethylbenzene). Thus, the additional oxidation makes it possible to decrease the process temperature by 200°C for ethane and by 100°C in case of propane and ethylbenzene. Using the membrane reactor permits one to increase the conversion value by the selective hydrogen removal from the reaction zone and to shift the equilibrium towards the products.

3 Conclusions

It has been shown that the "conjugated" reaction in the membrane reactor is to be the most appropriate choice for embodiment of hydrocarbons dehydrogenation processes. The process of conjugated dehydrogenation could be realized at significantly lower temperatures as compared with conventional dehydrogenation and dehydrogenation in membrane reactor.

Keywords: self-oscillations, methane oxidation, Pd catalysts

1 Introduction

Pd catalysts are widely applied for total methane oxidation. It is known [1,2] that self-oscillations of methane oxidation rate can appear over Pd catalysts in gas mixtures with relatively high methane content, which is undesirable for practice. Earlier we have studied a mechanism of self-oscillatory methane oxidation over Pd foil and powder [3-5] using thermogravimetry and mass-spectrometry. It was shown that during the oscillations periodic oxidation-reduction of Pd takes place as well as carbon accumulation-removal in PdC_x form. Mathematical model explaining the existence of methane oxidation oscillations over Pd was proposed in paper [5]. Authors of [6] have studied oscillations of methane oxidation over Pd/Al_2O_3 using QEXAFS method and confirmed main results obtained for Pd powder. However, some significant questions such as an effect of Pd particle size on oscillation parameters and temperature range of oscillations, quantitative relationship between Pd oxidation state and catalytic activity during the oscillation cycle were still unstudied. This work is addressed to clarify these aspects.

2 Experimental/methodology

Catalysts were prepared by impregnation of γ-Al_2O_3 and α-Al_2O_3 with palladium nitrate solution at different pH to obtain Pd particles of different sizes. Pd particle size was determined by TEM. Two 1%Pd/γ-Al_2O_3 catalysts had average Pd particle sizes of 5 and 16 nm (1Pd/Al-5 and 1Pd/Al-16 later). 5%Pd/α-Al_2O_3 catalyst (5Pd/Al later) contained larger agglomerates of Pd particles with diameter of 50-60 nm and smaller Pd particles of 2-7 nm, i.e. it had bimodal particle size distribution.

Catalytic experiments were carried out in a tubular quartz flow reactor. Both reactor and catalyst temperatures were measured by thermocouples. Methane-rich mixture 41.5% CH_4, 7.5% O_2, 2% Ar, 49% He was pre-mixed for all catalytic experiments.

Thermogravimetric analysis (TGA) was performed on Setaram SETSYS EVOLUTION 16/18 instrument coupled with Pfeiffer OmniStar GSD 301 quadrupole mass-spectrometer.

3 Results and discussion

Temperature ranges of self-oscillations were studied in the tubular reactor. Oscillations of methane oxidation were observed at following temperature ranges: 345-355°C (1Pd/Al-5), 320-350°C (1Pd/Al-16), 300-360°C (5Pd/Al), i.e. decreasing of Pd particle size results in shortening of temperature range of the oscillations. An increase of oscillation period as well as significant change of oscillation waveforms were also found.

Fig.1 shows oscillations of Pd catalyst weight and O_2, H_2O and CO_2 pressures in gas phase during methane oxidation over 5Pd/Al catalyst at 360°C in thermogravimetric setup. The oscillation cycle consists of two intervals (***a-b*** and ***b-a***). To recognize the nature of the weight

oscillations the reaction process was interrupted in C, B or D points, gas phase was pumped off and the catalyst was cooled down to 30°C. Then the catalyst was heated in CO-He mixture to measure a weight drop due to PdO reduction. The results obtained allowed to conclude that the weight increase during ***b-a*** interval was caused by Pd oxidation. This Pd oxidation accompanies with an increase of methane oxidation rate. In ***a-b*** interval Pd particles are reduced and partly carbonized, and demonstrate the highest catalytic activity. Minimum catalytic activity near ***b*** point in Fig.1 corresponds to metallic Pd having chemisorbed oxygen.

Fig.2 shows a relationship between CO_2 evolution rate and Pd oxidation degree (x of PdO_x) calculated using the gravimetric results. Catalytic activity of Pd is maximum at x=0. It drops to minimum and gradually increases with x rise from 0 to 0.3.

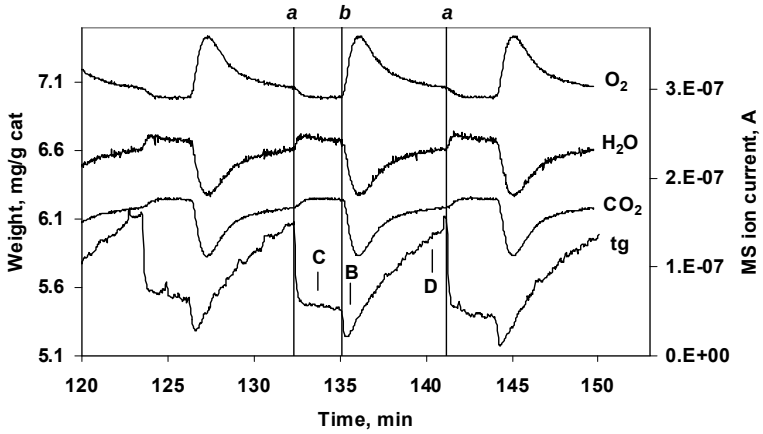

Fig.1 Oscillations over 5Pd/Al at 360°C

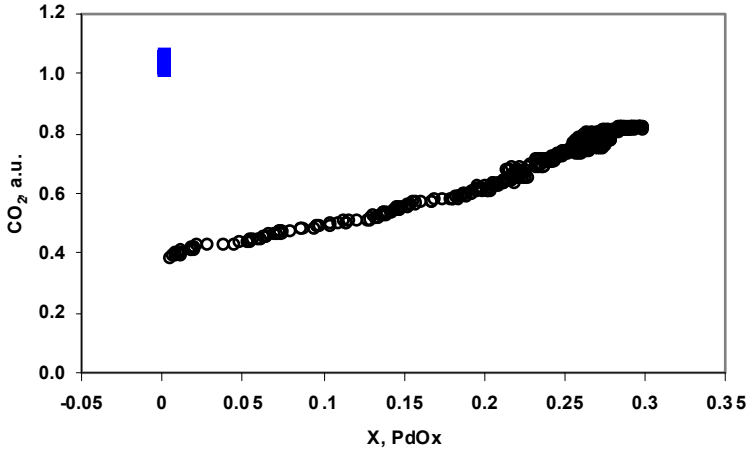

Fig.2 Effect of Pd oxidation degree on CO_2 evolution rate

Temperature hysteresis of methane oxidation rate and Pd state (Pd catalyst weight) was also studied over the Pd catalysts. The variation of Pd particle size was found to shift the temperature hysteresis interval. The nature of this phenomenon and its interconnection with the self-oscillations phenomenon are discussed.

Keywords: lanthanum oxycarbonate, lanthanum oxide, structure sensitivity, morphology effect, oxidative coupling of methane, low temperature

1 Introduction

The catalytic properties (activity and selectivity) of the solid particles could be intimately linked with the exposed crystallographic facets. For instance, the formation rate of ammonia from N_2 and H_2 on Fe crystal decreases according to the order (111) >> (100) > (110); MoO_3 shows catalytic anisotropy during propylene oxidation, with greater acrolein selectivity for the (100) plane and complete oxidation to CO_2 on the (010) facets. However, there have been rare reports upon the correlation of the catalysts for oxidative coupling of methane (OCM) with the crystallographic facets of the catalysts so far, since OCM reaction generally occurs at high temperature, and the catalysts (metal oxides) can be prepared through the calcination of metal hydroxide at high temperature that leads to the formation of sphere-shaped particles. It is found, recently, that catalysts (metal oxides) at a nanometer activate methane at lower temperatures, so it is possible that well-defined catalysts at a nanometer can be prepared via calcination at low temperatures and then used for OCM.

In the present work, we focus on the synthesis of $La_2O_2CO_3$ and La_2O_3 with a well-defined nanostructure, and explore the effects of exposed crystallographic facets or morphologies of the catalysts on the catalytic performances for OCM.

2 Experimental/methodology

Two types of $La_2O_2CO_3$ and La_2O_3 samples were synthesized.

$La_2O_2CO_3$-H: the precipitate $La(OH)_3$ obtained from the solution of $La(NO_3)_3$ was treated through a hydrothermal process, followed by desiccation and calcination in air at 500ºC.

$La_2O_2CO_3$-P: the precipitate $La(OH)_3$ was directly dried, and then calcined in air at 500ºC.

As a comparison, the referenced $La_2O_2CO_3$-H_{ref} was synthesized by a hydrothermal method too, based on the procedures reported by Shen[1].

If the $La(OH)_3$ samples are calcined in air at 700ºC, the samples are changed into La_2O_3. The related La_2O_3 samples are denoted as La_2O_3-H, La_2O_3-P and La_2O_3-H_{ref}.

The characterizations such as XRD, S(T)EM, and O_2(CO_2)-TPD were used to measure the physicochemical properties of the samples, and then the insight to the correlation of their catalytic performances in OCM with their surface structures can be given. The catalytic performances of these samples for OCM were tested at conditions: $m_{catalysts}$ = 100 mg, CH_4/O_2 = 3/1(molar ratio), GHSV = 30,000 $mL \cdot g^{-1} \cdot h^{-1}$.

3 Results and discussion

By SEM and XRD, we find that $La_2O_2CO_3$-H and $La_2O_2CO_3$-P are rod- and plate-like nanoparticles with diameters of ~20 nm, respectively. The former with the specific surface area

of ~70 $m^2 \cdot g^{-1}$ exhibits ~30% conversation of methane and ~50% C2 selectivity for OCM at 420°C, higher than the latter with the specific surface area of ~10 $m^2 \cdot g^{-1}$ (~27% conversion of methane, ~30% C2 selectivity at 500°C), displaying a shape effect of the catalysts for OCM.

For comparison of both the rod-like $La_2O_2CO_3$-H and $La_2O_2CO_3$-H_{ref} samples with almost the same specific surface area, we note that $La_2O_2CO_3$-H shows 20 times higher specific activity than $La_2O_2CO_3$-H_{ref}, which is corresponding to their O_2-TPD results. $La_2O_2CO_3$-H shows large oxygen storage capacity (OSC), in contrast, $La_2O_2CO_3$-H_{ref} almost does not adsorb any oxygen.

The further analysis illustrate that the exposed crystallographic facets of $La_2O_2CO_3$-H are significantly different from $La_2O_2CO_3$-H_{ref} (Fig. 1). For example, there are higher ratios of exposed facets with loose structures (e.g. $(1\bar{2}0)$ and $(2\bar{1}0)$) for $La_2O_2CO_3$-H than $La_2O_2CO_3$-H_{ref}, which are responsible for the difference between their catalytic performances in OCM.

Moreover, we find that the rod-like La_2O_3-H and La_2O_3-H_{ref} demonstrate similar structure sensitivity as $La_2O_2CO_3$-H for OCM. The rod-like La_2O_3-H (or -H_{ref}) has the same exposed facets as $La_2O_2CO_3$-H (or -H_{ref}), indicating that the morphologies of La_2O_3 from the decomposition of $La_2O_2CO_3$ are well kept. However, the catalytic performances (including stability) over La_2O_3 for OCM are inferior to $La_2O_2CO_3$. La_2O_3 can capture CO_2 in OCM and partially changed into carbonates, but $La_2O_2CO_3$ are stable through OCM for the tested 50 hrs.

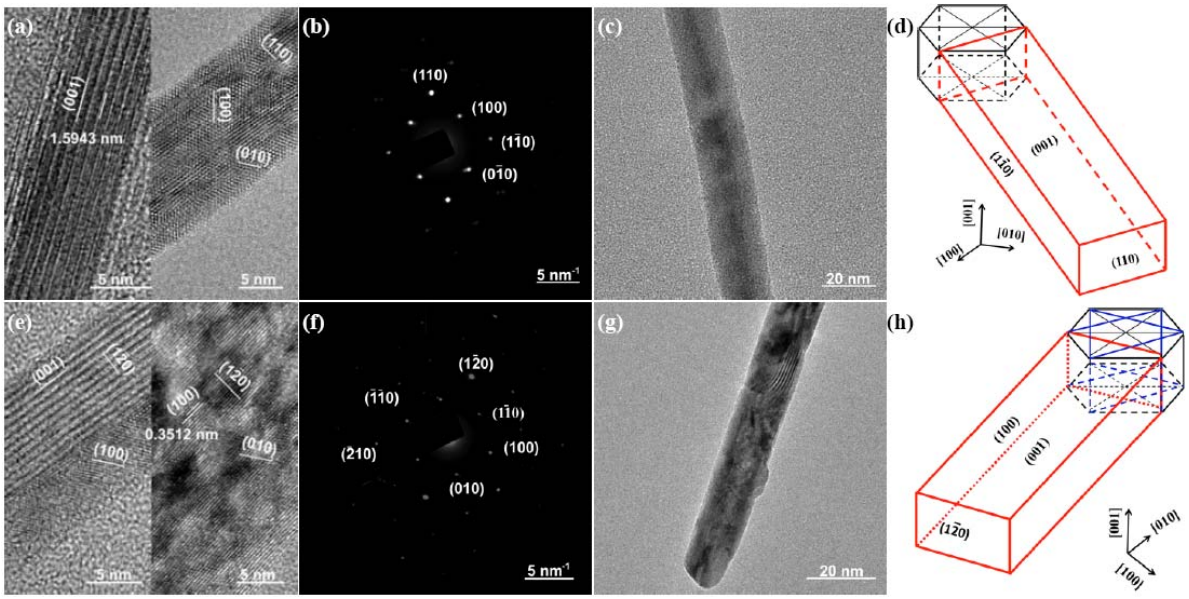

Fig. 1. HRTEM, TEM images, the selected area electron diffraction (SAED) patterns and the illustration of real shape of $La_2O_2CO_3$-H_{ref} (a-d) and $La_2O_2CO_3$-H (e-h).

4 Conclusions

The synthesized $La_2O_2CO_3$ and La_2O_3 samples for OCM exhibit significant shape effects and structure sensitivity. The catalytic performances of the rod-like sample are superior to the plate-like one, especially at low temperature (500°C below). The exposed facets with loose structure can enlarge OSC of the samples, and then enhance their activity in OCM. In addition, $La_2O_2CO_3$ is superior to La_2O_3 for OCM, and obviously more stable than La_2O_3.

Mechanism of Hydrogen Transfer Reaction from Naphthenes to 1-Hexene on Y and ZSM-5 Zeolites

Potapenko O.V.*, Doronin V.P., Sorokina T.P., Krol O.V., Likholobov V.A.

Institute of hydrocarbons processing of Siberian branch of Russian academy of sciences, Omsk, Russia

Keywords: hydrogen transfer, zeolite, deuterium, olefin, naphthene

1 Introduction

Intermolecular hydrogen transfer reactions are important in the transformation of hydrocarbons in catalytic cracking, alkylation and isomerization processes. Especially developed in our organization catalytic refining process should be noted in this context [1, 2]. To determine the mechanism of hydrogen transfer from naphthene (hydrogen donor) to 1-hexene (hydrogen acceptor) transformations of mixtures containing deuterated hydrocarbons on Y and ZSM-5 zeolites were investigated.

2 Experimental

Catalytic tests were performed on lab-scale unit with fixed bed catalyst at temperatures of 350 – 550ºC, weight catalyst to hydrocarbon ratio of 1 – 5, WHSV – 10 h^{-1}. In experiments Y-type zeolites in H- and HRE-forms and zeolite ZSM-5 in the H-form were used. The feedstock was represented by mixtures of model hydrocarbons: 1-hexene, cyclohexane, methylcyclohexane. Cyclohexane-d_{12} and methylcyclohexane-d_{14} were used as deuterated compounds.

The composition of gaseous and liquid cracking products was analyzed by gas chromatography. Additionally analysis of liquid products was made on a chromato-mass spectrometer 6890/5973N (Agilent Technologies). Analysis of quantitative content of deuterium in products was performed on isotope chromato-mass spectrometer DELTA V Advantage.

3 Results and discussion

In the conversion of mixture “naphthene - hexene-1” products of hydrogen transfer reaction (Olefine + Naphtene = Parfine + Arene) may be divided into direct and apparent. Direct products are hexanes with normal and isomeric structure. Apparent are other paraffins, such as butane. Apparent products formed when a cracking reaction occur before hydrogen transfer reaction. In the presence of a hydrogen donor (source of hydride ions), and a catalyst with high activity in hydrogen transfer reactions, saturated hydrocarbons formed (hexanes, butanes), otherwise unsaturated compound formed (hexenes, butylene). Ratio of selectivity of formation saturated and unsaturated compounds with the same number of carbon atoms, for example, butanes and butenes (hydrogen transfer coefficient) [3] characterizes degree of hydrogen transfer reactions.

HREY zeolite providing bimolecular hydrogen transfer reactions has a maximal effect on the selectivity of hydrogen transfer from naphthene to olefin. The high activity of Y zeolite as compared with zeolite ZSM-5 related with a high concentration of acid sites and the absence of steric constraints for the occurrence of bimolecular reactions. HZSM-5 zeolite has a pore structure with narrow channels, which restricts the occurrence of bimolecular reactions and leads to an increase in the selectivity of the cracking reactions.

The transformation of model mixtures containing deuterated cyclohexane on zeolites Y and ZSM-5 have revealed significant differences in product composition (table 1).

Table 1. Transformation of mixture cyclohexane – 1-hexene on different type zeolites (456ºC, catalyst to hydrocarbon ratio – 3. WHSV – 10 h^{-1})

Zeolite type	HREY	HZSM-5
Naphthene conversion. % wt.	72.2	99.1
Gaseous product selectivity. %	37.1	60.5
Liquid product selectivity (w/o cyclohexane). %	37.4	28.1
Hydrogen transfer coefficient	25.3	14.5
Deuterium transfer coefficient	45.9	12.9
Arenes C_7-C_9 selectivity. %	11.4	23.1

The use of zeolite HREY as catalyst characterized by large values of hydrogen transfer coefficient (HTC) and deuterium transfer coefficient (DTC) compared to zeolite HZSM-5. In the case of HREY value DTC exceed HTC, in the case of HZSM-5 conversely. The predominance of deuterium in unsaturated compounds at transformation of mixture on HZSM-5 also point to occurrence of direct monomolecular cracking of naphthene (deuterated cyclohexane). HZSM-5 also catalyzed direct aromatization of initial hydrocarbons or intermediates – olefins and cycloolefins. It leads to increase in selectivity of the formation of aromatic compounds.

4 Conclusions

The reaction product composition is characterized by the occurrence of two competing reactions – cracking and hydrogen transfer. Cracking reactions occur predominantly at monomolecular mechanism on HZSM-5 zeolite. Bimolecular hydrogen transfer reaction from naphthene to olefin catalyzed by large pore zeolite HREY. Intermediates obtained on HZSM-5 zeolite can act as feedstock for bimolecular hydrogen transfer reactions on HREY. The mechanism of hydrogen transfer from deuterated naphthene to olefin suggests four steps: 1) activation of the olefin molecule on Brensted acid sites and carbocation formation, 2) reacting of the carbocation (on surface) with a hydrogen (deuterium) donor molecule (hydride-ion transfer step), 3) desorption of paraffin with a single deuterium atom and formation surface carbocation (from hydrogen donor molecule), 4) decomposition of the carbocation with restoration of active site.

Micro-kinetic Model of Dry Reforming of Methane on Doped Pyrochlore Catalysts

Polo-Garzon F., Bruce D.A.*

Department of Chemical and Biomolecular Engineering, Clemson University, USA

* DBRUCE@clemson.edu

Keywords: syngas, pyrochlore, DFT, micro-kinetic model, reaction mechanism, dry reforming of methane

1 Introduction

The dry reforming of methane (DRM) using CO_2 has long been considered a viable method for converting methane from geological or biological sources into syngas, which can then be readily used in the production of a variety of chemicals and particularly liquid fuels. Though DRM holds great promise, the high temperatures required for the reaction have made it very difficult to find catalysts that exhibit high activity for extended periods. [1]

Pyrochlores are crystalline oxides having high thermal stability and a general formula of $A_2B_2O_7$, where *A* represents a rare-earth metal and *B* represents a transition metal. Initial experimental efforts by others showed that pyrochlores are active for DRM but the tested catalysts exhibited poor long term stability [2]; however, more recent data suggest that this trend in deactivation may not be applicable to all pyrochlores. $La_2Zr_2O_7$ (LZ) is a pyrochlore structure which has shown good long term stability, so that efforts have been made to tailor its catalytic properties, showing Rh as a promising dopant to enhance catalytic performance for DRM [3, 4]. We employed Density Functional Theory (DFT) to calculate the activation barriers for elementary reaction steps on the plane (011) and (111), concluding that the plane (111) is the catalytically active for DRM. A micro-kinetic model (MKM) is built and its predictions match experimental data which strengthens the hypothesis that the CHO dehydrogenation step is the rate determining step (RDS). This later deduced qualitatively from the activation barriers alone.

2 Experimental/methodology

Computational: First principles calculations were performed employing the Vienna *ab initio* simulation package (VASP), which is based on a plane-wave DFT code. The exchange correlation functional used is the generalized gradient approximation using the implementation of Perdew, Burke and Ernzerhof (GGA-PBE). Activation energies were calculated for selected elementary reactions using the climbing image nudged elastic band method (CI-NEB) and the remaining activation energies were estimated by a Bronsted-Evans-Polanyi (BEP) relation derived from our DFT data. The open source code SUNDIALS was modified to create the MKM for a batch reactor. The model outputs the time evolution of the partial pressure of gas phase species and the time evolution of the adsorbates coverage

Experimental: The catalyst synthesis is performed using the modified Pechini method. The metal precursors (for La, Zr, Rh) were the corresponding nitrates. After the appropriate heat treatment is carried out on the material, characterization is performed by means of XRD, SEM and EDX.

1 Results and discussion

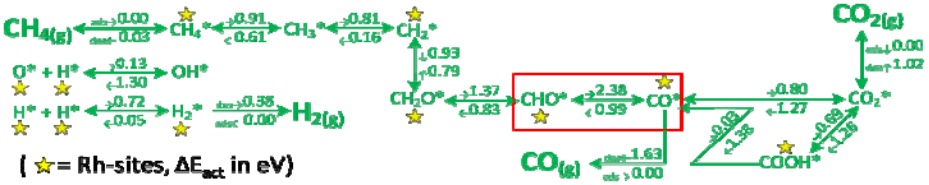

Fig. 2 Main reaction pathway on plane (111) for the 2 wt% Rh-substituted LZ. The values above, below and next to the arrows are activation energies in eV.

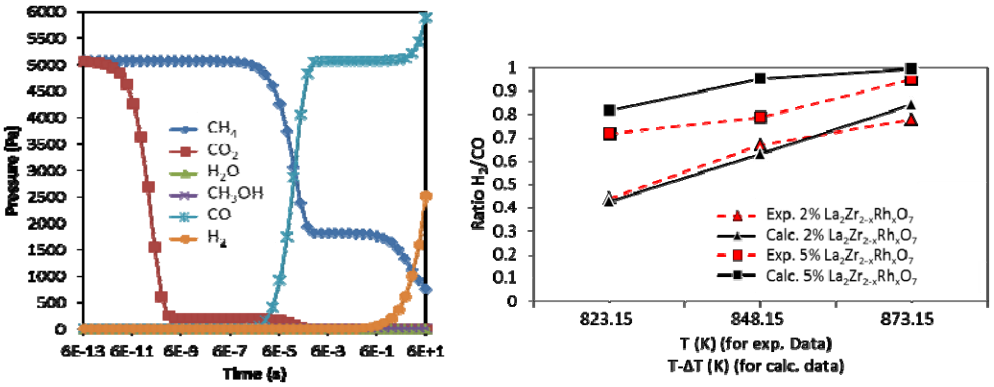
Fig. 1 shows the main reaction pathway on the plane (111). These activation energies, along with all other barriers for steps not as relevant (not shown in this document) are used in the MKM of a batch reactor. From Fig. 2a), it is observed how H_2 presents late desorption, suggesting that the first CO formed proceeds from CO_2 (RDS on CH_4 dehydrogenation). Additionally, the strong CO_2 decay goes along with the strong adsorption of CO_2. As seen in Fig. 2b), the MKM reproduces in great manner the experimental data for different temperatures for the 2 wt% Rh-substituted LZ, whereas it does it only in a moderate way for the 5 wt% Rh-substituted LZ, being these discrepancies probably due to neglecting the existence of Rh-Rh sites in our model, which could be present on the surface when the doping is 5%.



a) b)

Fig. 2 MKM outputs a) P vs. residence time in the modeled batch reactor at 823.15 K + $\Delta T_{correction}$, with $\Delta T_{correction}$ = 150 K. 2% LRhZ, b) Ratio H_2/CO vs. T. Calculated data correspond to a batch reactor after 1 min residence time. Experimental data from [3]

2 Conclusions

Our MKM model for a batch reactor successfully reproduces the experimental data for a plug flow reactor at different temperatures and a pressure of 1 atm and GHSV = 48,000 mL/g_{cat}/h, after 200 min time on stream. The model elucidates the reaction mechanism due to the pressure and coverage time evolution it outputs and furthermore it allows to quantitatively evaluate the influence of different operating conditions. DFT calculations are being performed to find what additional dopant would reduce the activation barrier for CHO dehydrogenation and then the MKM will be used to predict the net effect on the H_2/CO ratio. This catalyst will be then synthesized, characterized and tested.

Keywords: methane, propane, benzene, alkylation, isomerization, catalyst

1 Introduction

Reactions proceeding between low molecular (C_1-C_4) alkanes with new C-C bonds formation are paid much attention lately. These are non-oxidizing methane aromatization, benzene -propane dehydroalcylation and bimolecular n-butane isomerization. Mechanisms of these reactions are not clear enough and require further researches. This report comprises the results of our studies in this field.

2 Experimental

Objects of the study were bimetal-alumina catalysts prepared by adsorptive treatment, sulfated zirconia and their mechanical mixtures with H-form of zeolites.

The samples testing were carried out by studying reactions involving the C-C bonds formation in the methane-propane and benzene-propane alkylation, as well as bimolecular isomerization of n-butane, n-hexane, and mixtures thereof.

Experiments were carried out in a flow reactor at 150-400ºC, atmospheric pressure and GHSV 350-1500 h^{-1}. The state of supported metals was characterized by diffusive reflection IR spectra of adsorbed CO as a test molecule. The role of acidic sites in the reactions was studied by selective poisoning of catalysts with ammonia.

The reaction products were analyzed by gas chromatography.

3 Results and discussion

Studies of CH_4: C_3H_8 (1: 1) mixture conversion over unreduced bimetal-alumina catalysts (see table) shown those activity in aromatization of the mixture. Products yields and distribution are temperature-dependent. As is seen from the tab.1, lower temperature facilitates an increase in yields of alkylbenzenes and C_{4+} hydrocarbons.

Lowering the temperature promotes the formation of propene and outgoing of methane, moreover methane consumption and C_{4+} hydrocarbons yields pass through a maximum. This indicates the methane involvement to the propane alkylation.

The methane substitution to benzene and application of H-form zeolites as an acid catalysts allow obtaining isopropylbenzene at 180-200ºC (see fig.). Strict hydrogen reducing of bimetal-alumina catalyst leads to irreversible catalyst deactivation during iso-C_{4+} and cumene formation. Such loss of the samples activity indicates the participation of the catalyst inner oxygen in the C-C bonds formation between those molecules.

Fig. Benzene conversion and IPB and C_3H_6 yield on MC PRAC as a function of an experiment time. T=200°C, GHSV=500h^{-1}; C_6H_6:C_3H_8=1:9; MC PRAC +HM

Study of the low temperature isomerization of n-butane, n-hexane and mixtures thereof over Ni / MOR-SO_4^{2-}/ZrO_2 found that they are characterized by the higher weighted alkanes formation in contrast the original molecules (tab.2).

Table 2. Conversion of n-C_4H_{10} and n-C_6H_{14} (1:1 mole) over Ni/MOR/SO_4^{2-}/ZrO_2 H_2:CH=3:1; $T_{hydrotreatment}$=350º;GHSV=350ч$^{-1}$

Temperarute, ºC	**Conversion,* %**		**Selectivity, %**		
	n-C_4H_{10}	n-C_6H_{14}	C_1-C_3; n-C_5	i-C_4-C_6	C_7
120	18(12)	32(35)	6	64	30
170	60(32)	65(86)	49	73	18
220	88(67)	92(95)	37	59	4

This can be explained by bimolecular formation and decomposition of intermediates. SO_4^{2-}/ZrO_2 systems are known to be characterized by the presence of uncompensated positive charges that exist in the bimetal-alumina systems. Taking these into account the activation of C-C bonds formation in the studied reactions can be explained by the valence unsaturated oxygen atoms appeared in the catalytic systems, which are stabilized by pulling hydride ions from lower alkanes molecules, Based on these results a possible mechanism for the new C-C bonds formation in the studied reactions is proposed.

Keywords: integration, refining, petrochemicals, refining complex, combining production, feasibility

1 Introduction

As far as the globalization of its trade and economic connections is concerned, Azerbaijan, enjoying its vast energy resources, is increasingly involved in integration processes worldwide, including those in the fuel and power sector, which is progressing in four directions: oil and gas production - refining - gas processing - petrochemicals, and is determined by a harmonic combination of adjacent industries. The decisive link in this particular chain is refining.

As a result of national economy integration into the global system, the oil industry situation is a direct consequence of global oil market prices, and amounts of oil export are defined by the capacity of domestic market and development of refining facilities. If refining industry lags behind, the involuntary export of crude and semi-products increases.

The analysis of global refining trends and market structure gives clear evidence that in conditions of unstable global energy prices and growing cost of produced resources the national economy is short to sustain itself and progress based on natural resources alone. So it comes necessary to develop conversion industries, refining and petrochemicals among them, even more so because external loans and investments cannot solve all national problems, and budget resources are not infinite.

The strategic importance of refining sector made it necessary to develop an oil strategy that has underlain the entire oil industry, refining included. Such strategy, developed in the Republic of Azerbaijan under the supervision of Heydar Aliyev, has been implemented with success.

2 Experimental/methodology

The strategy builds upon the increasing efficiency of the oil industry; it stipulates the gradual replacement (diversification) of crude export with export of high added value petroleum / petrochemical products.

The Institute of Petrochemical Processes has for many years conducted researches dedicated to developing such integrated crude refining strategy that would boost the efficiency of each individual facility and the industry as whole; these researches are targeted to set up the basis for the full-through development of the national refining industry. This plan is based on wide-scale innovations and investments that are necessary for profound modernization of the industry and development of the domestic market.

The complex refining schemes have been developed with consideration of features of Azerbaijani crudes, energy and petrochemical infrastructure, internal petroleum demand and export capabilities, prospective requirements for products with an account of environmental and economic imperatives on which a facility and market operates and structures itself.

Considering the advantage of converting crude to finished petrochemical stock, we have developed several options of integrated petrochemical industry development. To that end, both petrochemical industry development options have been studied:

- independently at petrochemical facilities, with reviewing issues of supplying feedstock to

steam crackers (gases (natural and associated) and naphtha from a refinery;

- directly at a refinery through integration between refining and petrochemical production.

3 Results and discussion

The pyrolysis unit efficiency increase and effective feedstock supply shall be attained through integration of refining, gas processing and petrochemical industries. On the other hand, integration with petrochemicals boosts the efficiency of the very oil refining. We can state an example of boosting the quality of gasolines via oxygenates ex petrochemical plant, or producing semi-synthetic oils by oil fraction alkylation with alpha-olefins plus implementing hydrocracking within the complex, which helps ramp up the resources and improve the diesel fuel quality; thus being said, it should be also noted that introduction of such hydrocracker at refineries is limited due to its high energy and capital consumption and hydrogen flow rate.

Implementing both options at the same time, we can optimize hydrocracking process in terms of CAPEX and capacity of both steam cracker and lube base oil unit. Therefore, integration between refining and petrochemicals is a win-win.

The increasingly stringent requirements for product quality call for additional conversion using costly hydrogenation processes, HC among them, which operate in severe pressure / temperature conditions, as well as new catalysts and process systems. Naturally, this results in increased refining cost and does not always solve the problem. In order to make the production of environmentally friendly petroleum products at constant market prices for oil and products profitable for a producer, we made a technoeconomic assessment of each individual process and the facility as whole when developing the said complex schemes. The technical and economic analysis has shown that such project could be feasible if hydrocracking would be used as a feedstock for SC or to produce highly viscous lubes (VI > 120).

4 Conclusions

The technoeconomic analyses of complex schemes have established that the plant integration and modernization of conversion scheme help significantly reduce operating costs, while the margin jumps 2 to 3 times compared to split crude refining at refineries and petrochemical facilities.

The study made on the premises of refining 10 MTA of crude and processing 10 BCMA of gas established that the maximum IRR of a refinery is 15-17%, while in refining-petrochemicals integration scenario it rises to 25%, and to 35% if gas processing is integrated with refining and petrochemicals.

Keywords: Fischer-Tropsch synthesis, tubular reactor, heat transfer, heat-exchange coefficient

1 Introduction

In this paper, the process of heat transfer, as well as the necessary conditions for conducting high-FT process in a tubular reactor, while maintaining a quasi-isothermal mode of operation.

2 Experimental

Heat transfer is the main factor which obstructs creation of high-performance Fischer-Tropsch synthesis (FTS) by reason of high exothermicity of the process, although activity of modern FTS catalysts allow to perform the synthesis at high gas volume rates (3000-5000 h^{-1}) [1,2]. Therefore two ways are applied for intensification of the FTS. The first way supposes improvement of apparatus design (application of tubular reactors, three-phase reactors, slurry and fluidised reactors), while the second way comprises fluid-dynamic refinement [3].

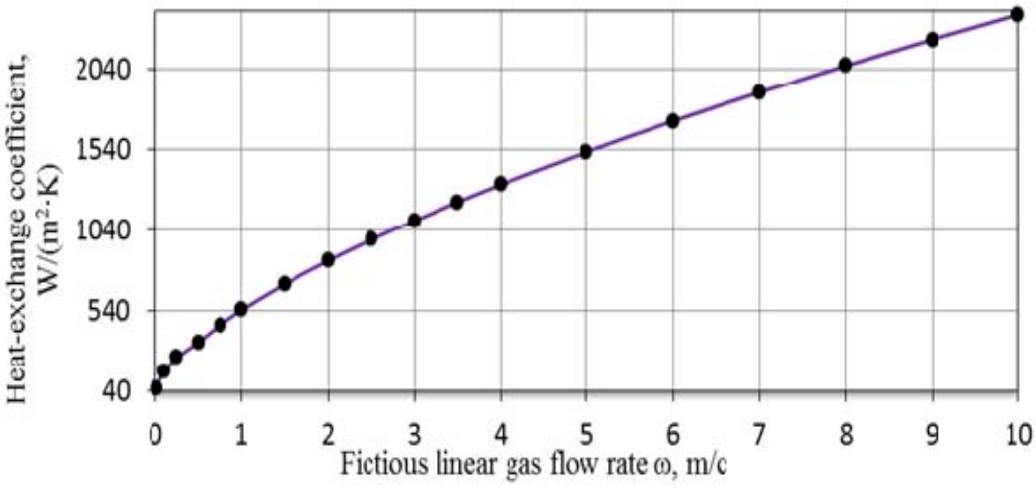

Fig. 1. Dependence of heat-exchange coefficient from fictious linear gas flow rate in tubular reactor

Heat-exchange coefficients required for distinguishing maximal conversion of CO and maintenance of stable temperature regime were calculated for reactor tubes of different diameters (20-50 mm) at gas volume rates (GVR) from 1000 to 5000 h^{-1} (see Table and Figure 2).

Table. Hydrodinamic parameters required for maintenance of quasi-isothermal regime in tubular reactor

GVR, h^{-1}	Heat-exchange coefficient, $W/(m^2 \cdot K)$	Required fictive gas rate, m/s
1000	500	1,0
2000	1000	3,0
3000	1500	5,0
4000	2000	8,0
5000	2500	>10,0

3 Results and discussion

The next parameters were applied for calculations: syngas composition (% vol.) – CO – 33, H_2 – 67; temperature – 200 °C; pressure – 2,0 MPa; catalyst particles diameter – $2{,}5 \cdot 10^{-3}$ m; porosity – 0,4. Heat-exchange coefficients were calculated by the known method [4], physical-chemical properties of reaction media were calculated by the "Technologist" software by using Peng-Robinson thermodynamic package [5].

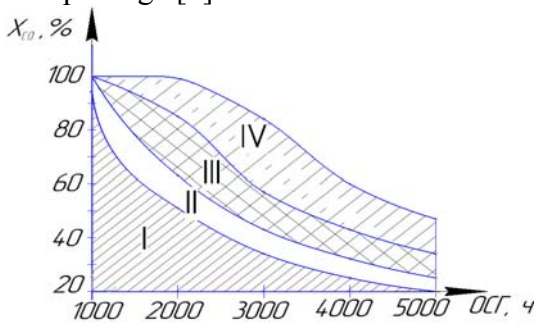

Fig. 2. Dependence of maximal conversion of CO (X_{co}) from gas volume rate at quasi-isothermal regime in tubular reactor for various diameter tubes: I – 50 mm; II – 40 mm; III – 30 mm; IV – 20 mm

4 Conclusions

Our study revealed that application of tubular reactor for the high-performance FTS is possible only at specific hydrodynamic regimes.

Keywords: ethanol reforming, structured catalyst, Fechraloy microchannel plates, Ru+Ni/SmPrCeZrO

1 Introduction

Structured catalysts with active components supported on ceramic or metallic substrates are attractive for generation of hydrogen/syngas from biofuels in the compact reformers [1-3]. Due to a good thermal conductivity of metal substrates, formation of cool spots within the structured reactor leading to coking can be prevented [2]. In this work, experimental and numerical studies of ethanol steam reforming (ESR) over a structured package consisted of five stacked microchannel corundum – protected Fechraloy plates covered with a layer of Ni+Ru/$Sm_{0.15}Pr_{0.15}Ce_{0.35}Zr_{0.35}O_2$ active composition have been performed.

2 Experimental/methodology

The microchannel Fechraloy plates (20*50*1.5 mm, one side flat, one side with 15 channels of 0.4 mm depth provided by IMM, Germany) were protected by supporting a thin (5–10 μm) corundum sublayer by detonation spraying [2]. $Sm_{0.15}Pr_{0.15}Ce_{0.35}Zr_{0.35}O_2$ (SmPrCeZrO) oxide synthesized by Pechini route was promoted by 2% Ru+2%Ni supported by the incipient wetness impregnation using acetone solution of binuclear Ru-Ni nitrocomplex. Ru+Ni/SmPrCeZrO (4 wt.%) was supported on plates by slip casting slurries in isopropanol with polyvinyl butyral followed by drying and calcination under air at 700°C for 2 h. A structured packing consisted of five plates was tested in ESR at 500 - 900°C in concentrated feeds with the gas flow rate up to 2 m^3/h using a pilot reactor and earlier described procedures [2]. Kinetic modeling was carried out by using a pseudo-homogeneous plug-flow reactor model and a step-wise reaction scheme described in [2].

3 Results and discussion

A power-law kinetic model with effective parameters was proved to be quite sufficient to simulate reaction behavior under experimental conditions:

$$r_I\left[\frac{mol}{m^2\cdot s}\right]=k_I\cdot x_{Eth} \quad (1)$$

$$r_{II}\left[\frac{mol}{m^2\cdot s}\right]=k_{f,II}\cdot x_{CH_4}^{\alpha_{II}}\cdot x_{H_2O}^{\beta_{II}}\cdot\left[1-\frac{Q_{II}}{K_{eq,II}}\right],\ \text{where}\ Q_{II}=\frac{p_{CO}\cdot p_{H_2}^3}{p_{CH_4}\cdot p_{H_2O}}; \quad (2)$$

$$r_{III}\left[\frac{mol}{m^2\cdot s}\right]=k_{f,III}\cdot x_{CO}^{\alpha_{III}}\cdot x_{H_2O}^{\beta_{III}}\cdot\left[1-\frac{Q_{III}}{K_{eq,III}}\right],\ \text{where}\ Q_{III}=\frac{p_{CO_2}\cdot p_{H_2}}{p_{CO}\cdot p_{H_2O}}; \quad (3)$$

$$r_{IV}\left[\frac{mol}{m^2\cdot s}\right]=k_{f,IV}x_{CH_4}^{\alpha_{IV}}\cdot x_{H_2O}^{\beta_{IV}}\cdot\left[1-\frac{Q_{IV}}{K_{eq,IV}}\right],\ \text{where}\ Q_{IV}=\frac{p_{CO_2}\cdot p_{H_2}^4}{p_{CH_4}\cdot p_{H_2O}^2}. \quad (4)$$

Here, x_i and p_i are mole fractions and partial pressures (atm) of components in reactions of ethanol decomposition into CH_4 , CO and H_2 (1) followed by the reversible reactions of steam reforming (2), water-gas shift (3) and complex shift reaction $CH_4+2H_2O \leftrightarrow 4H_2+CO_2$ (4); Q_r reflects the reaction approach to equilibrium. Isothermal reactor model was applied.
Figure 1 compares the temperature dependences of experimental data with equilibrium values and those predicted by kinetic modelling with optimized kinetic parameters.

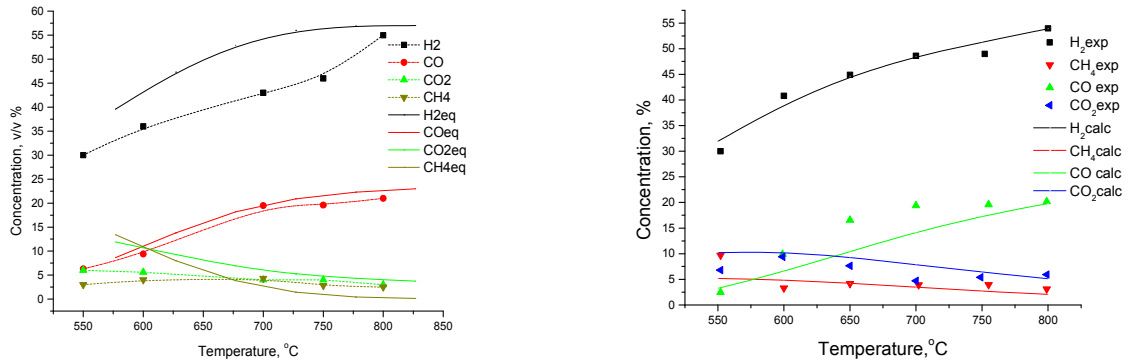

Fig. 1. Temperature dependencies of products concentration for ESR over structured package. Experimental data versus equilibrium (left) or calculated by modeling (right) values. Feed 30%EtOH+60%H_2O+N_2, contact time 0.3 s.

At high temperatures, concentrations of products approach the equilibrium level, while at lower temperatures H_2 concentration is lower due to both incomplete conversion of ethanol as well as the presence of such by-products as C_2H_4 and C_2H_6, their maximum content at 600 °C being equal to 3% and 1%, respectively. The simple reactor and kinetic models proposed in this work provide a good description of the experimental data, thus demonstrating efficient heat and mass transfer within catalytic package not limiting the catalyst performance.

4 Conclusions

The structured package comprised of five stacked microchannel corundum – protected Fechraloy plates covered with a layer of Ru+Ni/SmPrCeZrO active component has demonstrated a high performance in the ethanol steam reforming at the pilot scale. At intermediate (600-800°C) temperature range and high reagent concentrations, a high syngas yield close to equilibrium was obtained. The numerical study of the performance of the structured reactor on the base of step-wise reaction scheme with effective parameters provides a good description of the experimental data, thus demonstrating efficient heat and mass transfer within the package of microchannel catalytic plates.

Catalytic Hydrodeoxygenation of Microalgae Biodiesel over Sulfur-Free Nickel Supported Catalyst for the Production of Biofuels

Hachemi I.*, Mäki-Arvela P., Kumar N., Murzin D.Yu.

Åbo Akademi University, Turku, Finland

* imane.hachemi@abo.fi

Keywords: hydrodeoxygenation, catalysis, nickel, chlorella microalgae, green diesel

1 Introduction

Production of sustainable energy is receiving more and more attention in the last decades. The concern about available resources has increased the interest in developing second generation biofuels from non-food feedstock as microalgae, which is highly advantageous and offers potentially great opportunities in biofuels production. From cultivation until processing, microalgae posses many advantages compared with the land feedstock [1].

A number of problems associated with the high oxygen content in fatty acids raw materials requires an upgrading step. Hydrodeoxygenation (HDO) has become a practical alternative method for the production of green diesel. In view of the foregoing, non-precious metal catalysts comprising supports other than carbon, particularly Ni on oxidic supports and hydrotalcite materials are beginning to attract attention as feasible catalysts for the conversion of lipids into fuel-like hydrocarbons via deCOx [2-6].

2 Experimental/methodology

Catalysts containing nickel supported on H-Y zeolites were synthetized by the wet-evaporation impregnation method. These materials were studied as sulfur-free catalysts for the production of green diesel. The catalytic HDO of fatty acids was performed in a semi-batch reactor at 300 °C under a total pressure of 30 bar using dodecane as a solvent. In a typical experiment 1 g of the substrate diluted in 100 ml of dodecane was injected along with 0.25 g of the catalyst with a particle size lower than 63 μm. Prior to an experiment and before injection of the deoxygenated liquid into the reactor, the catalyst was reduced at the temperature obtained from TPR. Several characterization methods were considered in order to determine the synthesized catalyst physicochemical properties. The characterization included BET, SEM, EDXA, TEM, TGA, TPR, NH_3-TPD and CO_2-TPD.

Chlorella microalgae (Fuqing King, Drarmsa Spirulina Co, Ltd, China) was used as a source of fatty acids methyl esters (FAME) in the HDO experiment. This latter was obtained from transesterification of dry algae using 20 wt% H_2SO_4 as a catalyst for 4 h at 60°C. Chlorella microalgae crude oil contains a mixture of saturated and unsaturated methyl esters plus a small fraction of acids. The composition of the saturation order of FAME is illustrated in Table 1.

Table 1. Composition of fatty acids methyl esters in *Chlorella* microalgae.

Components	Mols (%)
Unsaturated FAME	34
Saturated FAME	62
Saturated Acids	1
Unsaturated acids	3

3 Results and discussion

Nickel impregnation over H-Y zeolites permitted the preparation of a nanoparticle catalyst. TEM images show the Ni particle distribution with 4 nm as an average particle diameter (Figure 1). The metal particle size plays a major role in the HDO reaction, the small particle size facilitates a high initial catalytic activity and a high uniformity ensures high catalyst stability [7].

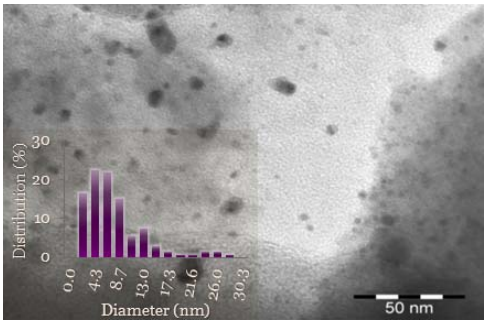

Fig. 1. TEM micrograph and metal particle distribution

Nickel supported materials were shown to be promising catalysts in the HDO of fatty acids, able to realize quantitative transformation of FAME into diesel-range alkanes as high-grade second generation biofuels under mild conditions. The conversion was moderately rapid with a total conversion attained in approximately 120 minutes, under mild operating conditions, yielding aliphatic hydrocarbons. Table 2 illustrates the yields and selectivities obtained after 6 hours of HDO of FAME over 5 wt% Ni/H-Y.

Table 2. Yield and selectivity after 6 hours of hydrodeoxygenation of fatty acids methyl esters with 94% conversion level.

	Yield (%)				Selectivity (%)				
Product	C15	C16	C17	C18	C15	C16	C17	C18	Saturated acids
FAME	14	30	19	31	14	30	19	32	4

4 Conclusions

Ni nanoparticles prepared by the wet impregnation method were investigated in the catalytic hydrodeoxygenation of fatty acids methyl esters derived from *Chlorella* microalgae. The obtained results proved the efficiency of Ni supported on H-Y zeolites in producing diesel-range hydrocarbons. This catalyst has a very interesting catalytic activity as it does not require the addition of sulfur and further purification of the products. Moreover, it was noticed that the reaction follows both hydrodeoxygenation and hydrodecarboxylation paths allowing the production of hydrocarbons with the same carbon chain as the reacting ester and one carbon shorter hydrocarbons.

Application of the Dioxo-Mo(VI) Complex Anchored on a TiO_2 in the Oxidation of DDT with Molecular Oxygen, under UV-Irradiation

Manucharova L.A.*, Bakhtchadjian R., Tavadyan L.A.

Nalbandyan Institute of Chemical Physics, National Academy of Sciences of the Republic of Armenia, Yerevan, Republic of Armenia

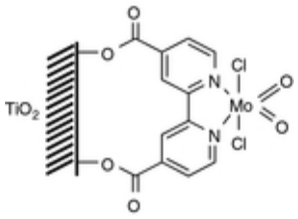
* loriettam@yandex.ru

Keywords: catalytic oxidation, dioxo-Mo(VI)complex, DDT, UV-irradiation

1 Introduction

Dioxo-Mo(VI) Complexes, bearing organic ligands, exhibit an oxidative capacity towards a great number of the organic compounds of the different classes (hydrocarbons, alcohols, phosphines, etc.). In the presence of the oxidant agents (such as O_2, H_2O_2, O_3 and others), enable to re-oxidize the reduced metallic centers of the complex, these reactions become catalytic. As show the investigations in recent years, the catalytic activity of these complexes rises under UV-irradiation or visible light, when they are supported on the solid surfaces or anchored on the solid matrix by chemical bonds[1].

In the present work the feasibility of the catalytic activity of dioxo-molybdenum(VI)-dichloro [4,4′-dicarboxylato-2,2′-bipyridine], anchored on TiO_2 has been tested in the oxidation reaction of DDT (1,1,1-Trichloro-2,2-bis(4-chlorophenyl)ethane) with molecular oxygen, under UV-irradiation (λ= 253.7 nm), in acetonitrile solution. DDT is a persistent organic pollutant, the direct catalytic transformation or degradation of which with O_2 by chemical methods, in our knowledge, is not known. In chemical industry the oxidation of DDT to dicofol usually is performed as a multistep process including: elimination of HCl from DDT; chlorination of DDE (1,1-bis-(4-chlorophenyl)-2,2-dichloroethene) to tetramer (dichloro diphenyl tetrachloro ethane); hydrolysis of tetramer to dicofol by para-toluene sulfuric acid). Unfortunately, the AOP technologies, successfully applied for the purification of wastewater, for several reasons, are not completely applicable in a large scale chemical transformation of DDT to dicofol.



2 Experimental

The dioxo Mo-complex was fully characterized by different methods, including ^{13}C CAP NMR[2] spectroscopy. The experiments were carried out by a special protocol. Each experimental cycle was consisted of two consecutive periods: in the first period the reaction mixture (a suspension of DDT in acetonitrile, containing the anchored complex) was exposed under UV-irradiation in stirring conditions, in argon atmosphere and in the absence of molecular oxygen during about 6-7 h. Then, in the second period, the aim of which was the re-oxidation of the reduced metallic centers ($Mo^{IV} \rightarrow Mo^{VI}$), was kept without UV-irradiation and in the presence of molecular oxygen (2-2,5 h). Before the beginning of a new experimental cycle, dioxygen was thoroughly removed from the reaction mixture.

3 Results and discussion

The results show a significant increase of the consumption of DDT in the course of the first

periods of the experimental cycles in the presence of the anchored complex in comparison with the results on the "pure" TiO2 (absence of the complex). As a result of 4 consecutive experimental cycles, the amount of the consumed DDT reaches up 35% for 30h, while in the absence of the anchored complex on the "pure" TiO_2 surface, even in two time more amounts in the reaction media, it is about 13%.

In the same time, the turnover number, calculated as Δ[DDT] / [anchored complex], increases about 5.7 times becoming 3,7 for 32 h. These facts indicate the catalytic role of the anchored complex in the reaction.

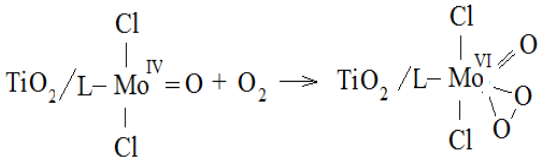
The reaction products include a great number of the chlorinated and non-chlorinated organic compounds (C_2-C_{14}), as well as the products of the complete destruction of DDT, such as CO_2, H_2O, HCl. Taking into account the results of the chromatographic analyses (GC-MS) and overall amounts of Cl^- ions, determined by chemical methods, the amounts of the completely dechlorinated products are estimated as 45-47% and, correspondingly, 53-55% the partially dechlorinated or non-dechlorinated organic compounds.

The main product of the reaction is dicofol, the maximal yield of which is about 21%. The results of the chosen experimental protocol permits to conclude that the formation of dicofol, apparently, occurs via a transfer of the oxo-atom from the anchored Mo-complex to the bibenzylic carbon-atom of DDT

$$(ClC_6H_4)_2C(H)CCl_3 + O{=}Mo^{VI}(O)(Cl_2)|[L]/TiO_2 \rightarrow (ClC_6H_4)_2C(OH)CCl_3 + \\ + Mo^{IV}(O)(Cl_2)[L]/TiO_2 \quad (1)$$

where, L is 4,4′-dicarboxylato-2,2′-bipyridine ligand.

The periodical re-oxidation of the reduced complex ($Mo^{IV}(O)(Cl_2)[L]/TiO_2$) , with molecular oxygen in the "dark" reaction in the second periods of the experimental cycles may occur by the formation of oxo-peroxo moieties in Mo(VI) complexes:



(2)

Due to the reaction (2), the amount of oxygen atoms enable to oxidize DDT (or other compounds present in the reaction mixture) may be doubled in comparison with that in the initial complex. As show the experimental data, the consumed amounts of DDT nearly are doubled, and, at the same time, the yield of dicofol is increased about 1.5 times in the first period of the second experimental cycle, after the "dark" reaction in the first experimental cycle.

The second main product of the reaction DDE (1,1-bis-(4-chlorophenyl)-2,2-dichloroethene (yield 9%) may be formed from DDT or dicofol by different channels, probably, involving also reactions of OH or HO_2 radicals, photogenerated on the TiO_2, under UV-irradiation[3]. Other reaction products, contain the chlorinated and non-chlorinated compounds not only of the oxidative decomposition (4,4'-dichlorobenzophenone (DBP), CO_2, H_2O, H^+ and Cl^- ions), but also of the reductive decomposition (DDD (1,1-dichloro-2,2-bis(p-chlorophenyl)ethane), DDM (2,2-(bis(p-chloropheny)-methane, 1,1-diphenyl methane, in overall amounts about 13-14%).

Apparently, the complex mechanism of the overall reaction include a combination of the primary oxo- or peroxo-atom transfer to DDT with a number of the further free-radical reactions. In any case, the feasibility of the direct photocatalytic oxidation of DDT with molecular oxygen opens an attractive opportunity for the elaboration of an alternative method of the oxidation of DDT in "mild" conditions, using the transition metal oxo-complexes, anchored particularly on the TiO_2 under UV- irradiation or visible light.

Petroleum-Saturated Sands of Azerbaijan

Samedova F.I.*, Gasanova R.Z., Logmanova S.B., Badavi Y.E.

Institute of Petrochemical Processes named after acad. Y.H.Mamedaliyev, Azerbaijan NAS, Baku, Azerbaijan

Keywords: alternative source, refining, hydrocarbon feedstock, bituminous sands, Kirmaky, basis, oil

1 Introduction

In the IPCP Azerbaijan National Academy of Sciences research on the rational use of oil-saturated earth of Azerbaijan to produce valuable petroleum products, including base oils, has been carried out.

By the method of solvent extraction from oil-saturated sand deposits of Balakhany and Mashtaga organic part was isolated, which has a high density (1143.9 kg/m^3 at 20ºC), high resin-asphaltene substances (14.2%) and low (0.906) paraffin contents. It contains Ni; Fe; Zn; Mn; Cr; Mg; Pb; Co, etc.

The problem of rational refining of the alternative sources of heavy and superheavy hydrocarbon feedstock becomes progressively urgent one. The sources for obtaining hydrocarbon feedstock are oil-bearing shales, bituminous sands, etc. The world reserves, for instance, of oil-bearing shales are estimated to be 2-3 tril. tons.

The investigations have been carried out to evaluate the properties of Azerbaijan bituminous sands of Kirmaky deposit. From the bituminous sand with extraction method there has been isolated an organic part.

As a result of the fractionation of extraction products and compounding following narrow fractions of oil products were obtained, % (w): boiling up to 180°C - 13; 180-240°C – 7.5; 240-350°C – 4.3; 350-500°C - 32.6; above 500°C - 42.6. These yields and qualities are similar to those of analogical fractions of heavy Balakhany oil except oil fraction viscosity index, which is 44 instead of 14.4 from the natural oil.

The product from petroleum-saturated sand features by high content of asphalto-resinous substances and low content of paraffin; from it the narrow fractions boiling up to 300, 300-500 and above 500°C have been isolated.

2 Experimental/methodology

By catalytic processing of oil fraction, boiling at 350-500°C, in two stages with olefins in the presence of $AlCl_3$ the possibility of using this fraction as an alternative raw material for the base oil with viscosity index 80-97 units was revealed. However, this method of processing the oil-saturated earth energy consuming and environmentally unsafe because of the use of large amounts of toxic solvent.

A new method, has been worked out which provides oil-saturated earth hydroforming without prior separation of the organic part of it, which is loaded into the reactor of pilot plant and processed with flow of hydrogen.

3 Results and discussion

Fraction 350-500°C was compared with oily fraction from Balakhany heavy oil (BHO). The investigations showed that the product from bituminous sand in quality is close to oily fraction from Balakhany heavy oil.

The comparative data of quality of oily fractions from comparable feedstock are the following:

	From petroleum-saturated sands	from Balakhany heavy oil
Bailing range, °C	350-500	360-460
Yield on feedstock, %	27.7	25.43
Density at 20°C, kg/m^3	937.3	937.7
Viscosity, mm^2/s, at		
100°C	11.1	9.22
40°C	180.6	-
Viscosity index	25	8.5
Acid number, mg KOH/g	1.82	0.56
Pour point, °C	-10	-27
Refractive index, n^{20}_D	1.5245	-

The oily fraction from a product in the amount of 27.7%, on organic part has been subjected to furfurol (300 %) selective treatment and followed by aftertreatment with gumbrine. The residue by its properties corresponded to bitumen.

The investigations showed that selective treatment fails to improve viscosity-temperature properties of a product, its viscosity index remained at low level. Viscosity at 100°C is 10.5mm^2/s, it contained 11.8% methane-naphthenic, 88.72% aromatic hydrocarbons, including 9.3% resins.

The catalytic treatment of this product has been conducted with olefins in the presence of catalyst ($AlCl_3$). The process proceeded at 60°C, contact time 3 hours.

Then from the product of catalytic treatment there has been isolated by fractionation a fraction boiling at 350-450°C with yield 19.14% on product, its viscosity at 100°C was 4.62mm^2/s, viscosity index 28.

Fraction 350-400°C isolated from reaction product was subjected to catalytic retreatment with olefins. As a result an oil has been obtained with viscosity index 96.9. The analysis of group-hydrocarbon composition of an oil obtained showed that content of methane-naphthenic hydrocarbons in oil increased from 11.8% to 66.06%, aromatic hydrocarbons decreased from 88.20% to 33.94%. Simultaneously from the residue of reaction product boiling at above 350°C (with viscosity 57-61.7mm^2/s at 100°C) by catalytic retreatment with olefins the oil has been obtained with viscosity 34.9mm^2/s at 100°C and viscosity index 89.

There has been also studied the possibility for using light fraction from the product of reaction I step boiling up to 350°C (content of olefins in it ~45%) which in a mixture with fresh olefins has been used as olefin feedstock. Using mixture as olefins provided the obtaining oil with viscosity index 80, i.e. the possibility has been established for circulation of light fraction boiling up to 350°C in catalytic treatment process.

Thus, the organic part of bituminous sand has been used as the alternative feedstock for preparation of oil products including base oils with viscosity index 80-96.9.

4 Conclusions

The group composition of oil extracted from the earth after hydroforming is similar to that of oil fields in Azerbaijan. Processing of oil fraction of hydroformed crude oil can improve viscosity index of base oils up to 100 and above.

Thus, the methods of processing the organic part of oil-saturated earth were developed, which allow to get petroleum products, including base oils, with a high degree of saturation.

Keywords: methane, partial, oxidation, dry, reforming, synthesis, gas, complex, oxide, cobaltates

1 Introduction

Synthesis gas production from natural and associated petroleum gases is important stage of global petrochemistry business [1]. Syngas is traditionally produced by highly endothermic steam reforming (SRM) of natural gas [2]. However, this process provides a high H_2/CO ratio (>3), which is not suitable for Fischer–Tropsch and methanol syntheses. Syngas with a more suitable H_2/CO ratio of 2 or lower can be produced via methane partial oxidation (POM) or by dry reforming of methane (DRM). Partial oxidation and CO_2 reforming of methane have the potential to reduce the cost of syngas and can be applied in solar energy storage and/or CO_2 utilization technologies [3]. Traditional Ni-supported catalysts for POM and DRM suffer from deactivation due to the coke formation or sintering processes. An alternative approach to catalyze POM and DRM is to use the perovskite-like oxides which can produce highly dispersed active metal particles under reduction environmental and prevent the coke formation and sintering processes.

2 Experimental/methodology

Perovskite-like materials - $Nd_{2-x}Ca_xCoO_4$ (x = 1 and 0.75) and $La_{2-x}Sr_xCoO_4$ (x = 1 and 0.75) were prepared by solid-state synthesis method. The samples were characterized by XRD, SEM, HRTEM and H_2-TPR before and after catalytic test. POM and DRM tests were carried out in a flow fixed-bed quartz reactor. Prepared materials were heated from room temperature to desired one under CH_4/O_2 or CH_4/CO_2 mixture. Also the tests with preliminary reduction step under pure H_2 were performed. The outlet gas composition was analyzed by online gas chromatography with TCD.

3 Results and discussion

Results of POM experiments revealed that for all the catalysts, the conversion of methane as well as the selectivity of CO/H_2 formation increases with temperature, whereas the selectivity of CO_2-formation decreases. In the case of $NdCaCoO_4$ CO selectivity was closed to 100% with CH_4 conversion was near 90%. CH_4 conversion and CO selectivity remained constant at least for 140h under the reaction stream [4] (figure 1). $NdCaCoO_4$ catalyst was also active in DRM process. CH_4 and CO_2 conversion achieved 96 and 93%, respectively, at W=14 $l*g^{-1}*h^{-1}$ and CH_4/CO_2 =1.1. The time on stream test over $NdCaCoO_4$ catalyst revealed that CH_4 and CO_2 conversions were constant at least for 30h (W=19-25 $l*g^{-1}*h^{-1}$; CH_4/CO_2 =1) (figure 1). The activity and selectivity of La-containing catalysts in POM reaction were found significantly lower. $La_{2-x}Sr_xCoO_4$ samples catalyzed mostly deep oxidation of methane to CO_2 and H_2O.

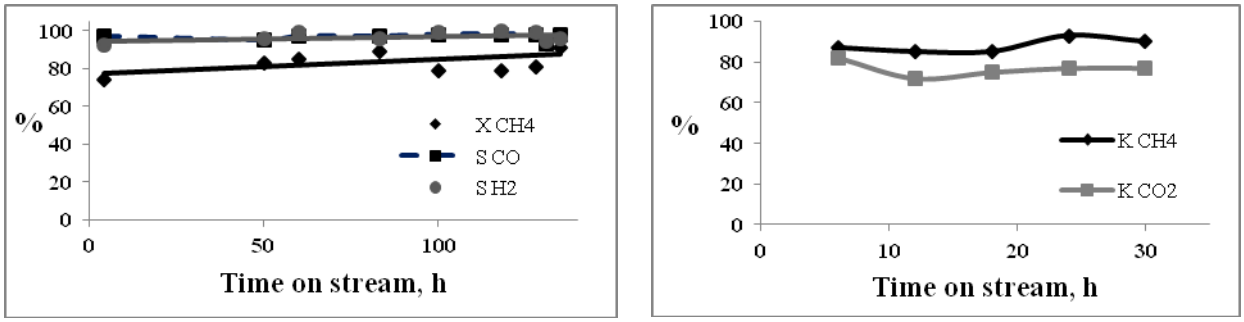

Fig. 1. Time on stream test over $NdCaCoO_4$: POM (left plot) and DRM (right plot)

The difference in the catalytic activity of synthesized materials might be clarified by H_2-TPR analysis which was performed for the fresh-prepared samples. As for the Nd-containing samples the active Co metal particles were formed at much lower temperatures compared to the $La_{2-x}Sr_xCoO_4$ catalysts. Moreover, In case of the La-containing samples the temperature of Co^0 formation was even higher than the reaction temperature zone.

The next step of the present study was to perform the POM with H_2 preliminary reduction treatment in order to create the active Co metal particles before reaction. Nevertheless, the catalysts showed the same trend – the most active material was $NdCaCoO_4$ when the less active one was $LaSrCoO_4$. XRD analysis of the spent catalysts revealed that completely reduced $LaSrCoO_4$ was partially reoxidized again to the perovskite-like structure during the POM process. These results might be explained by geometric factors. The calculated Goldschmidt tolerance factor for $LaSrCoO_4$ and $NdCaCoO_4$ are 0.97 and 0.93 respectively. These tolerance factors indicate that considering solely geometric factors lanthanum, the largest ion in the series, forms the most stable perovskite structure which is difficult to reduce to obtain active metal particles. On the other hand, once reduce stable perovskite it is much easier to reoxidize it again to the initial structure.

4 Conclusions

$NdCaCoO_4$ demonstrate high activity, selectivity and stability in both POM and DRM processes. It was found the strong relationship between reducibility and activity of perovskite-like cobaltates.

Keywords: SHS-intermatallides, polymetallic catalysts, nanostructures, deep oxidation, reduction processes

1 Introduction

Complex multicomponent intermetallides produced by self-propagating high-temperature synthesis (SHS) were precursors of new polymetallic catalysts. The catalysts demonstrated high activity and selectivity in oxidation [1-3] and reduction processes [4].

2 Experimental/methodology

SHS is an energy efficient short-stage process of the general scheme:

$$\Sigma MO_X + \mu Al \rightarrow [\text{intermetallic alloy}] + \nu Al_2O_3$$

where ΣMO_X is a mixture of oxides of transition metals and rare earths, the intermetallic alloy consisted of higher and lower intermetallides with unreacted aluminum. After ignition, highly exothermic reaction passed in a combustion wave regime. The temperature reached as high as $2500^{O}C$ and higher, therefore all the products were in liquid state. The total reaction time was only a few seconds. The polymetallic alloy was leached by alkaline solution to produce the catalyst. The essential feature of the developed method was stabilization of prepared catalysts by treatment of hydrogen peroxide solution. It is necessary to prevent self-ignition of the samples in the air by removing hydrogen adsorbed during leaching and by formation of a thin oxygen layer on the catalyst surface. After that the catalysts were stable even in oxidation processes at high temperatures.

3 Results and discussions

The structure of the catalysts granules included the lower non-leached intermetallides as supports for highly disperse, disordered and partially amorphous metallic phases. Their specific surface reached more than 40 m^2/g. Oxo-metallic two-level nanostructures were observed on the surface of the all investigated catalysts. The primary levels of structure were flat hexagons of ~1 μm in diameter and less then 100 nm in thickness. The hexagons consisted of granules of 10-30 nm in size or thin unresolved geometric figures as secondary level structures (Fig.1,2).

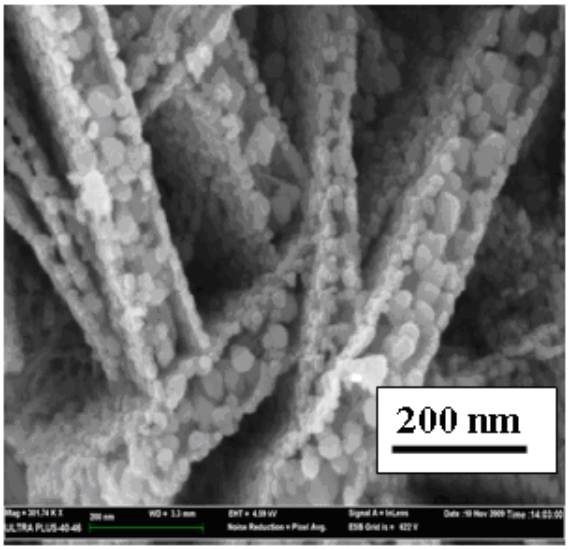

Fig. 1.SEM micrograph of surface of Fe-Mn-Ce catalyst for deep oxidation

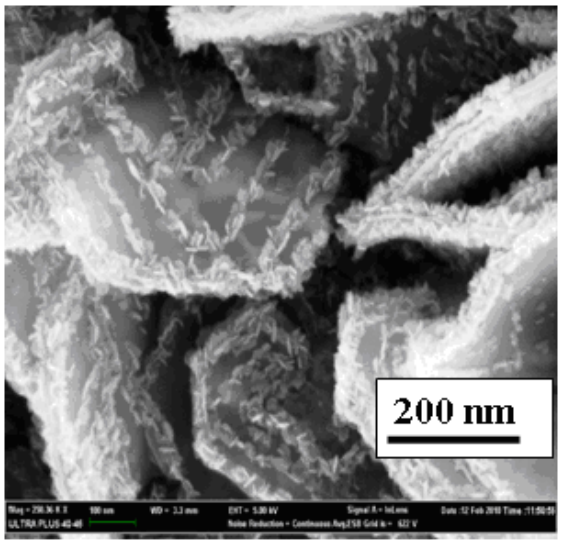

Fig. 2. SEM micrograph of surface of Co catalyst for FT process

(Ni, Fe)-Co-Mn(Ce) catalysts were highly active and stable in the deep oxidation of CO and hydrocarbons up to 450^{O}C. The temperature of 100% conversion was 150-200^{O}C for CO and 250-300^{O}C for propane under gas space velocity 120,000 h^{-1}.

Cobalt based catalysts with promoters such as V,Zr,Ce,La were tested in Fischer-Tropsch (FT) process and demonstrated high activity (~70% CO conversion) and a very high selectivity to heavy hydrocarbons (up to 94%) . The value of ASF chain growth factor **α** reached 0.94 and the product contained a large amount of solid paraffins [4]. The samples of the catalysts were not subjected to any preliminary activation by hydrogen treating at 400^{O}C in contrary to the traditional supported cobalt catalysts.

Other samples of polymetallic catalysts were tested in the process of hydrodesulfurization (HDS) of heavy oil fractions as well. Mo-Ni catalyst was very active in purification of diesel fraction at 350^{O}C, weight velocity of 1 h^{-1} and hydrogen consumption of 300 ncm^3/cm^3. The total sulfur content was reduced from initial 9900 ppm to 31 ppm. The catalyst was used without preliminary treatment by sulfur compounds and calcination.

The activation of the catalysts with formation of metallic (for FT) or sulfide (for HDS) active centers might take place at initial stages of the reactions because of light reducibility of surface nanostructures.

4 Conclusion

Therefore, the new polymetallic materials produced from SHS-intermetallides are very perspective catalysts for oxidation as well as reduction processes. We suppose that highly disordered structure of the materials with branched nanostructured surface is the main reason of extraordinary properties of the catalysts.

Cooperation of Kazan (Volga Region) Federal University and PJSC "Nizhnekamskneftekhim" in the Development of Catalysts for the Petrochemical Industry

Lamberov A.A.*

Kazan (Volga region) Federal University, Department of Chemistry, Kazan, Russia

* Alexander.Lamberov@kpfu.ru

Keywords: petrochemical technologies, catalysts

1 Introduction

As is known, up to 90% of petrochemical and oil refining processes are implemented using catalysts which are their major scientific component. Catalysts determine the quality and cost price of the final product, they are the main core of innovative technology in these industries.

2 Experimental/methodology

Work on real catalytic processes in the Kazan University began in 2000 with the development of a catalyst for pyrolysis gasoline hydrogenation. By the time it was stopped the production of domestic catalyst KIM-1 due to its numerous disadvantages. In all reactors of the "SK" plant were loaded the catalysts produced by foreign companies «BASF» and «Shell». By 2003, this problem was solved and after a series of pilot tests, the catalyst KDO had been integrated into industrial practice PJSC "Nizhnekamskneftekhim" instead of imported analogues. In 2005 the catalyst for production of styrene from ethylbenzene had been tested successfully. This catalyst will be produced on the platform of catalyst plant after increase it capacity.

Later, in 2010-2013 this catalyst and its operation technology were the most significantly upgraded by Kazan University together with the PJSC "Nizhnekamskneftekhim". Received by that moment by the Kazan (Volga Region) Federal University funds were used to strengthen the material and technical base to create a "Laboratory of adsorption and catalytic processes". Then the laboratory was equipped with the most modern equipment for the synthesis, study and testing of catalysts. In the latter case it is unique flow catalytic reactors having a volume from 1 cm^3 to 30000 cm^3, in which may be realized industrial operating conditions of the 12 basic processes of PJSC "Nizhnekamskneftehim" on the real industrial feed.

Under the integration of PJSC "Nizhnekamskneftekhim" and Kazan (Volga region) Federal University in 2010 Research and Education Center "Petrochemistry and Catalysis" was created, and in 2013 it was opened the same name Master's Degree Program, which trains the masters and specialists for PJSC within work programs agreed by leading experts of "Nizhnekamskneftekhim".

In 2004 was designed the catalyst for dehydrogenation of isoparaffins and in 2007 together with the specialists of "L.Y. Karpov Chemical Plant" was launched the production of catalyst KDI with capacity of 1,200 tons per year on the above plant.

This catalyst after a series of pilot tests are operated at the "IM" plant of PJSC "Nizhnekamskneftekhim", but it does not cover all the needs of the company. In 2013 together with the specialists of the "Nizhnekamskneftekhim" under the Decree of the Russian Federation № 218 (III stage) was initiated an innovative project to develop the own production of the dehydrogenation catalyst KDI-M and of the modernization of the technological process of isobutylene production. To date, the plant reached its design capacity and successfully operated.

The developed technology is unique and patented in Russia. By creating a stronger contacts

between the primary particles the mechanical strength of the catalyst granules is increased, which results in low catalyst consumption rates per ton of olefin. Crystalline homogeneity of catalyst and uniform distribution of the active components in the granule determined the higher yield and selectivity of action. A low abrasive effect on reactor internals are due to close to the spherical shape of the catalyst granules and its specific granulometry.

Today, as part of this project the Kazan (Volga region) Federal University employs more than 60 researchers. Widely involved scientists of related disciplines - physics and mathematics, there is close cooperation with scientists from the University of Architecture and Construction. In the IV quarter of 2014 in the technological center of K(V)FU the experimental workshop on development of the technology of catalysts production was opened, and in 2015 the department of "Chemical industries" and the department "Industrial Catalysis" was organized for specialist training.

In close cooperation with specialists of PJSC "Nizhnekamskneftekhim" were also successfully developed: a series of catalysts for the selective hydrogenation of hydrocarbon fractions of ethylene production, the isomerization catalysts and zeolite adsorbents. All developments are protected by patents of the Russian Federation. The resulting industrial samples of these catalysts have successfully completed pilot testing in an industrial conditions and have a high degree of readiness for the introduction into commercial operation.

University not only develops the new catalysts, but also carries out works on the modernization of technological equipment producing monomers. Reactors for hydrogenation of pyrolysis gasoline were modernized, a highly efficient cyclone equipment of dehydrogenation units were developed and implemented, in a pilot plant was tested the process flowsheet of heat supply in the catalyst beds of isoamylenes dehydrogenation, taking into account the obtained results the modernization of industrial technology was started.

3 Results and discussion

Successful cooperation of PJSC "Nizhnekamskneftekhim" and K(R)FU allows to build optimistic plans for the future.

PJSC "Nizhnekamskneftekhim" requested the University to develop catalysts for the processes:

- hydrogenation of acetophenone,
- dehydrogenation of butane to butadiene,
- methyl-phenyl-carbinol dehydration.

It may be noted that all the participants of the project: scientific, technological and design centers of PJSC "Nizhnekamskneftekhim" and the laboratory of adsorption and catalytic processes of Kazan (Volga region) Federal University realized its full potential in the format of the engineering center.

Keywords: oxidative dehydrogenation, ethane, ethylene, mixed-metal oxide, micro-channel reactor

1 Introduction

Oxidative dehydrogenation of ethane (ODHE) is a competitive process for ethylene production currently due to its high performance in terms of ethane conversion and ethylene selectivity as well as the low risk of carbon deposition theoretically. The $MoVNbTeO_x$ catalyst has been demonstrated as promising materials in the selective oxidation of alkanes, which usually consists of M1 and M2 crystalline phases and minor amounts of other phases. The M2 phase has no activity in the ODHE process and the catalyst performance increases with the M1 phase content in the $MoVNbTeO_x$ catalyst. The phase-pure M1 catalyst is therefore ideal for obtaining a high productivity in the ODHE process.

In the present work, different post-treatment processes were applied to produce phase-pure M1 catalysts which contain different chemical compositions and surface areas. We further prepared the phase-pure M1 $MoVTeNbO_x$ catalyst on metal-ceramic complex substrates by a dip-coating method. The performance of the M1-PVA catalyst plate in a micro-channel reactor approached an ethane conversion of ~ 60% and ethylene selectivity of ~ 85% with a high catalyst productivity of 0.64 $kg_{C2H4}/kg_{cat}/h$.

2 Experimental/methodology

Figure 1 shows the general preparation procedure of $MoVNbTeO_x$ catalysts by hydrothermal synthesis and, thereafter, by various post-treatment methods. The properties of the catalysts before and after reaction were characterized by XRD, BET, ICP, XPS, SEM and TEM. These catalysts were evaluated at different temperatures (340–460ºC) with different feed composition to investigate the effect of different post-treatments on the catalyst performance (i.e., ethylene selectivity, productivity and stability) in the ODHE process.

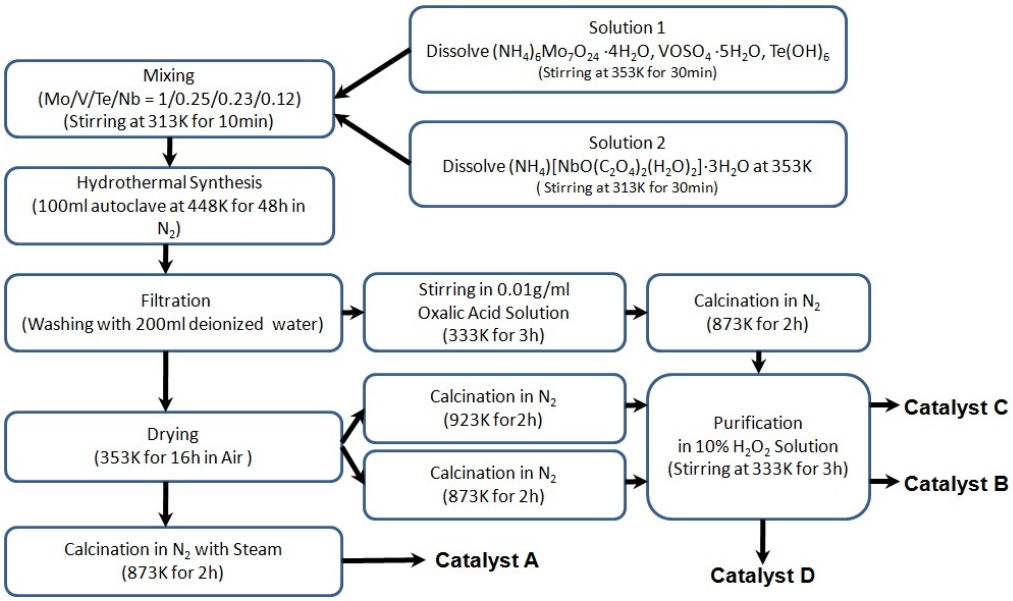

Fig. 1. Hydrothermal synthesis of phase-pure M1 catalyst

3 Results and discussion

Figure 2 shows a comparative study of M1 catalyst performance in a fixed bed and a micro-channel reactor.

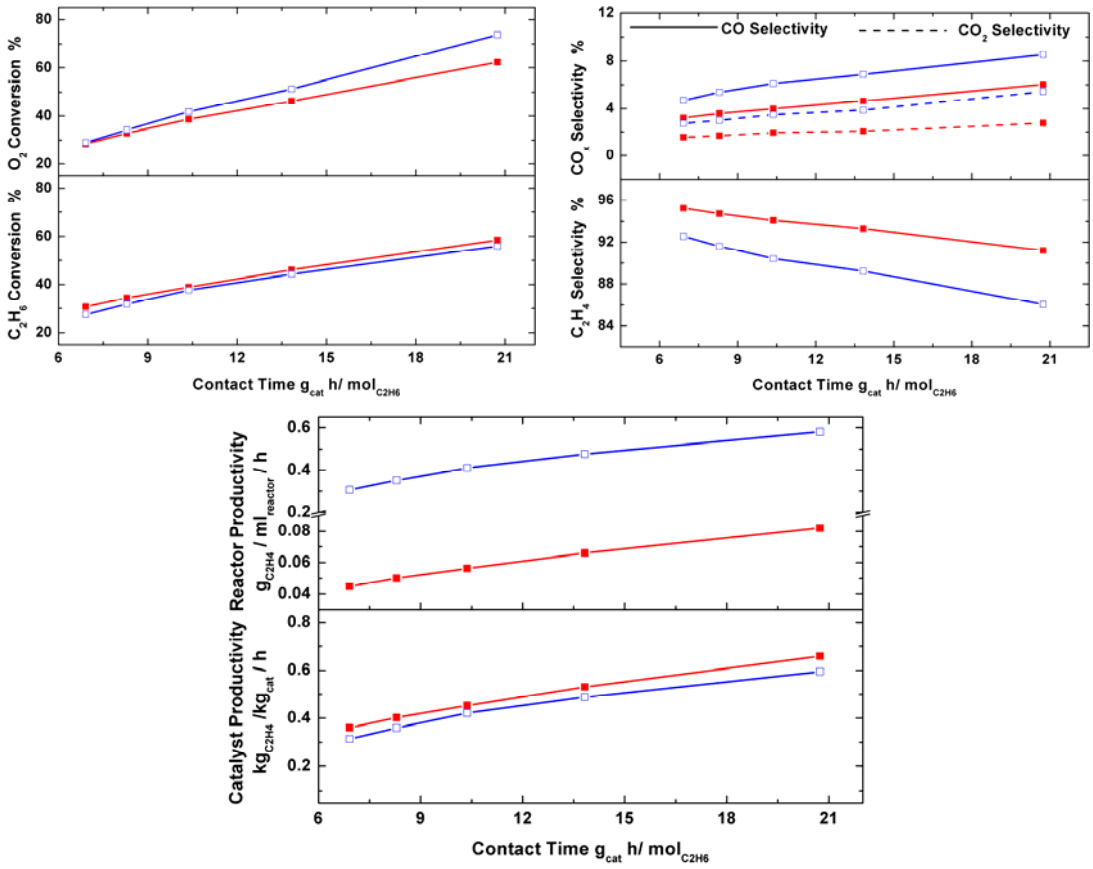

Fig. 2. Ethane and oxygen conversion, ethylene and carbon oxides selectivity, catalyst productivity and space time yield as functions of contact time for M1 catalyst in fixed-bed reactor (■) and in micro-channel reactor (□). Experiments were performed at 400 °C and 1.0 atm with a C_2H_6/O_2/He molar ratio of 30/20/50 at reactor inlet.

4 Conclusions

Catalytic performances of phase-pure M1 $MoVTeNbO_x$ catalysts can be effectively tuned by appropriate post-treatments, showing promising petentials for commercialization of the ODHE process.

Keywords: biodiesel, hydrodeoxygenation, hypercrosslinked, polystyrene

1 Introduction

Last decades the development of tryglycerides (TG) conversion is geared towards the alternative of diesel fuel. The biodiesel is the second in order of inportance type of biofuels [1]. Biodiesel can be used both as pure and as mixture with petrol diesel. The synthesis of biodiesel fuel is based on two processes: (i) transestherification of TG with methanol and (ii) hydroprocessing of fatty acids. The second process allows the producing the fuel similar petrodiesel both the composition and properties [2].

The literature data shows the mechanism of the carboxylic acids conversion to the saturated hydrocarbons through two ways: direct decarboxylation and initial decarbonylation with the formation of olefine and futher hydrogenation of obtained product [3]. The process of catalytic hydrodeoxygenation (HDO) includes both of the passways.

2 Experimental

Synthesis of the Catalyst The HPS fractions with mentioned diameter 60 ~ 100 μm and mass 3 g, previously treated with acetone and dried to the constant weight, were impregnated for 8 ~ 10 min with 6 mL of solvent mixture, consisted of 4 mL tetrahydrofuran, 1 mL of methanol and 1 mL of solution of Na_2PdCl_4 in water. The treated polymers were dried at a temperature 70±2°C for 30 min. Then the obtained samples of catalyst were treated with solution of Na_2CO_3 with concentration 2,76 g/L for 15 min, washed with distilled water and dried for 1,5 hour at a temperature 70±2°C. As the result the metallopolymeric systems with Pd loading 1% (1%-Pd/HPS) were synthesized. The catalysts were previously reduced by hydrogen at a temperature 300°C for 3 hours.

The synthesized catalytic systems were analyzed by transmission electron microscopy, low-temperature nitrogen physisorbtion, X-ray photoelectron spectroscopy.

Hydrodeoxygenation of fatty acids Stearic acid (SA) (ChimMedService, Russia) was used as a model substrate for catalytic HDO. The process was carried out in stainless steel batch reactor (PARR Instrument, USA) varying the pressure 0.2-1.8 MPa, the temperature 230-260°C and SA initial concentration 0.05-0.2 mol/L. Pd-containing catalysts with metal loading varied from 1%(wt.) up to 5%(wt.) based on polymeric matrix of hypercrosslinked polystyrene were synthesized by wet impregnation method. *n*-Dodecane (Sigma Aldrich) was used as the solvent. Liquid samples were analyzed using GC-MS.

3 Results and discussion

The kinetic curves based on the experimental data (Fig.1) were investigated by the method of transformation, which consist of the linear transformation of reaction time by the multiplication of reaction time by the coefficient η [3]. So the complete conjunction of kinetic curves with the curve relevant to the maximum reaction rate was reached out. This curve was chosen as “standard” with η = 1 (see Fig.1, curve 1).

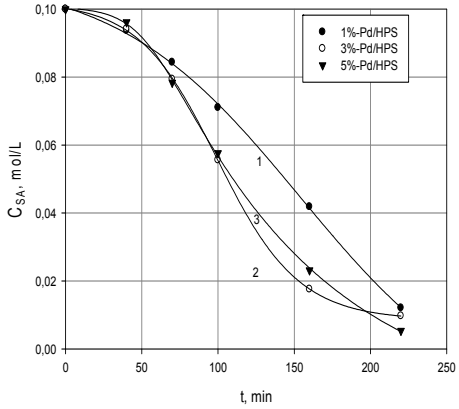

Fig. 1. Kinetic curves of stearic acid hydrodeoxygenation

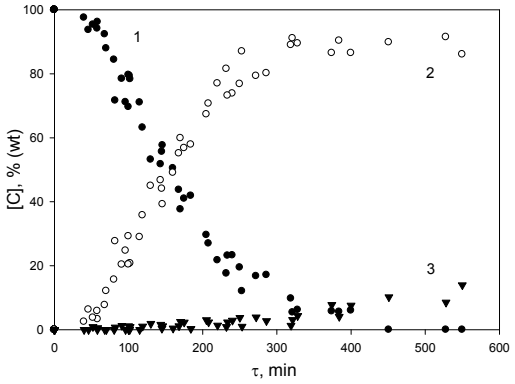

Fig. 2. Transformed curves

It is noteworthy that the linear transformation of the reaction time leads the conjunction of kinetic curves both the SA usage and reaction products formation (Fig. 2).

The data of influence of the catalyst structure on the hydrodeoxygenation rate are shown in Table 1.

Table 1. Activity and physical-chemical properties of the catalysts

Catalyst	Transformation coefficient	Conversion*, %	Selectivity**, %	S_{BET}, m^2/g	D_m, nm	Pd state
1%-Pd/HPS	1	87.9	98.9	1120.0	32.1±0.1	Pd_n (4<n<7) Pd(0)
3%-Pd/HPS	1.26	90.3	98.5	705.0	35.6±0.1	-
5%-Pd/HPS	1.27	94.6	96.2	539.0	7.6±0.1; 25.0±0.1	Pd_n (9<n<13) Pd(0)

*after 220 minutes
**regardig to n-heptadecane

4 Conclusions

Based on the experimental data, the followed conclusions can be done:

- similar mechanism of catalytic influence;
- the processes passing on the catalysts are identical because the kinetic curves of stearic acid and reaction products are completely congruent in the coordinates of concentration – adjusted time ($\tau = \eta \cdot t$);
- the calculated transformation coefficient can be used as the measure of catalytic activity.

High Throughput Testing of Naphtha Reforming Catalysts

Kirchmann M.*, Haas A., Hauber C., Böltken T.

Hte GmbH, Heidelberg, Germany

* marius.kirchmann@hte-company.de

Keywords: naphtha reforming, refinery processes, high throughput, catalyst testing

1 Introduction

Increasing global demands for high-octane fuels, the tightening of environmental regulations and the optimization of refineries has led to an increasing demand for efficient catalyst testing capacity. Catalytic naphtha reforming as one of the key processes is a challenging application for the parallel testing of catalysts due to multi-component feeds with related complex chemistry and varying feed and product properties. Catalytic naphtha reforming is done industrially in different processes and requires for a time-efficient testing approach an accelerated decay protocol for semi-regenerative reforming (SRR) with very slow deactivation whereas continuous catalyst regeneration (CCR) needs a test protocol suitable for relatively fast catalyst deactivation. Another challenge is testing the catalysts under industrially relevant conditions to yield reformate with a constant research octane number (RON).

Herein, we present the latest developments of high throughput technology for testing catalytic naphtha reforming catalysts in 16 parallel reactors under industrially relevant conditions to yield reformate with a constant research octane number (RON). The presentation includes information on appropriate test protocols and the required analytical setup to analyse complex multi-component feeds and products. Research octane numbers (RONs) are calculated based on the distribution of Paraffins / Iso-paraffins / Aromatics / Naphthenes / Olefins (PIANO). In connection with a fully automated data evaluation it will be shown that catalysts can be precisely characterized and differentiated by activity, selectivity and deactivation. The temperature is adjusted automatically for each of the 16 parallel reactors to keep the RON of the reformate or C_{5+} at a constant specified target value for time on streams up to 1000 h.

2 Experimental/methodology

All experiments were carried out in a 16-fold parallel fixed bed reactor system. The unique process control guarantees constant pressure (2-30 barg), flow, feed concentration and temperature (up to 570°C) for very long run-times. The reactor system also allows for sequential start-up of the reactors and product analysis which means that catalysts with different deactivation time-scales can be compared at constant time-on-stream.

3 Results and discussion

The most important performance parameters for reforming catalysts are reformate or C_{5+} yield, research octane number (RON), activity (temperature) and lifetime. Complete on-line GC-analysis identifies more than 130 components in the gas phase. The hydrocarbon distribution of heavy naphtha feed and corresponding reformate is shown in Figure 1 for one exemplary catalyst. It can be seen that paraffins and naphthenes are strongly reduced and converted to aromatics and lights (C1-C4). The RON is calculated from the PIANO distribution by appropriate models and decreases during time on stream due to deactivation of the catalysts.

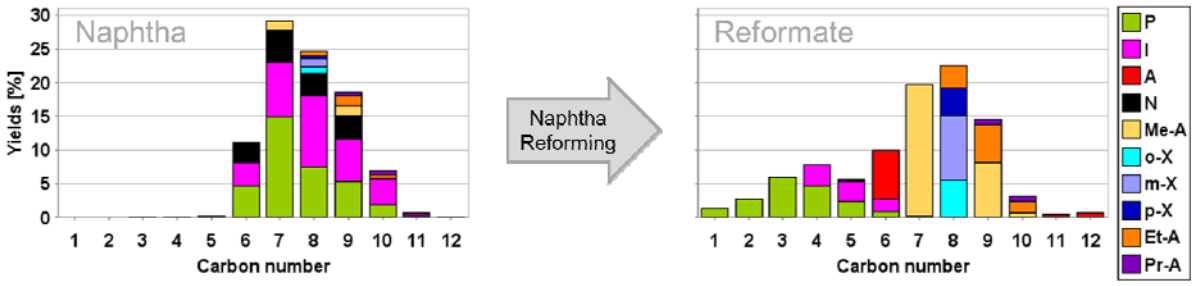

Fig. 1. Product yields of naphtha feed and resulting reformate based on complete on-line gas phase GC-analysis of more than 130 components. Me-A, Et-A and Pr-A indicate methyl-, ethyl and propyl-aromatics. The xylene isomers are abbreviated as o-, m-, and p-X.

In order to keep the octane number constant and operate under *iso*-RON conditions, the temperature is regularly adjusted for each of the 16 parallel reactors by a fully automated data evaluation process. Due to highly optimized naphtha reforming catalysts, the performance parameters of different catalysts are hard to distinguish and require statistical evaluation supported by high-throughput technology for reliable results. Since statistical significance for single-fold pilot plant testing is either limited or time consuming to obtain, high throughput testing of naphtha reforming catalysts can have a real benefit and leads to a precise catalyst differentiation with regard to activity, selectivity and lifetime under industrially relevant conditions.

4 Conclusions

Despite the various challenges, high throughput testing of naphtha reforming catalysts in 16 parallel reactors was achieved successfully under industrially relevant conditions. Detailed hydrocarbon GC-analysis with identification of more than 130 compounds allows a precise product analysis, calculation of PIANO distribution and RON calculation. Utilizing a fully automated data evaluation process, operation under *iso*-RON conditions at a constant specified RON target value is possible for time on streams up to 1000 h and more. In connection with high statistical significance of the results, high throughput testing leads to a reliable and precise catalyst differentiation with regard to activity, selectivity and lifetime.

How Small Catalyst Crystallites Can Be: the Case of Anatase

Yatsenko D.A., Tsybulya S.V., Vorontsov A.V.*

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* voronts@catalysis.ru

Keywords: nanoparticle, facets, crystallinity, XRD, DFT, DFA

1 Introduction

Building adequate models for heterogeneous catalysts is of vital importance for development of insights into the mechanisms of catalytic reactions. Since catalysis research has entered a new phase, marking the end of the era driven primarily by trial and error, theoretical models are being developed that allow not only explaining experimental results but also predicting novel catalysts and their properties. Despite vigorous developments in this field of theoretical heterogeneous catalysis, major issues concerning the effect of particle size on catalyst properties remain mainly unsolved in the small nanoscale domain, where the surfaces, edges and vertices of nanoparticles exert predominant influence on the catalytic and other properties. The present research tries to answer the question what is a minimal size of an oxide nanoparticle which is required for it to be visible as crystallite. Anatase nanoparticles of diverse sizes are taken as examples and their structure and properties are modeled and compared to experimental data.

2 Experimental

Nanoparticles (NP) of anatase with the size up to 3 nm are created by cutting them from the bulk anatase lattice with (001), (100) and (101) facets exposed. The structure of nanoparticles is optimized using density functional theory (DFT) methods as well as modern semiempirical methods for larger particles. X-ray diffraction (XRD) patterns are obtained using computer program DIANNA employing Debay equation [1].

3 Results and discussion

It is clearly demonstrated that there is a minimal size of anatase NP in order for them to show crystallinity that can be measured with XRD and EXAFS. The structure of small NP is very sensitive to the composition of their surface and distribution of hydroxyl groups over it. The crystalline core-amorphous shell structure is typical and agrees well to the experimental data. Even for ideal anatase NP, there is a strong inherent surface heterogeneity.

4 Conclusions

The results of the research can be used for further development of theoretical methods for describing heterogeneous catalytic processes on molecular and atomic scale and prediction of properties of catalytic nanoparticles in the very small domain (< 5 nm).

Catalytic Decomposition of Ammonium Nitrate on Cores of Oil Breeds

Batygina M., Dobrynkin N.*, Noskov A.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* dbn@catalysis.ru

Keywords: ammonium nitrate, core of oil, breed, nitric acid, formic acid

1 Introduction

The application of oil layers heating by the chemical decomposition of a binary mixes (BM) is one of perspective technologies of oil recovery increasing [1]. In the reaction of the BM decomposition hot gases under the pressure get into the oil layers, result in a saturation of oil by gas and the oil viscosity decrease. Due to it the oil can move from the layer to a chink in a mode of the pressure head drainage and then along the chink on a surface in the lift mode. Today the level of BM technology development for oil recovery increasing does not allow carrying out an operated process of ammonium nitrate decomposition. Application of specially developed catalysts and cores of oil breeds as catalysts can become a possible method of control over the process of decomposition.

2 Experimental

The experiments were spent in a glass thermostatic reactor connected with the reflux condenser in the temperature range 40-90°C during 5 hours. Water solution containing the ammonium nitrate, formic and nitric acids was used for ammonium nitrate decomposition. Industrial reforming catalyst AP-56 (0.56% Pt/γ-Al_2O_3) and cores of oil breeds were used as catalysts. The current concentrations of ammonium ions in working solutions were defined by means of universal ionomer EV-74 with use of special ionselective electrode ELIS-121NH_4. The element composition of cores (identified with X-ray phase analysis and X-ray fluorescence analysis), the area of a specific surface (S_{BET}) and a volume of pores are presented in Table 1.

Table 1. Physical and chemical characteristics of the cores

Core	Content of elements, % wt.								S_{BET}, m^2/g	Volume of pores, ml/g
	The easy (<F)	Si	Mg	Al	K	Fe	Na	Ti		
Core - bazalt	65,01	13,53	7,20	6,35	0,20	2,74	0,73	0,33	19	0,0431
Core - clay	56,76	23,76	1,74	8,87	2,35	3,30	1,07	0,41	25	0,0634
Core - sand	65,06	23,73	0,54	6,33	1,44	0,90	1,44	0,22	15	0,0141
	Ca	**S**	**P**	**Mn**	**Ba**	**Ce**	**Sr**	**Cl**		
Core - bazalt	3,52	-	0,09	0,08	-	-	0,15	-	19	0,0431
Core - clay	0,61	0,79	0,07	0,03	0,12	0,02	0,02	-	25	0,0634
Core - sand	0,14	0,08	0,02	-	0,04	-	-	0,06	15	0,0141

3 Results and discussion

We present herein the results of catalytic activity study of cores in ammonium nitrate decomposition. It is shown that catalyst introduction in a reactionary mixture allows to raise a degree of ammonium nitrate decomposition in 3-4 times (Fig. 1) at low temperatures, whereas

the use of catalysts does not effect on ammonium nitrate conversion at high temperatures.

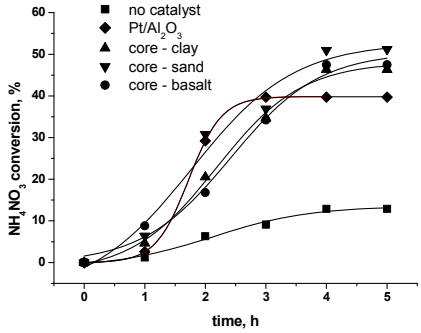

Fig. 1. Ammonium nitrate decomposition at T=51 °C (molar ratio HNO_3 : HCOOH : NH_4NO_3 = 7,8 : 3,4 : 1; HNO_3 : HCOOH = 2.3).

The influence of the ratio of used reagents on ammonium nitrate conversion is investigated at different conditions. The obtained data shows the linear growth of NH_4NO_3 conversion with increase of the content of nitric acid in solution at molar ratio HNO_3: HCOOH = 1. It has been shown that the dependence of degree of NH_4NO_3 decomposition on the ratio of nitric and formic acids represents a curve with a maximum in a point corresponding to the molar ratio HNO3: HCOOH = 2.7. The found value of the maximum is the general for various ratios of nitric acid and ammonium nitrate.

Savara and co-workers found recently [2] that ammonium nitrate decomposition can occur due to its oxidation by nitrous acid:

$NH_4NO_3 + HNO_2 \rightarrow N_2 + HNO_3 + 2H_2O$

The generator of nitrous acid is a system HNO3 - HCOOH in which there is a formation of NO and NO_2 according to the reactions [3]:

$2HNO_3 + HCOOH \rightarrow 2NO_2 + CO_2 + 2H_2O$

$2HNO_3 + 2HCOOH \rightarrow NO + NO2 + 2CO_2 + 3H_2O$

$2HNO_3 + 3HCOOH \rightarrow 2NO + 3CO_2 + 4H_2O$

Emitted NO_2 and NO just form nitrous acid at interaction with water according to the reactions [4]:

$2NO_2 + H_2O \leftrightarrow HNO_3 + HNO_2$

$2NO + HNO_3 + H_2O \leftrightarrow 3HNO_2$

The catalytic activity of core oil-bearing rocks of different nature (basalts, clays, sandstones) observed in the reaction of decomposition of ammonium nitrate for the first time. Activity of natural samples exceeds that of commercial catalyst. The observed regularities are explained on the basis of the proposed mechanism of the reaction.

Areas of Growth of PJSC «Nizhnekamskneftekhim»

Gilmanov Kh.Kh.*

PJSC «Nizhnekamskneftekhim», Nizhnekamsk, Russia

* shakirovams@nknh.ru

Keywords: petrochemical technologies, catalysts

1 Introduction

The level of development of the Russian Federation economy at present is determined to a wide extent by the use in its productions of the state of the art technologies and materials. Petroleum chemistry and refining, being one of the most important branches of economy until the present time maintained their dependence on overseas supplies of a variety of materials and majority of catalysts.

2 Experimental

Today, when sanctions are introduced against Russia over foreign supplies, this issue becomes particularly burning for the petrochemical productions where the majority of processes not only are running in the presence of catalysts, but also determine their economic efficiency.

For PJSC «Nizhnekamskneftekhim», in the productions of which more than 70 imported materials and catalysts are used this situation creates a real threat of shutdown of certain production units.

Therefore, the issues of substitution of import catalysts for domestic equivalents developed jointly with the specialists of R&D organizations and higher educational institutions of the Republic are being closely studied in PJSC «Nizhnekamskneftekhim».

Since 2007 PJSC «Nizhnekamskneftekhim» in collaboration with the specialists of Kazan Federal University is working on catalyst development within the frame of cooperation between high educational institutions and enterprises of real sector of economy and is creating their production facilities in its enterprise premises.

In PJSC «Nizhnekamskneftekhim» all conditions are created for the successful work in this direction – there are proprietary research and technology and design centers, there is a workshop with pilot plants for development of new types of rubbers, qualified specialists with extensive production experience and operation in petrochemical industry.

3 Results and discussion

A Research and Technology Center is a multi-profile research division which is ensuring to a great extent a successful functioning of the company. The Center is developing and introducing new technologies, allowing to provide improvement of the efficiency of operating productions. The technologies for production of chlorobutyl – and bromobutyl rubbers developed in cooperation with OAO «Yarsyntez » specialists, development of SKD-L rubber and SKD-L rubber with low dynamic viscosity, block type DSSK rubber for synthesis of ABS plastics with participation of NIISK specialists that permitted PJSC «Nizhnekamskneftekhim» to completely refuse from purchasing import rubbers for production of impact polystyrene, can serve as an example.

Since 2006, the specialists of the Centre are looking into the matter of import substitution – developing domestic inhibitors and components of catalytic systems:

- the production of neodymium neodecanoate – the main component of the catalytic system for production of SKD-N rubber - has been created in the pilot workshop,

- the technology of concentrated TIBA production has been developed which enabled the company to refuse from the imported components of catalyst for production of polyolefins,
- based on the developments of the Centre the production of more than ten grades of polyethers and polyglycols has been created and mastered.

One of the basic technologies on isoprene direct synthesis from isobutylene and formaldehyde has been developed at participation of a Reseach and Technology Center and a Design Center together with specialists of "Evrochim SPb".

In recent years PJSC «Nizhnekamskneftekhim » actively increases existing capacities of main rubber and monomer production lines and builds up production units to manufacture new product types.

PJSC «Nizhnekamskneftekhim directs significant investments for development of its own catalytic systems and establishment of their production units.

Availability of its own catalyst will provide an opportunity for the Company to solve several important tasks , including:

- energy and raw material resources reduction using more advanced catalysts ;
- provision of process utilization by its own catalyst factory;
- competitive recovery through lower end product cost due to introduction of more effective catalysts ;
- import substitution, i.e. economic security of the Company.

Together with KFU specialists a native iron oxide catalyst for isoamylene dehydrogenation has been developed, its production has been established and catalyst has been introduced into isoprene production.

This catalyst completely replaced import analogues belonging to such famous Companies as Shell and BASF, it is manufactured at PJSC «Nizhnekamskneftekhim » in quantity of 300 tons /year , totally covering demands of the Company.

Isoparaffins dehydrogenation catalyst production of IDC grade has been launched at Mendeleevsky chemical plant named after L.Ya. Karpov. Capacity of this production unit accounts for 1200 tons /year. This catalyst is a substitution of Engelhard Company's import analogue.

More effective isoparaffins dehydrogenation catalyst IDC-M for isobutylene production has been developed and its construction has been completed. Established IDC-M production unit will allow to provide the PJSC «Nizhnekamskneftekhim » Company with microspheric catalyst and replace an out-dated IM-2201.

Within the import substitution frame, developments of n-butylene isomerization catalyst in isobutylene have been carried out. Pilot scale tests (giving positive results) have been performed at one of the isomerization systems of DB and HCC plant. This catalyst has been developed instead of an import analogue of Engelhard Company.

Developments of catalyst of acetylene hydrocarbons' selective hydrogenation in ethane - ethylene fraction, vinylacetylene selective hydrogenation in butadiene fraction, pyrolysis condensate hydrogenation as well as different adsorbent grades for cleaning and drying of hydrocarbon streams are at the finalization stage.

4 Conclusion

Projections for further cooperation between PJSC «Nizhnekamskneftekhim and KFU include development of catalysts of one stage vacuum dehydrogenation of n-butane to butadiene and acetophenone hydrogenation to methyl phenyl carbinol. Particular hopes are laid by the Company on the development of a new course in Kazan (Privolzhskiy) Federal University, i.e. creation of effective native catalysts for polymerization processes. Integration of laboratory and pilot plant capabilities of Research and Technology Center with scientists of the University will allow to guarantee competiveness and economic stability of PJSC «Nizhnekamskneftekhim».

Sensitization of Wide-Bandgap Oxides ZnO and TiO_2 to the Visible Region Using Intrinsic Point Defects, Surface 2D Nanostructures and Composites ZnO/Si, TiO_2/Si

Lisachenko A.A.*

St. Petersburg State University, Department of Physics, Saint-Petersburg, Russia

* a.lisachenko@spbu.ru

Keywords: photocatalysis, ZnO, TiO_2, spectral sensitization, "core-shell", $(Me_x O_y)$/Si nano-composites

1 Introduction

The wide-bandgap oxides TiO_2, ZnO are known to be active in photo-activated adsorption/desorption (PA, PD) of simple molecules and in a lot of redox reactions under irradiation in the near UV. However, the UV part of the solar spectrum does not exceed 4%. Therefore the sensitization to the visible region is a key problem for improving the effectiveness of these photocatalysts. At present, several methods are used to create active sites absorbing visible light, such as molecular chromophore deposition, anion/cation doping, pretreatment in plasmas of Ar, N_2 or H_2.

Previously, we have shown that intrinsic defects of F- and V-type can be used for to "self-sensitize" wide-bandgap oxides – insulators (BeO, Al_2O_3, MgO) and semiconductors (ZnO and TiO_2). Light absorption by these centers provides photoactivity in reactions of simple molecules (H_2, O_2, CO, CO_2, N_xO_y) in the sub-bandgap region.

The present report aims to enhance the effectiveness of F- and V-type by designing the near surface 2D structures consisting of these centers. Another aim was to design the composites ZnO/Si and TiO_2/Si.

The key features of the gas–solid interface photonics are revealed and exemplified by a number of heterogeneous systems: simple molecules (H_2, O_2, CO, CO_2, NO, N_2O) adsorbed on wide-bandgap metal oxides (BeO, Al_2O_3, MgO, ZnO and TiO_2). The emphasis is focused on the sub-bandgap excitations.

We investigate the sensitization of ZnO and TiO_2 using their intrinsic colored defects, 2D "core-shell" nanostructures ZnO/ZnO_{1-x}, TiO_2/TiO_{2-x} and composites ZnO/Si, TiO_2/Si. Photocatalytic reactions of $NO + CO = 1/2N_2 + CO_2$ and photo-induced isotope oxygen, as well as photo-adsorption/desorption of simple molecules (H_2, O_2, CO, CO_2, N_xO_y) are studied.

2 Methodology

In order to reveal the mechanisms of physical and chemical steps, the *in situ* investigations were carried out in the three phases: gas – adsorbate – surface. A variety of complementary *in situ* experimental methods for step-by-step investigations were used:

– mass-spectrometry (spectro-kinetic investigation in the gas phase, thermo-desorption spectroscopy of adsorbed species);
– optical (UV-VIS-IR, FTIR spectroscopy, photo- and thermo-stimulated luminescence);
– ESR spectroscopy of active centres and of adsorbed species;
– UV(8.43eV) photoelectron spectroscopy.

SEM, XRR, XRD, XPS, UPS methods were used for samples characterization.

The photo-desorption under UHV, the photo-adsorption and the photochemical reactions in the gaseous phase were studied using the static and the "flow-through" regime. The use of the isotope enriched molecules reveals the dynamics of photo-desorption/adsorption processes [1].

3 Results and discussion

The photocatalytic reduction of NO by CO into N_2 was performed at room temperature in static regime at 0.01-0.5 Torr. It is concluded that the photocatalytic activity of nonstoichiometric TiO_{2-x} in the visible region is associated with the localized electron-donor centers (Ti^{3+} ions, F and F^+ centers).

It is shown that under VIS irradiation e^- and h^+ are generated in pairs as in the case of UV irradiation. That is possible, if the structures "core-shell" TiO_{2-x}/TiO_2 are formed on the part of the surface thus decreasing the bandgap to 2.9 eV. The surface potential in "core-shell" TiO_{2-x}/TiO_2 is the result of superposition of the Schottky barrier in the TiO_2 meso-structure and of the near-surface quantum well potential of the reduced oxide TiO_{2-x}. The latter potential decreases the E_g value on the surface that explains the VIS activity. In the near-surface energy quantum well the energy levels are discrete, that explains the long lifetimes of the excited states and as a consequence the slow processes, the "memory" effect in the photo-adsorption and the photo-reactions for this oxide. The values of the quantum yield of the process in the visible region are measured. The quantum yield of Photo-induced Oxygen Isotope Equilibration (POIEq) in the sub-bandgap absorption region is ~30 times higher than in the fundamental absorption region of TiO_2.

Nano-layers of ZnO (thickness 2–100 nm) were deposited on the surface of *p*-Si(100), SiOx/*p*-Si(100) and *n*-Si(111) using the atomic layer deposition (ALD) technique. It was found that the illumination of the ZnO/*p*-Si(100) films with visible light ($\lambda > 500$ nm) in the oxygen flow results in the release of H_2O vapor and CO_2 as evidenced by the mass-spectrometry. No release of H_2O and CO_2 was detected if the bare silicon plate was illuminated in similar conditions. Therefore, a conclusion about the photocatalytic decomposition of the surface organic contaminations under the excitation of ZnO/Si system with visible light can be drawn.

4 Conclusions

Based on the obtained results we can expect that "self-sensitization" of $ZnO/ZnO_{1-\delta}$ and TiO_2/TiO_{2-x} based photocatalysts using the intrinsic point defects and the near-surface 2D-nanostructures is a real way to optimize the design of efficient photoactive catalysts for the use of solar energy. The silicon acts as a spectral sensitizer of ZnO film to the visible light. Thus the composites ZnO/*p*-Si(100) can be used as effective photocatalyst in UV-VIS region.

Comparing Alkylation of 3,4 Dimethylphenol with Propanols and Propenes into Oxide Catalyst

Aghayeva N.A.[1*], Taghiyev D.B.[2], Aghayev A.A.[1]

1 - Sumgayit State University, Sumgayit, Azerbaijan
2 - University of Catalysis and Inorganic Chemistry, Baku, Azerbaijan

* anazila88@gmail.com

Keywords: alkylation, 3,4 dimethylphenol, propanol-1, propene, cobalt, ferrite, catalyst

1 Introduction

Alkylation of aromatic compounds,in particular phenol with the alcohols and olefins is the most suitable method for producing their derivatives.Alkylphenols in particular propyl and isopropyl derivatives of methyl- and dimethylphenols finds its application in the preparation of medicaments, vitamins , fragrances , antioxidants and polymer materials for special purposes (ref 1)

2 Experimental

In report the results for investigation of alkylation reaction 3,4 dimethylphenol with propanol-1, proponol-2 and propene on Cobalt ferrite oxide catalyst were shown.Catalyst was synthesized by joint deposition of nitrate and oxalate salts of Co (II) и Fe (III) onto γ-Al_2O_3, followed by drying and calcination. The preliminarily found optimal content of $CoFe_2O_4$ in the catalyst is 22 wt %.Synthesized catalysts chemically homogeneous and have finely porous ferrite particles with mixed spinel structure.

The experiments carried out in reactor with fixed bed of ferrite catalyst, the volume of which is 10 cubic centimeter. Constituents of catalyst were analyzed via chromatographic and spectral methods.

3 Results

The impact of tempreture, load unit, mol ratio of initial components and hydrodynamic regime of the reactor on indicators of alkylation reaction between 3,4 dimethylphenol , propanols, and propene was investigated.

The content of produced catalyst depends on conditions of reactions and the structure of alkylation agent. The main products of alkylation reaction of 3,4 dimethylphenol with propanol-2 are 2 propyl 4,5 dimethyl and 2,6 dipropyl 3,4 dimethylphenol. In case of reaction 3,4 dimethylphenol with propanol-2 in presence of 2- isopropyl-4,5 dimethylphenols in alkyls prevails. Alkylation of dimethylphenols by propenes proceeds with low velocity and in result 2-isopropyl-4,5 dimethylphenol, trimethylphenol and ethyl-xylenol are formed.

The further regularities of comparative alkylation of 3,4 dimethylphenol with propanol and propene were identified (table)

Table1. Comparing results of alkylation of 3,4dimethylphenol with propanol and propene

Name		**Alkylation agent**		
Main product yield of the reaction per reacted 3,4 dimethylphenol %	**Propanol-1**	**Propanol-2**	**Propene ***	
-propyl ether 3,4 dimethylphenol	5.5	-	-	-
-2 propyl 4,5 dimethylphenol	83,0	-	3.5	-
2-isopropyl 4,5 dimethylphenol	-	87	70.5	73.5
3- isopropyl 4,5 dimethylphenol	-	3.5	7.4	10.8
2,6 dipropyl 3,4 dimethylphenol	7.5	-	-	-
Conversion of 3,4 dimethylphenol %	45.5	36,0	3.0	7.5

Conditions: T=330C, V=1h^{-1}, μ=1:1mol/mol

*results getting in autoclave, reaction time 3 hours.

- Alkylation ability of used agents is reduced in order :Propanol-1 > propanol- 2> propene
- selectivity of reaction of 2 propyl(isopropyl) 4,5 dimethylphenol is increased in order: Propene >propanol-2 >propanol-1
- Output of product 2 propyl(isopropyl) 4,5 dimethylphenol is increased in order: Propen >propanol-2 >propanol-1
- Alkylation of 3,4 dimethylphenol with propanol-1 is going by parallel-serial mechanism. In condition of catalyst O-(oxigen), C (carbon) alkylation of Xylenol is occurs , while in case of propanol-2 O-alkylation not present.

4 Conclusion

It was shown the high ortho-alkylation ability of Cobalt ferrite catalyst in alkylation reaction of 3, 4 dimethylphenol with propanol and low catalytic activity in reaction of 3,4 xylenol with propene.

Knowledge Extraction for Oxidative Coupling of Methane from Publications in the Literature

Odabaşı Ç., Yıldırım R.*

Boğaziçi University, Department of Chemical Engineering, Istanbul, Turkey

* yildirra@boun.edu.tr

Keywords: oxidative coupling of methane, data mining, knowledge extraction, support vector machine

1 Introduction

The conversion of methane to more useful chemicals and fuels is a big challenge in catalysis field, and the oxidative coupling of methane (OCM) is one of the most studied processes for this purpose. OCM yield seems to depend on very large number of variables such as catalyst type, preparation and operation conditions; a huge amount of data was generated in literature to investigate the effects of these variables on the process yield. However, due to the complexity of relations among the large number of variables, the major trends and correlations in the literature cannot be effectively identified with traditional approaches. We need more systematic and effective approaches and tools to extract knowledge from such a complex literature.

Data mining is a field of computer science to extract knowledge from a database. It helps to spot the patterns that are too hard to detect with the naked eyes, and use these patterns to derive conclusions or make predictions using classification, clustering and estimation techniques. This approach could be used in the field of catalysts to extract knowledge from the publications in the literature as it was tested in previous works [1-3]. One of the most popular data mining techniques is the support vector machine (SVM), which can be used for both classification and prediction [4].

The aim of this study is to build a SVM model for the lanthanum based catalysts [5-6], which are among the promising alternatives, using the published data in the literature.

2 Experimental/methodology

I Database generation

A detailed research has been performed on the published works on OCM reaction, which can be reached online (mostly in the databases of Web of Science, Springer, Elsevier and American Chemical Society). Exactly 34 of them were found to be suitable for data extraction and used for database generation (remaining articles were not suitable to extract data that fit our purpose).Then, a database containing 525 experimental data was prepared covering the effects of various conditions on C_2 yield.

II Computational Work

Data was standardized to bring all of the variables into proportions with each other. Then, support vector machine method was implemented to extract knowledge from the database. Standardization and the organization of the database were performed in Matlab 2014a while the SVM model was build using Weka 3.7.7 which is a user-friendly data mining software.

First, the SVM parameters (C, γ) were optimized by using the whole dataset; the parameter set, which gives the minimum root mean square error (RMSE), was selected. Then, to test the predication ability of the model; the data belonging one publication was removed from the data set, a model was re-built using the remaining publications and used to predict the one publication that was removed from the data set. The same procedure was repeated for all publications.

3 Results and discussion

Parameters (C, γ) were optimized by using 5 fold cross validation on the whole dataset and the parameter set was found a (80, 0.1). The optimum parameters were used to predict the data in the whole database and the results were shown in Figure 1(a); the experimental data points could be predicted correctly with a small error percent.

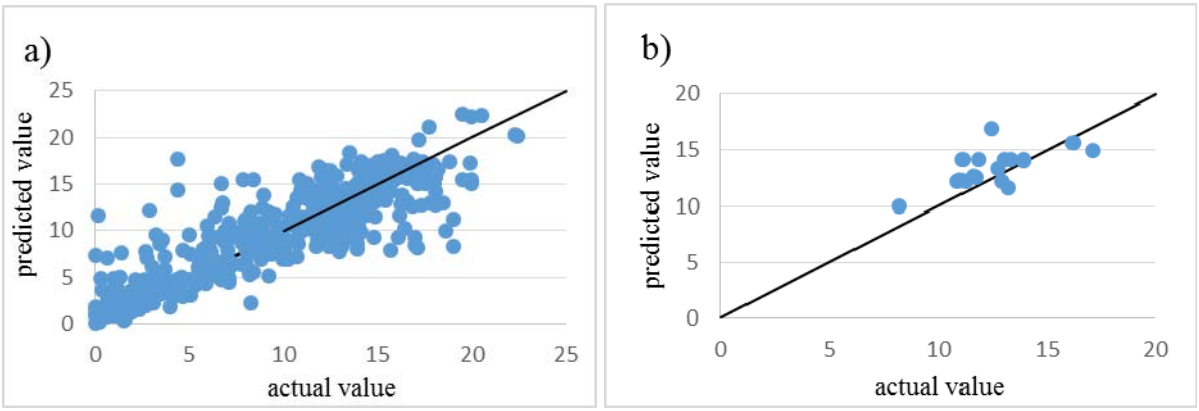

Fig. 1.a) Modelling of training set with optimal parameters (80, 0.1) b) Prediction of the unseen data points with their optimum parameters [7]

Figure 1(b) shows an example for the analysis performed for individual publications. The actual values were the C_2 yields drawn from that publication while the predicted values refer to the model predictions for the experimental conditions at which the actual results were reported. The results were quite satisfactory considering that the predictions were performed by using a model that is constructed from the other publications in the literature.

4 Conclusions

It can be concluded that data mining tools can be indeed very beneficial to analyze the past data to extract knowledge for OCM reaction as well as other similar systems with large number of publications in the literature.

Keywords: heterogeneous catalysis, vegetable oil, alkanes, olefins, algae

1 Introduction

In TIPS RAS was found that ethanol [1] and rapeseed oil [2] could be converted into a number of fuel hydrocarbons over industrial Pt/Al_2O_3 catalyst. Aim of the current work is ethanol and rapeseed oil high selective conversion into fuel components and monomers over $Pt\text{-}Sn/Al_2O_3$ catalysts with different molar ratio of active components.

2 Experimental/methodology

For catalytic experiments the original catalyst containing 0.4 wt % Pt and 0.75-1.2 wt % Sn was prepared by incipient wetness impregnation of $\gamma\text{-}Al_2O_3$ with a solution of the heterometallic complex $(PPh_4)_3(Pt(SnCl_3)_5)$ in dichloromethane [3]. Prior to each experiment, the catalyst was treated with hydrogen for 14 h at 450°C. Catalyst testing was performed in a PID Eng & Tech microcatalytic fixed-bed flow reactor unit, equipped with relevant instrumentation and control devices, under pressure 50 atm of H_2, temperature 400-480 °C, and substrates space velocity in the range of 1.2 h^{-1}. Both gaseous and liquid organic products in aqueous and organic phases were identified by GC-MS. The local structure and charge state of platinum were studied by XAFS spectroscopy.

3 Results and discussion

Over $Pt\text{-}Sn/Al_2O_3$ catalysts ethanol converts into alkanes and olefins C_3-C_8 fraction (Fig. 1). Over $1Pt\text{-}1Sn/Al_2O_3$ catalyst ethanol mainly converts into methane and carbon oxides. Total yield of hydrocarbons C_3-C_8 did not exceed 16 wt.%. Over$1Pt\text{-}3Sn/Al_2O_3$ catalyst aim fraction yield increased up to 23 wt.%. Oxygenates dominates among ethanol conversion products generally consisted of diethyl ether.

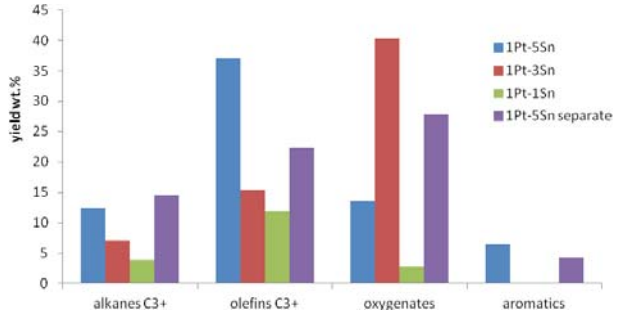

Fig. 1. Ethanol conversion products over Pt-Sn-containing catalysts.

Over 1Pt-5Sn/Al_2O_3 catalyst the maximum yield of hydrocarbons C_3-C_8 was obtained equal 50 wt.% calculated on passed carbon. Also aromatics were obtained with yield of 6 wt.%. C_1 products yield did not exceed 2.5 wt%. It should be noted that monometallic catalyst Sn/Al_2O_3 is not active in ethanol conversion into hydrocarbons. Consequently Sn content in Pt containing catalyst led to significant changes in ethanol conversion into hydrocarbon fuel components and olefins.

Rapeseed oil conversion over Pt-Sn/Al_2O_3 catalysts were investigated. Over 1Pt-5Sn/Al_2O_3 the highest yield of C_{3+} hydrocarbons was reached equal 99.5 wt.% from which 84 wt.% was C_{18} fraction and 4.5 wt.% C_3-C_4 fraction (Fig.2). Among C_{18} fraction was found 23 wt.% of olefins of which 7-10 wt.% were linear alpha olefins. Products of cracking and decarboxylation processes did not exceed 8 wt.%. Moreover, total yield of C_1 products (methane, carbon oxides) observed lower then 0,1 wt.%. Over 1Pt-1Sn/Al_2O_3 catalyst significant yield of alkane C_{17} was observed equal 30 wt.% while over 1Pt-3Sn/Al_2O_3 decarboxylation process significantly decreasing and alkane C_{17} yield was only 5 wt.% but hydrocarbons C_1-C_4 yield reaches 25 wt.%.

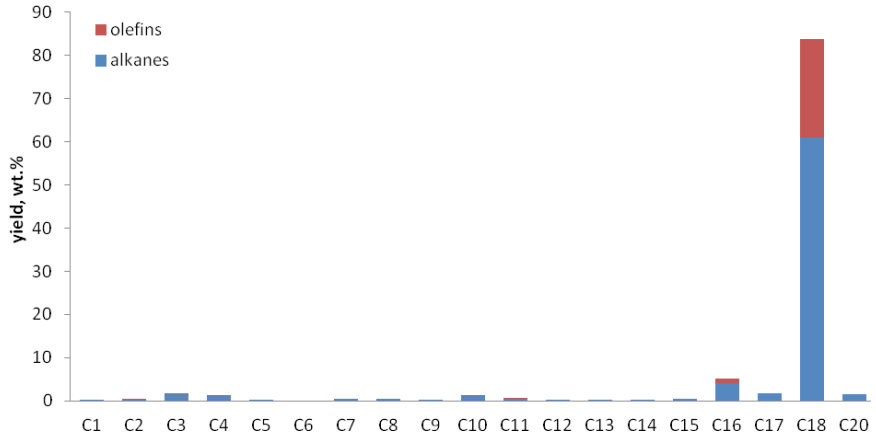

Fig. 2. Composition of the products of rapeseed oil hydrogenolysis in the presence of the 1Pt-5Sn/Al_2O_3 catalysts.

4 Conclusions

The most prospect catalyst for ethanol and rapeseed oil conversion was found to be 1Pt-5Sn/Al_2O_3. Over that carbon mass of initial oil could be converted into alkanes and olefins with only two C_{18} and C_3-C_4 fractions. So selective process may be only when oxygen of initial oil converts in water. Optimal conditions for ethanol conversion were found, that provides yield of alkanes and olefins C_3-C_8 up to 50 wt.%. Obtained results allow minimizing loss of initial carbon weight due to cancelation of carboxyl fragment of fatty acids and glycerol conversion into methane and carbon oxides.

Novel Catalytic Route for the Oxidative Dehydrogenation of Ethane and Propane over CeO_2-Based Catalysts

Kang J., Xie Q., Yu F., Zhang Q., Wang Y.*

State Key Laboratory of Physical Chemistry of Solid Surfaces, Collaborative Innovation Center of Chemistry for Energy Materials, National Engineering Laboratory for Green Chemical Productions of Alcohols, Ethers and Esters, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, China

Keywords: lower alkanes, lower olefins, oxidative dehydrogenation, cerium oxide

1 Introduction

Lower olefins, mainly ethylene and propylene, are among the most important building-block chemicals. The depletion of crude oil has stimulated the development of non-petroleum routes for the production of light olefins. The production of lower olefins from lower alkanes has attracted much attention under the current background of the emergence of large quantity of shale gas. The non-oxidative dehydrogenation of lower alkanes is strong endothermic and thermodynamically limited reactions. In contrast, oxidative dehydrogenation is an exothermic reaction and can be performed at moderate temperatures. However, the selectivity of lower olefins is usually very limited at a considerable alkane conversion due to the deep oxidation, i.e., the formation of CO and CO_2 (CO_x), in the presence of O_2. To increase the olefin selectivity at a high alkane conversion is a particularly challenging task.[1, 2] We developed a new two-step route for the transformation of CH_4 into C_3H_6 via CH_3Cl and found that CeO_2 was an efficient catalyst for the oxidative chlorination of CH_4 to CH_3Cl.[3] Recently, we discovered that CeO_2 could catalyze the direct formation of C_2H_4 or C_3H_6 from C_2H_6 or C_3H_8 with high selectivity in the presence of HCl and O_2. Here, we report this new catalytic system for the oxidative dehydrogenation of C_2H_6 and C_3H_8.

2 Experimental

CeO_2 nanocrystals with different morphologies were synthesized by a hydrothermal method. The modified CeO_2 catalysts were prepared by the impregnation. The catalysts were characterized by various techniques including XRD, SEM, TEM and H_2-TPR. The catalytic reaction was performed on a fixed-bed flow reactor operating at atmospheric pressure. The products were analyzed by on-line gas chromatography.

3 Results and discussion

We first investigated the catalytic performances of various metal oxides including La_2O_3, CeO_2, Eu_2O_3, Nd_2O_3, Dy_2O_3, Tb_4O_7, Fe_2O_3, Co_3O_4, CuO, V_2O_5, Al_2O_3 for the oxidative dehydrogenation of C_3H_8 in the presence of HCl and O_2 and found that CeO_2 exhibited the highest C_3H_6 yield. Over CeO_2 nanorod catalyst, C_3H_6 yield could reach 21.3% with a C_3H_6 selectivity of 56% at 773 K. We investigated the effect of various modifiers on catalytic performances of CeO_2 nanorods. Several modifiers such as MnO_x, MgO, MoO_x, V_2O_5, CuO, could further enhance C_3H_8 conversion or C_3H_6 selectivity (Fig. 1). The C_3H_6 selectivity could be improved significantly over the MoO_x-modified CeO_2 nanorod. The C_3H_6 yield could reach 45% with a C_3H_6 selectivity of ~80% over the 8 wt% MoO_x-CeO_2 catalyst under the optimum condition. To the best of our knowledge, this is highest C_3H_6 yield achieved to date for the oxidative dehydrogenation of C_3H_8.

We clarified that HCl played a critical role in selective formation of C_3H_6. The presence of HCl not only enhanced C_3H_8 conversion but also changed product selectivity significantly over the 8 wt% MoO_x–CeO_2 catalyst (Fig. 2). CO_2 was the main product in the absence of HCl. The increase in the partial pressure of HCl significantly decreased the selectivity to CO_2 and increased that to C_3H_6. Thus, the presence of HCl is required for the selective formation of C_3H_6.

To understand the reaction pathway for the formation of C_3H_6, we investigated the effect of the contact time (*W/F*) on product selectivities at 773 K. The results showed that the selectivities to C_3H_6 and C_3H_5Cl decreased and that to CO_x increased with increasing the contact time. This suggests that C_3H_6 and C_3H_5Cl may be formed as a primary product directly from C_3H_8, and CO_x was the secondary products. Further studies are needed to clarify the C_3H_6 formation mechanism.

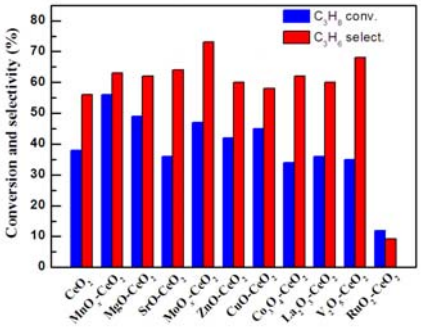

Fig. 1. Catalytic performances of the modified CeO_2 nanorods in the presence of HCl and O_2. Reaction conditions: catalyst, 0.1 g; $P(C_3H_8)$ = 18 kPa, $P(O_2)$ = 18 kPa; P(HCl) = 10 kPa; F = 48 mL min^{-1}; T = 773 K.

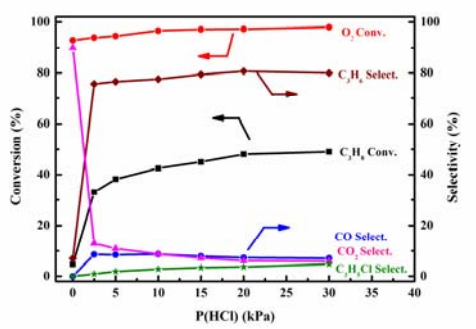

Fig. 2. Effect of HCl partial pressure on the catalytic performance of the 8 wt% MoO_x-CeO_2 catalyst. Reaction conditions: catalyst, 0.2 g; $P(C_3H_8)$ = 18 kPa; $P(O_2)$ = 9 kPa; F = 48 mL min^{-1}; T = 773 K.

We also investigated the oxidative dehydrogenation of C_2H_6 over the CeO_2-based catalyst in the presence of HCl. The yield of C_2H_4 reached ~70% over the 8 wt% MnO_x–CeO_2 catalyst at 723 K. Our catalyst was also very stable and no significant decreases in both C_2H_6 conversion and C_2H_4 selectivity were observed during a 100 h reaction.

We did not observe the formation of Cl_2 during the reaction. H_2-TPR studies showed that the reduction of Ce^{4+} to Ce^{3+} could occur under the reaction conditions. We propose that HCl is activated on catalyst surfaces, generating an active Cl species, which accounts for the selective formation of C_3H_6 or C_2H_4. We speculate that the reduction of Ce^{4+} to Ce^{3+} plays a key role in the activation of HCl to form an active Cl species. The additive, i.e., MoO_x or MnO_x may participate in the reoxidation of Ce^{3+} to Ce^{4+} by O_2.

4 Conclusions

We developed a novel catalytic route for the oxidative hydrogenation of C_3H_8 to C_3H_6 and C_2H_6 to C_2H_4 at moderate temperatures in the presence of HCl. CeO_2 was found to be an efficient catalyst and the modification of CeO_2 by MoO_x or MnO_x further enhanced the formation of C_3H_6 or C_2H_4. The 8 wt% MoO_x–CeO_2 catalyst provided the highest C_3H_6 yield, which approached 50%. We suggest that the redox between Ce^{4+} and Ce^{3+} plays a key role in the activation of HCl to form an active Cl species for lower alkane activation.

Single-Step Hydrotreatment of Lipids to Produce High Quality Biofuel

Wang C., Tian Z.*, Qu W., Li P., Ma H., Xu R.

Dalian National Laboratory for Clean Energy, Dalian Institute of Chemical Physics, Dalian, China

* tianz@dicp.ac.cn

Keywords: lipids, biodiesel, biojet, deoxygenation, isomerization

1 Introduction

Lipids can be converted to biodiesel or biojet fuel via hydrotreatment process. Generally, the existing technology consists of two steps, in which the deoxygenation of lipids to *n*-alkanes and isomerization of *n*-alkanes to *iso*-alkanes are carried out separately, and this will consume considerable hydrogen and energy. To combine the deoxygenation and isomerization reactions in a single step is attractive. However, big amount of water produced in the deoxygenation reaction will poison the isomerization catalyst, which make the single-step process very difficult to be carried out. In this work, a single-step hydrotreatment process for producing biodiesel or biojet fuel from lipids by using bifunctional catalysts was devised, and mechanism of the reactions and structure-activity relationship of the catalysts were also discussed.

2 Experimental

The Pt/zeolite catalysts used for the single-step hydrotreatment process were prepared by impregnation method. Zeolite such as SAPO-11, ZSM-22, ZSM-23, ZSM-5 or Beta was used as the support. The catalytic process was carried out in a 10 mL fixed-bed reactor. The soybean oil was used as feedstock, and the reaction conditions were as follows: 300-380 ^{o}C, 1-8 MPa and 0.2-30 h^{-1}(LHSV). After 3 h reaction, the products were collected and analyzed by GC-MS. The catalysts were characterized by XRD, N_2 adsorption, FT-IR, Pyridine-IR, NH_3-TPD, TPR, XPS, H_2-chemisorption and so on. For the bench-scale evaluation, a 100 mL fixed-bed reactor was used and the reaction conditions were as follows: 330-370 ^{o}C, 4-6 MPa and 1.0 h^{-1}(LHSV).

3 Results and discussion

Table 1 presented the catalytic performance of the catalysts prepared by using six zeolite supports. It can be found that high liquid yields were obtained over the mildly acidic catalyst such as Pt/S1, Pt/S2, Pt/S3 and Pt/Z3. Meanwhile, high selectivity of isomerization was obtained over Pt/S1, Pt/Z1 or Pt/Z2 with more medium and strong Brønsted acidity.

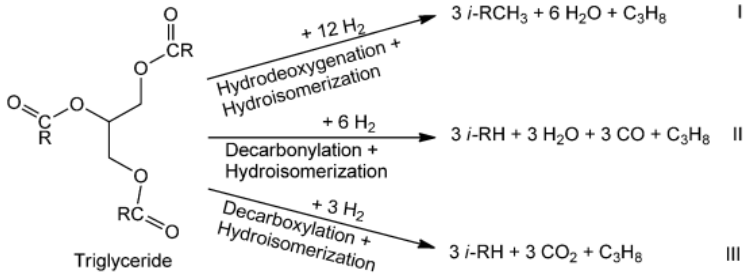
Table 1. Effect of the acidity of the catalyst

Catalyst	Str. L acidity ($\mu mol_{Py}.g^{-1}$)	Med. & Str. B acidity ($\mu mol_{Py}.g^{-1}$)	Catalytic performance			
			Liquid yield (%)	S_{alkane} (%)	$S_{isomerization}$ (%)	C17/C18
Pt/S1[a]	16.8	19.6	92.4	100	63.3	2.4
Pt/S2	7.0	6.7	93.3	100	13.4	3.3
Pt/S3	0.4	0.9	91.9	93.1	5.4	10.2
Pt/Z1	32.5	132.2	57.7	100	84.3	2.5
Pt/Z2	36.7	132.1	63.3	99.2	80.3	1.7
Pt/Z3	1.0	12.4	92.8	96.7	14.7	5.0

[a] SAPO-11 and ZSM-22 zeolite supports without treatment are named S1 and Z1, respectively. The supports after acid-treatment are named S2 and Z2, and those after alkali-treatment are named S3 and Z3.

The reaction scheme of the single-step process is illustrated as Scheme 1[1-4]. There are three parallel pathways including decarboxylation, decarbonylation and hydrodeoxygenation when

lipids are deoxygenated to *n*-alkanes. As mentioned above, water produced in the deoxygenation step is harmful to the isomerization catalyst. Therefore, pathways II and III are more favorable, since the decarboxylation and decarbonylation reactions will produce less water and consume less hydrogen. The ratio of C17 yield to C18 yield (C17/C18) was used to define the ratio of decarboxylation plus decarbonylation versus hydrodeoxygenation. As shown in Table 1 and Fig. 2, it was found that the C17/C18 was significantly influenced by the strong Lewis acidity of the catalyst. Over the catalysts with less Lewis acidity such as Pt/S3 or Pt/Z3, the C17/C18 reached more than 5, which was much higher than that over other catalysts. These results indicated that more decarboxylation (or decarbonylation), isomerization reactions and less cracking reactions will proceed over the catalyst with more medium Brønsted and less strong Lewis acidity[2].



Scheme 1. Plausible reaction pathways of the single-step hydrotreatment

Based on the above results, a bi-metals/zeolite catalyst was developed, and the process was scaled-up in a 100 mL fixed-bed reactor in more than 1000h run (As shown in Fig. 3). The catalyst showed good stability and the product showed excellent properties. The freezing point and octane number of the biodiesel (>290 °C distillate) reached -30 °C and 75, respectively, while the freezing point of the biojet (130~290 °C distillate) reached less than -50 °C .

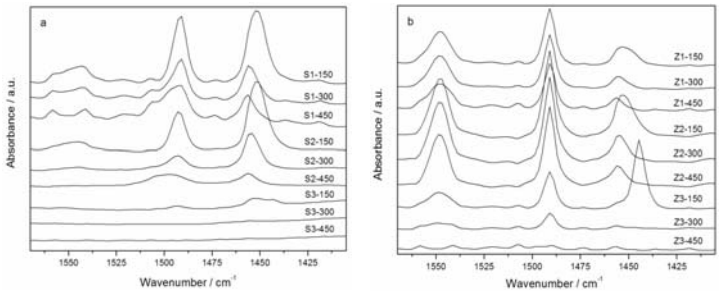


Fig. 2. Pyridine IR spectra of SAPO-11 and ZM-22 supports
S1-150 represents the S1 sample at a pyridine desorbed temperature of 150 °C

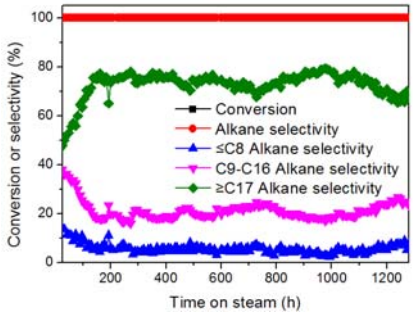

Fig. 3. 100 mL bench-scale evaluation

4 Conclusions

A single-step hydrotreatment process to produce biofuel from lipids was developed, which will perhaps overcome the main problems such as high consumption of hydrogen and energy in the existing processes[5]. Under the drive of traditional energy consumption, this processes will provide new solutions for effective conversion of biomass to liquid fuels.

Keywords: heavy oil, restructuring, nanocatalysts, ultrasonic treatment

1 Introduction

Carbon nanomaterials - carbon nanotubes, nanofibers, 3d-metal carbides, nanodiamonds are represent the latest generation of nanosystems. Metal carbides, nanodiamonds are widely known for their ability to catalyze reactions of isomerization, aromatization, hydrogenation but has never before been used as independent catalysts of thermal cracking of heavy oil feedstocks.
At present days scientific direction that can adjust processes crude oil processing through the optimization of the structural composition of the oil disperse systems are actively developing.
The subject of this work was to determine the catalytic activity of nanocarbon systems in the process of thermal cracking of petroleum fractions and thereof residues in synchronous restructuring of oil dispersion system under ultrasonication.

2 Experimental

As an object of research were used Kaliningrad oil fractions (density 0.884 g / cm3, the total sulfur content is 0.053%).This vacuum gas oil (360-470 ° C) and heavy residue (boiling above 380 ° C).Weight of the sample of oil fraction in one experiment is 5 g.Thermal cracking of petroleum feedstock was processed in steel autoclave (volume 10 cm3) in a batch mode in an argon atmosphere at 450 ° C and pressure 0.5-0.7 MPa, the process duration was 120 or 180 minutes.As catalysts were used multilayer carbon nanotubes (catalytic gas-phase pyrolysis of ethylene), 3d-metal carbides, nanodiamonds (ND is products of recycling blasting agents), molybdenum disulfide (mechanical activation during 8 h. in inert atmosphere).Weightofthecatalystinoneexperimentis0.3g (about 6% by weight of the objects which was loaded into the reactor).Qualitative and quantitative composition of the gaseous and liquid products of the cracking of petroleum feedstock were determined by gas chromatography and the gravimetric method. Ultrasonic treatment of the samples was carried out in the ultrasonic disperser (UD-20).

3 Results and discussion

In actual conditions of an atmospheric distillation of heavy oil residue after autoclaving (thermal cracking at 450 ° C for 2 hours) there was no light fractions in temperature range 60-220 ° C.However, pretreatment of the sample in the ultrasonic, followed by autoclaving it under the conditions described above provides output of light fractions in amount of 7% by weight.At the same time, the joint ultrasonic treatment of heavy oil residue and nanocatalyst ensures the formation of light products of thermal cracking at 45-55% depending on the type of catalyst.It gives reason to suppose that the structure of heavy oil residue is changing by ultrasonic waves in the presence of nanosystems in the more favorable direction to proceeding of thermal cracking reactions, rather than under another conditions (ultrasonic treatment of heavy oil residue and subsequent addition of nanocatalyst).As can be seen from the histogram shown in

Figure 1, the highest output of light fractions, ceteris paribus, is observed in the presence of nanocatalysts ND+MoS2, and amounts to 55.2%. Slightly less output for multilayer nanotubes - 49.2%; for WC - 44,3%, for ND - 38.8%.Thus, the amount of gases produced in the specified series changes in the range of 2-5% and the amount of formed coke is less than 1%.

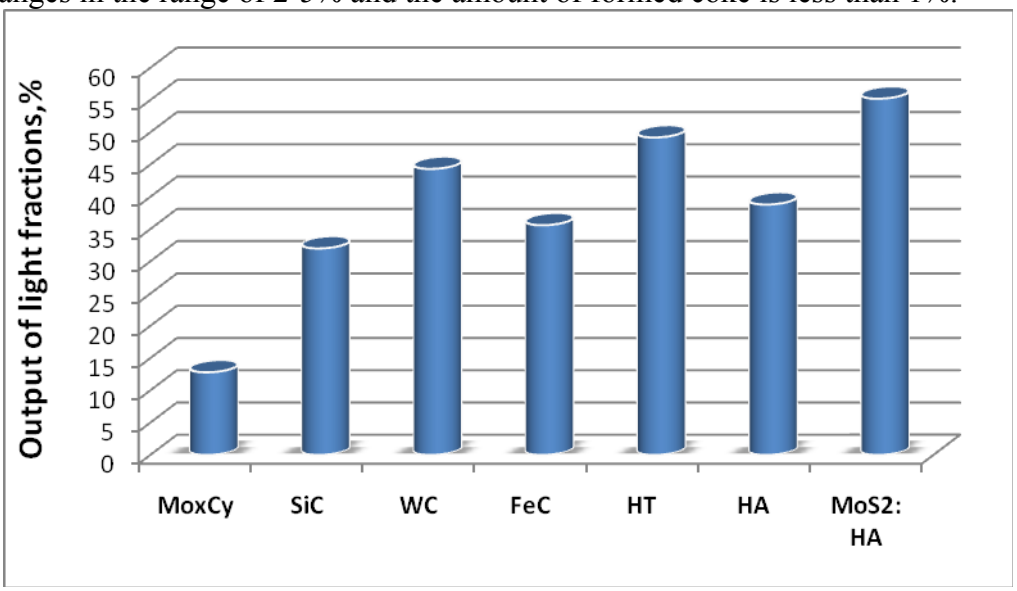

Fig 1. Activity of nanocatalysts in the thermal cracking of heavy oil residues

It is noteworthy that the use as a catalysts multilayer carbon nanotubes allow to reduce catalyst consumption by an order of magnitude; for that nanotubes was discovered the effect of "reinforcement" of heavy oil residue, making it easy to use them repeatedly and to separate from the products by simple decantation of the latter.The report also discusses the results for the thermal cracking of vacuum gas oil in the presence of listed above nanosystems with ultrasonic treatment and without it, the results of thermal analysis for residues products of thermal cracking; also discusses issues relating to the advantages of using of nanosystems for highly paraffin oil fractions (vacuum gas oil and heavy residues).

4 Conclusions

First time was demonstrated the effectiveness of joint ultrasonic treatment of oil disperse systems and nano-carbon catalysts, as a preparatory stage in the process of thermal cracking.The effect of joint treatment appears in increasing of output of light fractions.Were identified nanosystems with a high level of activity in the thermal cracking reactions with low specific consumption of catalysts (0.4 % by weight)

Keywords: methane, oxidation, OCM, structure of ferrospheres, ferrospinel

1 Introduction

Binary systems on the base of transition metal oxides with spinel structure are effective catalysts for deep oxidation of methane [1]. At the same time these systems practically have not been studied in the oxidative coupling of methane (OCM). In particular, it was found that the high selectivity of the formation of C_2-hydrocarbons (C2) is observed for systems on the base of zinc and calcium ferrospinels [2, 3]. In the study of the catalytic properties of ferrospheres with the content of Fe_2O_3 ($C(Fe_2O_3)$) in the range of 36–92 wt.% it was shown that at low $C(Fe_2O_3)$ < 88 wt.% the main route of methane oxidation is the deep oxidation. At $C(Fe_2O_3)$ > 89 wt.% OCM becomes the predominant process.[4]. In order to elucidate possible fundamental reasons for the different OCM performance, we thoroughly characterized ferrospheres with $C(Fe_2O_3)$ in the range of 76–98 wt.% in terms of their composition, morphology, microstructure of the iron-containing phases, and catalytic properties.

2 Experimental/methodology

The separation of narrow fractions of constant composition containing Fe_2O_3 in the range 76–98 wt.% was carried out according to [5] by using consecutive stages of grain-size classification, magnetic separation and separation by density. Fly ashes of FS and CS types from the combustion of a high calcium coals used as the raw material. The major component composition was determined by chemical analysis according to GOST 5382-91.

Catalytic activity tests were carried out in a fixed-bed 4–8 mm i.d. quarts reactor at 750°C under total pressure 1.3 at of the feed mixture CH_4:O_2:N_2 = 82:9:9 vol.% with on-line analysis of the feed and the product gases by chromotograph Agilent 7890A GC equipped by high performance columns.

Phase composition of ferrospheres characterized by X-ray powder diffraction, the full profile crystal structure analysis was done using the Rietveld method with the derivation difference minimization refinement.

SEM-EDS study of polished sections globules of ferrospheres narrow fractions was performed using a microscope TM-3000, equipped by energy-dispersive spectrometer Bruker XFlash 430H.

3 Results and discussion

Catalytic properties. Fig. 1 shows the steady-state yields of the two main products of the oxidation of methane: CO_2 ($Y(CO_2)$) and C_2-hydrocarbons (Y(C2)) as a function of $C(Fe_2O_3)$ in ferrospheres. According to the nature of the dependence $Y(CO_2)/C(Fe_2O_3)$ and $Y(C2)/C(Fe_2O_3)$ ferrospheres can be divided into two groups (Fig. 1). For the first group there is observed a monotonic reduction of $Y(CO_2)$ by one order of magnitude and a stable low value for Y(C2)

with increasing of C(Fe_2O_3) (Fig. 1a). For the second group there is a sharp increasing Y(C2) when the content of Fe_2O_3 = 89 wt.% and a subsequent certain its decrease with increasing C(Fe_2O_3). A similar dependence is observed for Y(CO_2) (Fig. 1b).

The different catalytic activity of the ferrospheres narrow fractions obviously associated with a different phase composition, structural characteristics of iron-containing phases in the ferrospheres of the different morphological types. In ferrospheres with C(Fe_2O_3) in the range of 67–88 wt.% a ferrospinel lattice parameter increases in the range of 8.344–8.396 Å and reaches a value characteristic for stoichiometric magnetite. The observed increase of the lattice parameter is explained by the substitution of ions Al^{3+} and Mg^{2+} in the structure of ferrospinel by iron ions. For ferrospheres with C(Fe_2O_3) > 89 wt.% the parameter exceeds the value 8.396 Å, which can be explained by the different levels of doping of magnetite by calcium oxide.

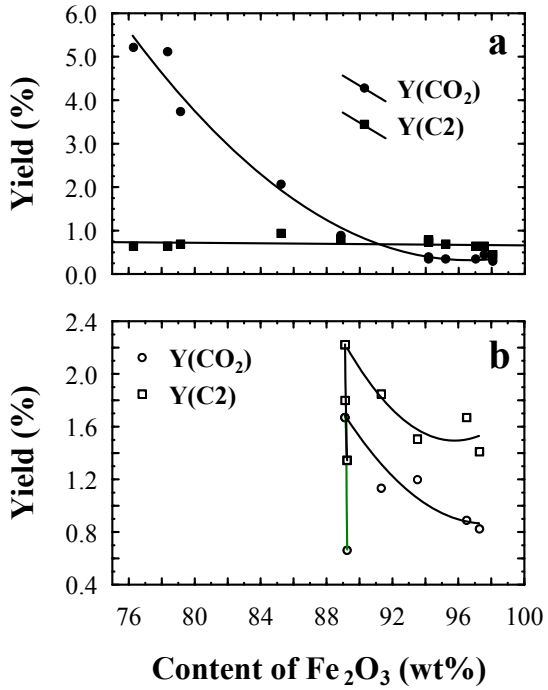

Fig. 1. The yield of the methane oxidation products at 750°C as a function of the total iron content in ferrospheres of group 1 (a) and 2 (b).

The composition of the individual globules. SEM-EDS study of the chemical compositions of polished sections of individual globules of fractions with C(Fe_2O_3) = 78.4, 93.5 and 95.2 wt.% with different activity in the OCM process and methane deep oxidation was carried out. In particular it is shown that for a fraction C (Fe_2O_3) = 78.4 wt.% with the predominant activity in methane deep oxidation the ratio of globules content of the skeletal-dendritic and block-like structures is 2:1. In fraction with C(Fe_2O_3) = 93.5 wt. % with the highest contribution in OCM the globules ratio of the skeletal-dendritic, block-like and sheet-like types is 1:6:1. The fraction with C(Fe_2O_3) = 95.2 wt.% with low activity in both reactions contains globules mainly block-like type.

4 Conclusions

The detailed analysis of the obtained results including chemical composition of individual ferrospheres of different morphological types allows us to conclude that the globules with high Al_2O_3 and MgO content and skeletal-dendritic structure are responsible for the deep oxidation of methane. The reaction OCM takes place on the sheet-like type globules with high CaO content. The block-type globules have a low activity in both reactions.

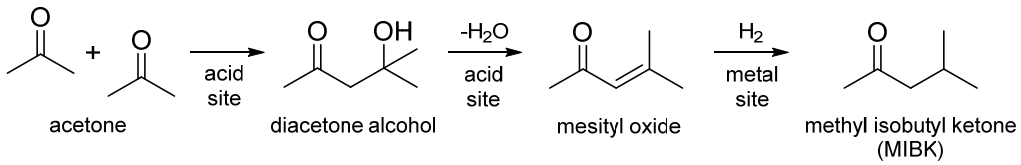
Keywords: MIBK, acetone, nanoparticles, mesoporous, recrystallization, zeolite

1 Introduction

As a consequence of the continuing depletion of fossil resources, the future chemical industry must gradually rely on renewable resources such as biomass to produce bulk and fine chemicals. An important chemical that is that is currently produced directly or indirectly from propylene is acetone. A large amount of acetone is produced via the cumene process and is therefore tied to the production of phenol. Other processes involve the direct oxidation of propylene or the hydration to isopropanol, which is then oxidized to acetone. Fortunately, acetone can also be produced by fermentation [1] and with the on-going developments in biomass processing it seems likely that bio-acetone may become an equally important platform molecule for the production of a broad range of chemicals from biomass.

One of the products that can be produced from acetone is methyl isobutyl ketone (MIBK). Traditionally, this is done in a three step process involving the base-catalyzed aldol condensation of acetone to diacetone alcohol, an acid-catalyzed dehydration to mesityl oxide and a metal-catalyzed hydrogenation to MIBK [2], see ***Scheme 1***. Heterogeneous bi-functional catalysts that contain both acid-base and metal active sites and are able to catalyze all three reactions in one step without separation of the intermediates have therefore attracted considerable interest.



Scheme 1. One-step process for production of MIBK from acetone.

Here, we present the latest results from our on-going investigations of zeolite encapsulated metal nanoparticles and their activity and selectivity as bi-functional catalysts for the direct production of MIBK from acetone. In this reaction, the zeolite facilitates the acid catalyzed aldol condensation of acetone to mesityl oxide, while the metal nanoparticles (Ni, Pd or Pt) catalyze the following hydrogenation to MIBK.

2 Results and discussion

In order to study the effect of morphology and the close proximity between the acid and metal active sites, the metal nanoparticles (Ni, Pd and Pt) were supported on a conventional ZSM-5 zeolite as well as on a mesoporous and a recrystallized ZSM-5 zeolite. All metals were deposited by simple incipient wetness impregnation followed by drying and reduction under hydrogen.

The mesoporous zeolite was prepared by carbon-templating following the method developed by Jacobsen et al. [3] In this method, a carbon source (e.g. carbon black) is impregnated with the zeolite precursors before the material is subjected to hydrothermal crystallization. During the subsequent calcination, the carbon template is removed by combustion to leave the mesoporous catalyst.

The recrystallized zeolite was prepared by an alkaline dissolution-reassembly process performed in the presence of a surfactant [4]. The alkaline dissolution was performed in an aqueous solution of ammonium hydroxide and cetyl trimethylammonium (CTAB) at room temperature and the reassembly was performed in an autoclave under hydrothermal conditions. After the recrystallization the zeolite was washed, dried and calcined to remove the remaining surfactant. ***Figure 3***A show how the recrystallization result in the formation of intra-particles voids and mesopores that provide ideal conditions for the formation small and disperse metal nanoparticles upon simple impregnation (here shown with Ni). The nanoparticles are situated inside the zeolite rather than on the outer surface, but remain readily accessible through the inherent microporous structure. ***Figure 3***B show the N_2 physisorption isotherms of the investigated zeolites.

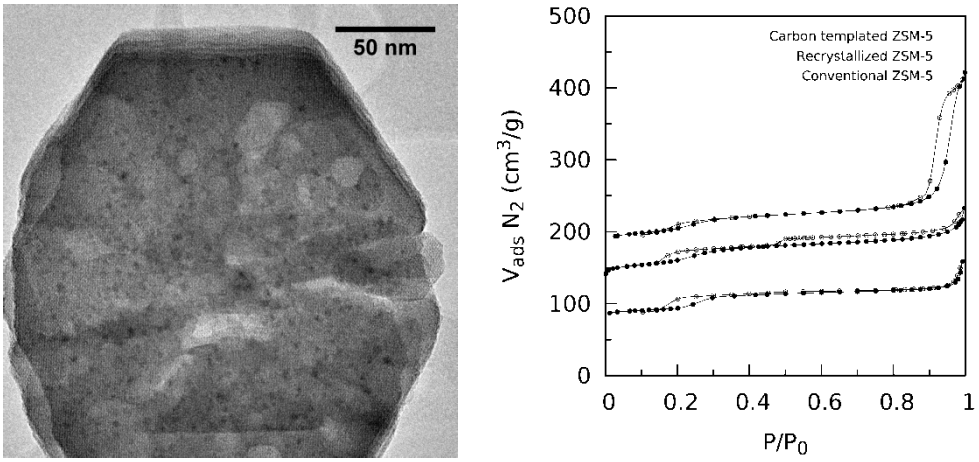


Figure 3. A) TEM image of Ni nanoparticles encapsulated in recrystallized zeolite ZSM-5. B) N_2 physisorption isotherms of the investigated zeolites at 77 K. Please note that the isotherm of the recrystallized and carbon templated and zeolite is offset by 50 and 100 cm^3/g, respectively.

3 Conclusion

In conclusion, we have investigated different zeolite supported metal nanoparticles (Ni. Pd and Pt) as bi-functional catalysts for the direct production of MIBK from acetone. Furthermore, we have developed a new and simple method to encapsulate metal nanoparticles in zeolites. Although encapsulated metal nanoparticles have many potential applications, previous attempts to encapsulate metal nanoparticles in zeolites have relied on expensive additives and complex synthetic procedures. Until now, the exploration and exploitation of zeolite encapsulated metal nanoparticles has therefore remained very limited. In contrast, our method is simple, effective and scalable and we therefore hope that impregnation of recrystallized zeolites may become a useful tool in the development of new and efficient bi-functional heterogeneous catalysts.

The Role of Cobalt Sulphide Particles in Alumina Supported CoMo HDT Catalysts

Pimerzin Al.A.*, Nikulshin P.A., Mozhaev A.V., Pimerzin A.A.

Samara State Technical University, Samara, Russia

* al.pimerzin@gmail.com

Keywords: hydrotreating, heteropolycompounds, cobalt sulphide, CoMoS, hydrogen spillover

1 Introduction

The objective of the research was to investigate the effect of the modifying alumina surface with cobalt sulphide on the physicochemical characteristics of the CoMoS active phase formed from Co_2Mo_{10}HPA as well as catalytic properties of the $Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts. Moreover, the role of cobalt sulphide particles on the surface of alumina supported CoMo-catalysts and the assumption about hydrogen spillover over catalyst surface from cobalt sulphide particles to CoMoS phase crystallites were studied.

2 Experimental/methodology

Commercial sample of alumina (with specific surface area 220 m^2/g, pore volume 0.74 cm^3/g, effective pore radius 31.5 Å) was used in this work. Co-modified carriers Co_x/Al_2O_3 As well as $Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts were prepared by wetness impregnation of alumina with aqueous solutions containing the required amounts of Co (II) nitrate and Co_2Mo_{10}Am, respectively.

The catalysts were analyzed using X-ray powder diffraction, N_2 physisorption, high-resolution transmission electron microscopy and X-ray photoelectron spectroscopy. The catalysts were tested in the hydrodesulphurization (HDS) of dibenzothiophene and 4,6-dimethyldibenzothiophene and the hydrodenitrogenation (HDN) of quinoline.

3 Results and discussion

The catalysts with equal Mo loading, precursor and morphology of the active phase and differ only in Co_9S_8 phase content on the surface demonstrate significant difference in catalytic properties in DBT HDS. $Co_2Mo_{10}/Co_{8.1}/Al_2O_3$ catalyst with high amount of Co_9S_8 demonstrated the same activity at 275°C as it was obtained at 300°C on no-modified catalyst previously. This result corresponds to evaluated value of spillover effect. This outcome is cautiously interpreted in favor of spillover effect due to cobalt sulphide ability to accumulate and activate molecular hydrogen.

The same trends may be observed for the HDS of 4,6-DMDBT. The increase of Co loading in support resulted in the growth of CoMoS active sites efficiency. *TOF* values increase more than twice with cobalt sulphide addition to alumina support. Reference *TOF* value is 0.13×10^4 s^{-1} while $Co_2Mo_{10}/Co_{8.3}/Al_2O_3$ catalyst demonstrate 0.47×10^4 s^{-1} *TOF* in 4,6-DMDBT HDS. $Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts with Co content in alumina more than 4 wt.% demonstrate a considerable increase of *TOF* (Fig. 1). That happens due to the increase of hydrogenating activity which was confirmed by the 4,6-DMDBT HDS selectivity ratio. It grew from 5.5 to 7.5 with Co addition to alumina.

In case of Qui HDN, catalytic activity grew less than in HDS reactions. The extent of denitrogenation increased from 35 to 42 % with cobalt addition to support, whereas *TOF* almost doubled.

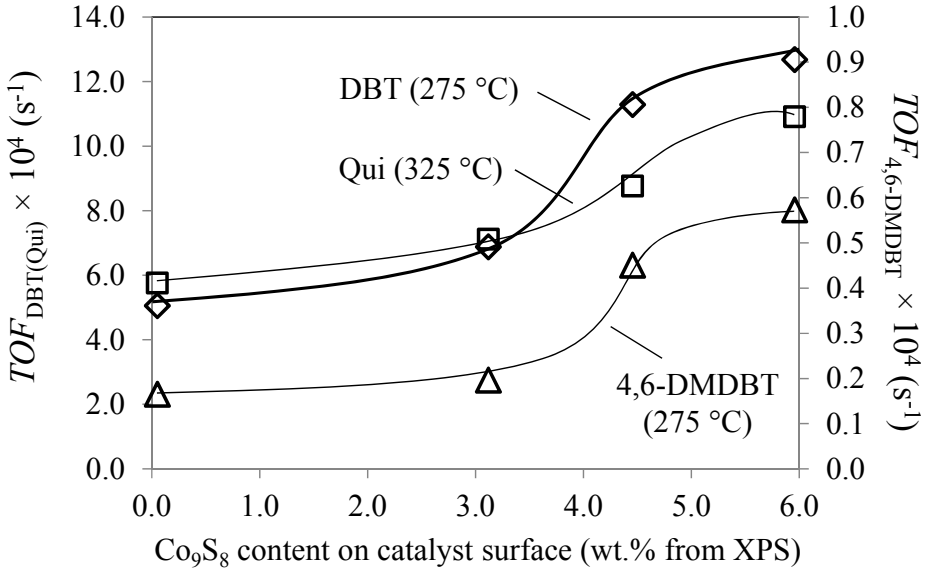

Fig. 1. Dependence of *TOF* values of DBT and 4,6-DMDBT HDS (at 275 °C, 40 h^{-1}) and Qui HDN (at 325 °C, 20 h^{-1}) reactions over $Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts on Co_9S_8 content

4 Conclusions

$Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts synthesized using Co_2Mo_{10}Am and Co-modified alumina had equal morphology, composition and promotion degree of the formed CoMoS active phase. Prepared samples differed from each other only in Co_9S_8 phase concentration on their surfaces, which increased with cobalt addition to the support. That is why, the investigation of the role of cobalt sulphide particles in HDT catalysts became possible.

It was shown that highly dispersed cobalt sulphide particles located on the catalysts surface exerts beneficial effect on the catalytic properties of $Co_2Mo_{10}/Co_x/Al_2O_3$ catalysts. Obtained results, also, make it possible to reassess the role of cobalt sulphide particles in HDT catalysts. The sufficient quantity of Co_9S_8 particles located on the catalysts surface can play the role of a donor of activated hydrogen, which can spill over to CoMoS active phase species over alumina surface and, thereby, increases TOF of the reactions. Therefore, cobalt sulphide entities have a positive effect on the efficiency of promoted CoMoS active sites in hydrogenolysis of heterocyclic compounds. Determined enhancements of the *TOF* values of HDS, HYD and HDN reactions on CoMoS sites are useful for developing new highly effective catalytic materials.

All presented results have been discussed in more details in [1].

Keywords: biofuel, hydrodeoxygenation, Ni-containing, catalysts

1 Introduction

Increase in energy consumption, environmental issues creates the need to develop alternative methods of energy production from biomass. Renewable biofuels are needed to partially displace petroleum derived transport fuels [1] and diversify local energy source in some region. Although the use of vegetable oils as a fuel is still considered today [2], they have certain drawbacks that lead to problems in the long-term operation of internal combustion engines [3]. Removing of oxygen from esters (biodiesel) and triglycerides by hydrodeoxygenation is required for production of hydrocarbons – biofuels competitive with conventional fossil derived fuels [4]. Ni - containing catalysts are known to be active in the hydrodeoxygenation of vegetable oils [5], Ni-Cu alloys exhibit activity in the hydrodeoxygenation of biodiesel [6], nickel-molybdenum alloys are known to have higher chemical resistance to acids as compared with monometallic nickel catalysts [7]. The aim of this study is the investigation of hydrodeoxygenation of esters in the presence of Ni-containing catalysts modified by Cu and Mo.

2 Experimental/methodology

Hydrodeoxygenation experiments were performed in continuous flow reactor over heterogeneous catalysts. The hydrodeoxygenation catalysts performance was tested at P = 1 MPa and 300 °C. The feed rates of Ar, as a carrier gas, and hydrogen were 15 and 5 L/h, respectively. Methyl palmitate and ethyl caprate mixture was used as a substrate. LHSV was 3 h^{-1}. Catalysts fraction was from 0.2 to 0.5 mm and was reduced before reaction at 520 ºC and P = 0.1 MPa by hydrogen. After reduction, the reactor was cooled to a 300 ºC and the substrate was added to the feed. The liquid phase was sampled once per hour. The gas products obtained in the hydrodeoxygenation reaction were analyzed by GC during the experiments, liquid phase was analyzed by GC and product identification was made using GC-MS technique.

3 Results and Discussion

In our work hydrodeoxygenation process was conducted over Ni - based catalysts (Ni-Cu/Al_2O_3, Ni-Mo/Al_2O_3 and Ni-Cu-Mo/Al_2O_3). In our work Ni/Al_2O_3 catalyst was modified by copper. On the one hand it was shown that increasing of copper content (Table 1) in the Ni-Cu/Al_2O_3 catalysts led to decreasing conversion of esters (Figure 1). On the other hand the increase in the copper content led also to an decrease in the production of undesired product - methane. Conversion of the esters in the presence of unmodified Ni/Al_2O_3 catalyst was higher than in the presence of catalyst modified by Cu (Figure 1).

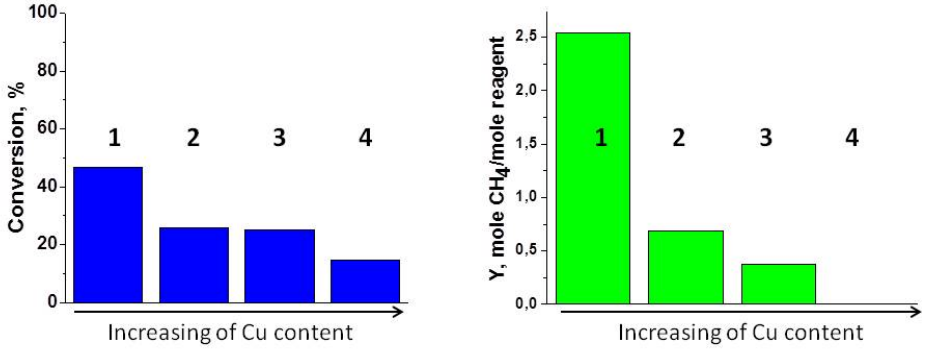

Fig. 1. Conversion and degree of methanisation in the presence of catalysts Ni-Cu/Al2O3, and Ni-Cu-Mo/Al2O3 at 300 ºC, $P_{hydrogen}$= 0.25 MPa and LHSV = 3 h^{-1}.

Alumina supported copper is not active in the reaction of esters hydrodeoxegenation and oxygen containing products only were formed in the presents of Cu/Al_2O_3 catalyst.

Table 1. Elemental analysis of nickel catalysts before reducing treatment.

Catalyst	Ni	Cu
1	10	-
2	9	1.5
3	8	2.5
4	14	-

In the next step of our investigation the influence of molybdenum on activity of Ni-based catalyst in esters hydrodeoxygenation reaction was studied. Ni-Cu catalyst were additionally modified by molybdenum. The maximal conversion of esters has been observed over Ni-Cu-6.9Mo/Al_2O_3 catalyst with alkanes as main products. Yield of alkanes increased with Mo content increasing. According to the XRD and HRTEM data, all samples after reduction contain solid solutions with different compositions [8]. It was shown by XPS that HDO increase with increasing of 4+ oxidation state of Mo on the surface of the Ni-Cu-Mo/Al_2O_3 catalysts [8]. Kinetic model of hydrodeoxygenation reaction of ester over Ni-Cu-Mo catalyst was proposed.

4 Conclusion

Correlations between molybdenum and copper content, structure and surface of the Ni based catalysts and their activity in the hydrodeoxygenation reaction of esters were observed. It was shown that catalytic activity correlate with the content of Mo^{4+} form on the surface of Ni-Cu-Mo catalysts [8] and Ni/Cu relation in the content of the Ni-Cu catalysts.

Keywords: n-hexadecane, hydroconversion, Pt/ZSM-5, Pt/silica-alumina, acidity, mesoporosity

1 Introduction

Production of hydrocarbons by the gasification of biomass and subsequent Fischer–Tropsch (FT) reaction is a very promising route for renewable fuel production. The F-T process produces a high amount of F-T waxes, which are then upgraded by hydrocracking. Hydrocracking is carried out over bifunctional catalysts composed by a hydrogenating–dehydrogenating component (usually a highly dispersed noble metal) supported on an acidic carrier, which provides the cracking/isomerization function. Ideally, a balance between the two functions is required to produce a fuel with high cetane number (linear alkanes) and simultaneously good cold flow properties (branched alkanes) [1]. The purpose of the current work is to investigate the effect of acidity and mesoporosity of Pt/based catalysts supported on conventional or mesoporous ZSM-5 carrier and a commercial, amorphous, mesoporous silica/alumina support on the hydrocracking of F-T waxes using n-decahexane as the model compound.

2 Experimental/methodology

A commercial ZSM-5 zeolite (SiO_2/Al_2O_3 ratio: 30) was subjected (a) to calcination (400°C/3h/air) to transform the ammonium to the proton-form (H-ZSM-5) and (b) to alkaline treatment of H-ZSM-5 with a solution of NaOH for the desilication of the zeolitic framework and mesoporosity formation. The desilicated sample was acid treated with an HCl solution to remove the extra-framework Al debris and restore the initial Si/Al ratio. The derived sample was calcined (400°C/3h/air) to obtain the final material in its H-form (herein labeled as ZSM-5(meso)). A commercial silica-alumina was also used as a mesoporous support of moderate Brönsted acidity. Pt was impregnated on all three supports. All samples were calcined (400°C/3hr/air). Characterization was performed by BET, XRD, ICP and FTIR-pyridine adsorption for acidity measurement. Hydroconversion tests were realized on a high pressure test unit, equipped with a fixed bed reactor, using n-hexadecane as a model compound. The reaction was conducted at 30 bar, 275°C, using a weight hourly space velocity (WHSV) of $4h^{-1}$ and a H_2/HC molar ratio of 7.5. The liquid samples were analyzed with PIANO analysis, while the composition of the reaction off-gases was detected by a GC.

3 Results and discussion

Characterization results of zeolitic carriers are summarized in Table 1, while properties of silica-alumina and Pt-based catalysts are currently measured. Concerning the surface area of the materials, a slight decrease is initially observed due to the alkaline treatment (not shown here), which however is significantly increased after the acid treatment. Pore size distribution confirms that alkaline (not shown here) and acid treatments gradually lead to mesoporosity formation,

since the parent zeolite exhibits mainly microporosity. Acidity is a very important property of the zeolitic catalysts, as both hydroisomerization and undesired hydrocracking reactions take place over the acid catalytic centres. Alkaline treatment decreases the Brönsted and increases the Lewis acid sites (not shown here), simultaneously lowering the total acidity, a fact probably related with the formation of extraframework Al due to the targeted removal of Si, which can explain both the formation of Lewis centres and the decrease in total acidity. On the contrary, the further acid treatment leads to a slight restoration of the total acidity, mainly attributed to the significant increase in Brönsted acidity, derived via the dealumination of the zeolitic framework.

Table 1. Textural, acidic properties and chemical composition of the zeolitic carriers

Catalyst	Porosity characteristics			Acidic characteristics	
	Surface area (m^2/g)	Micro-porosity (cm^3/g)	Meso-Porosity (cm^3/g)	Brönsted sites (μmol/g)	Lewis sites (μmol/g)
H-ZSM-5	357	0.136	0.104	265.564	54.926
ZSM-5(meso)	600	0.141	1.149	156.071	115.507

In terms of catalytic efficiency, Pt/ZSM-5(meso) catalyst presented significantly lower activity compared to Pt/H-ZSM-5 (33.1% vs 64.5% conversion), which can be related with its quite lower Brönsted acidity. Moreover, the Pt/mesoporous zeolite catalyst favoured the production of isomers of lower C number (C_4-C_6). The higher pores sizes, due to mesoporosity incorporation, combined with the adequately retained acidity, seem to enhance undesired secondary cracking reactions, as evidenced by the drastically reduced C_7-C_{10} product components (Fig.1).

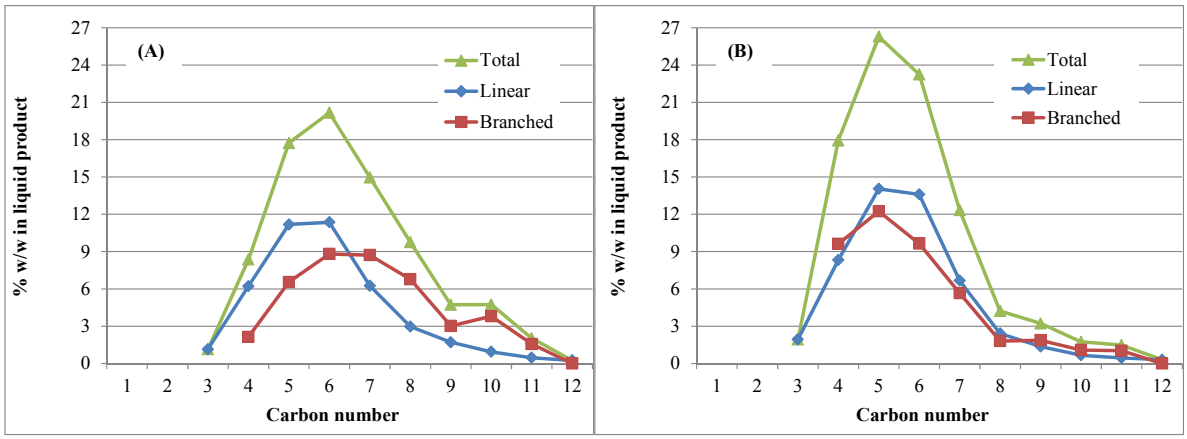

Fig. 1. Cracking product distribution on: (A) Pt/H-ZSM-5; (B) Pt/ZSM-5 (meso)

4 Conclusions

Bifunctional catalysts consisting of Pt on amorphous silica–alumina and zeolitic (ZSM-5) supports were prepared for the hydrocracking of n-hexadecane (n-$C_{16}H_{34}$). Introduction of mesoporosity in ZSM-5 was accompanied by changes in Brönsted and Lewis acid sites distribution. Evaluation of Pt/ZSM-5 catalysts performance showed significant differentiations in activity. Decreased acidity led to less active material, while the presence of mesoporosity additionally affected selectivity, slightly enhancing formation levels of C_4-C_6 products.

Keywords: solid acid catalyst, macroalgae, hydrolysis, carbohydrates, monosaccharide

1 Introduction

Nowadays the scientific community agrees that there is a need of using renewable resources, in order to keep production of chemicals and energy in the long term in a more sustainable way. Algae are organisms living in marine environments that have a huge potential to meet this challenge. Among the most outstanding properties in algae they contain substantial amount of carbohydrates, higher grow rates compared to terrestrial plants and absence of lignin which makes its carbohydrates more accessible to hydrolysis.

Hydrolysis of oligosaccharides using acid catalysts has been already reported, mainly using hemicelluloses as raw material and solid acid catalyst such as Smopex, Amberlyst and zeolites [1,2]. These works have obtained complete conversion and sugar yields up to 85 wt-% [3].
In this work, we report the catalytic hydrolysis of carbohydrates from green algae *Ulva rigida* using the catalyst Amberlyst-70 for production of sugars.

2 Experimental/methodology

175 mL of deionized water (DI, Millipore) were disposed in the 250 mL glass reactor over a heating pot. The heating pot was set up at 110°C in order to control temperature inside the reactor to be 90°C, which was monitored by a thermometer in contact with the reaction solution at all time. Once the set up temperature was achieved, 785 mg of Amberlyst-70, equivalent to 0.01 mol H+ eq./L, and subsequently 2,000 mg of previously freeze dry *U. rigida* were disposed into the reactor. The system was continuously agitated by a stirrer at 800 rpm. The reaction was carried out for 259 hours. Samples of 2.6 mL were taking at 0, 2 h and every 24 h until the end of the reaction time. Once reaction time was completed, the reactor was cooled down under a stream of running water and then filtered though a glass fiber filter. Fibers were thoroughly washed with deionized water, kept in freezer and freeze dried overnight. Samples, final solution and remaining fibers were kept in freezer prior monomer and carbohydrate analyzes in gas chromatograph as described in [4]. Several physicochemical methods such as OEC, TGA and EDXA were used to characterize the solid residue.

3 Results and discussion

Total carbohydrate content of fresh *U. rigida* resulted in 400 mg/g of dry algae reported by gas chromatography. Glucose content is high in *U. rigida*, accounting for 183 mg/g of dry algae, whereas rhamnose and xylose content were 81 and 39 mg/g of dry algae. On the contrary, cellulose content was very low; suggesting that the value of glucose reported may come from starch.

In order to quantify carbohydrate dissolution and carbohydrate hydrolysis into monomers, total carbohydrate content and total monomers content were analyzed in the liquid phase. Fig. 1 shows the carbohydrate dissolution and hydrolysis kinetics. The results show relatively fast carbohydrate release, 63.4 wt-% in 259 hours (relative to total carbohydrate contained in *U. rigida*), whereas carbohydrate hydrolysis to monomers was rather slow under these reaction conditions, achieving a maximum of 13.6 wt-%. The carbohydrate hydrolysis starts very slow during the first 100 hours of reaction, due to initial dissolution of carbohydrate species such as ulvan or starch. At 100 hours of reaction the carbohydrate hydrolysis of *U. rigida* started to increase slowly. These results clearly show that it is possible to verify monomers production by this method, although temperature is rather low to accelerate hydrolysis kinetics.

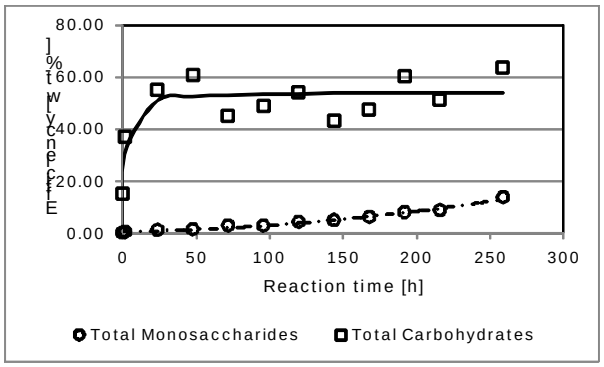

Fig. 1. Efficiency of catalytic hydrolysis of carbohydrates contained in *U. rigida*. Catalyst: Amberlyst 70 0.01 M H^+ eq., Temperature 90ºC.

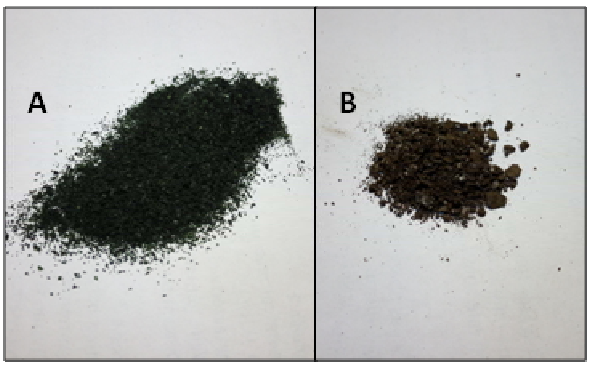

Fig. 2. (A) Pristine *U. rigida* sample. (B) Residue left after catalytic hydrolysis using Amberlyst 70 0.01 M H^+ eq. at 90ºC for 259 hours.

U. rigida samples fresh (A) and residue (B) are depictured in Fig 2a,b. The brown colour observed in the residue is related to its low carbohydrate content, accounting for 40.32 mg/g of dry treated algae, thus confirming carbohydrate removal from the pristine sample.

4 Conclusions

Catalytic hydrolysis of carbohydrate contained in macroalgae show great potential in terms of production of sugars for further applications such as biofuel production. However, more experiments are required to complement the present work and optimization of hydrolysis yields, by testing different catalyst, slightly increase of temperature and use of pressurized reactors.

Mesoporous Zeolites Synthesised with In Situ Generated Carbon Template

Abildstrøm J.O., Gallas-Hulin A., Mielby J., Kegnæs S.*

Technical University of Denmark, Kgs. Lyngby, Denmark

* skk@kemi.dtu.dk

Keywords: mesoporous zeolites, metal, nanoparticles, bifunctional, catalyst, hydrocracking

1 Introduction

Zeolites are among the most widely used industrial catalysts. The micropores in zeolite crystals have dimensions close to those of typical reactant and product molecules in many large-scale processes, and the structure is responsible for the characteristic size and shape selectivity typical of zeolite catalysts. However, a catalyst can only be efficient if the reactant molecules are able to diffuse into the crystal and react inside the pores. Thus, for some applications, the sole presence of micropores might result in an unacceptably slow diffusion of reactants and products to and from the active sites located inside the zeolite crystals. Several different strategies have been proposed to overcome this challenge, a multitude of these require however often costly reagents or are time consuming [1].

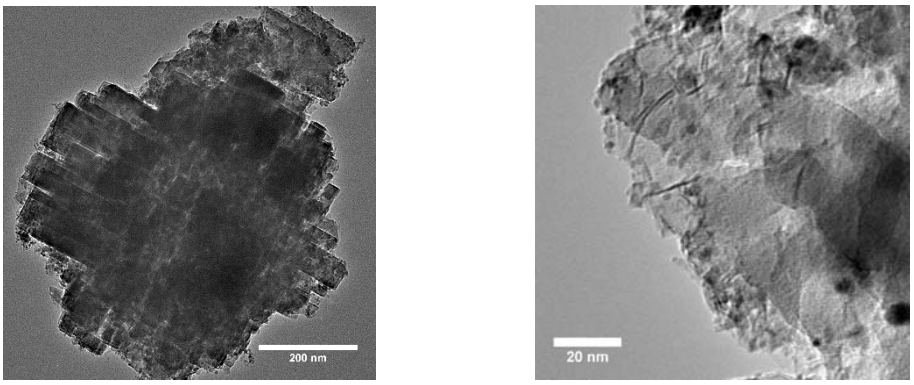
Here, we present a versatile method for the preparation of zeolites with an additional mesoporous system. This is done using *in situ* generation of a carbon template, directly onto the silica raw material. The carbon template is later removed by combustion, leaving mesopores. This method allows for careful control of the porosity of the mesoporous zeolite, and it does not depend on the availability of specialized carbon templates. The effect of the mesoporosity generated by this *in situ* carbon templating was tested in hydrocracking of n-octane.

2 Experimental

A carbon source was deposited on zeolite precursors by leading methane gas over metal nanoparticles on silica. Afterwards the material was subjected to a hydrothermal crystallization step, where the zeolites formed around the carbon-template. During the subsequent calcination, the carbon-template was removed by combustion to leave the mesoporous catalyst. The other mesoporous sample was prepared in a similar manner, except with the carbon source being BP-2000. All catalysts were tested for both stability and activity in a plug flow reactor for the hydrocracking of n-octane [2].

3 Results and discussion

The resulting zeolite revealed presence of an additional mesoporous system from physisorption, compared to a conventionally prepared ZSM-5. XRPD proved the formation of ZSM-5 crystal structure, even with the added carbon template during synthesis. TEM image, Figure 1(a), shows the resulting mesoporous zeolites with clearly visible mesopores, as well as metal nanoparticles. Figure 1(b) shows a close up of the zeolite and the metal nanoparticles, which are in the size range of 2-10 nm.



(a) (b)

Fig. 1. (a) TEM image of the *in situ* carbon templated HZSM-5. (b) TEM image close up of *in situ* carbon templated HZSM-5

By hydrocracking of n-octane, it is visible that the added generated mesopores are clearly an advantage, as there is an increase in both stability and activity compared to the conventionally prepared zeolite.

4 Conclusions

Mesoporous HZSM-5 zeolite was prepared by a cheap and innovative carbon templating method. Transmission electron microscopy and physisorption proved the existence of a secondary pore system in the zeolite, while still retaining the crystal structure. Metal nanoparticles were observed after the hydrothermal synthesis. The mesoporous zeolite showed an increase in both activity and stability compared to conventional ZSM-5 in a model reaction of cracking n-octane. Both improvements are believed to be a result of the introduced mesopore system, as it facilitates an increased mass transfer of reactants and products.

Keywords: biforming, AMS, radioactive, methane, heavy oils, oil refining, carbon

1 Introduction

Nowadays the demand on light oil fractions (naphtha, diesel, kerosene) is constantly increasing while sources of light oil, that is reach in light fractions, are running down. Therefore, heavy oils become more and more popular in oil refining industry. Heavy oil upgrading technologies usually use two groups of methods: carbon rejection methods (delayed coking, fluid coking etc.) and hydrogen addition methods (H-Oil, LC-fining etc.). Nevertheless, there are exist some alternative ways of oil refining that look promising but are not investigated well for using in industrial scales. One of them is biforming process. Biforming (from the words *Boreskov Institute* – the place where first experiments were carried out, and word *form*) is a quite new process in oil refining that use is held with hydrocarbon gases presence. The principle of the method is in integration of methane or other hydrocarbon gases (C_2-C_5) in liquid hydrocarbon molecules. In this paper the biforming process was investigated on mesoporous CoMoNi catalyst with the presence of ^{14}C marked methane. The methane integration was analyzed by acceleration mass spectrometry (AMS) of ^{14}C content in biforming products.

2 Experimental/methodology

Carbon probe preparation was carried out on lab scale device in four steps: 1) probe burning at 800 °C in O_2 (99% purity) flow ; 2) CO_2 sorption at 25°C ; 3) CO_2 desorption at 900°C; and 4) graphitization at 550°C, 0.12MPa in electrolytic hydrogen (99.9% purity) atmosphere for 3 hours. The carbon yield is 85% from the carbon quantity in a probe. Method gives the level of ^{14}C contamination no more than 2% of ^{14}C natural content.

^{14}C determination in the graphite probes was conducted using accelerator mass spectrometry (AMS) method. The method allows detecting the ^{14}C isotope in a concentration of 10^{-15} compared with the main isotope.

Biforming experiments were carried out on the lab scale apparatus described in paper [1]. Parameters of the process were as follows: temperature 420°C for biforming experiment and 20°C for methane solution experiment, pressure 15MPa, LHSV $1h^{-1}$, gas/feed volume ratio 1000. Tatar oil (^{14}C content below accuracy of carbon probe preparation method) was used as a feed for the process. Methane (97% purity) with ^{14}C mark (in form of methane with 99% purity) was used as reagent. The catalyst used in experiment was mesoporous alumina with CoMoNi active component.

3 Results and discussion

The investigation of biforming process was carried out in three steps:

1. Tatar oil ^{14}C analysis. This experiment has been carried out as a reference. According to the AMS analysis, the ^{14}C content in tatar oil is about 1.33% of ^{14}C natural level (Fig 1.) that is

below the accuracy of carbon probe preparation method. Result showed that there is dead carbon in tatar oil only (there is only ^{12}C carbon presented in tatar oil)

2. Methane solution experiment. The aim of this experiment is to take into account the solution of methane in oil. By the AMS method there was determined that the ^{14}C content in the product was 1.29% of natural level (Fig 1.). By this way experiment showed that methane is insoluble in heavy tatar oil. This is explained by the fact that methane is more soluble in light hydrocarbons than in heavy hydrocarbons.

3. Biforming process. The AMS analysis of biforming products gave in result only 1.29% of ^{14}C natural level (Fig 1.). The 14C content in biforming products showed that there is no methane integration in oil molecules. Therefore, the biforming process do not proceed with parameters used in the experiment.

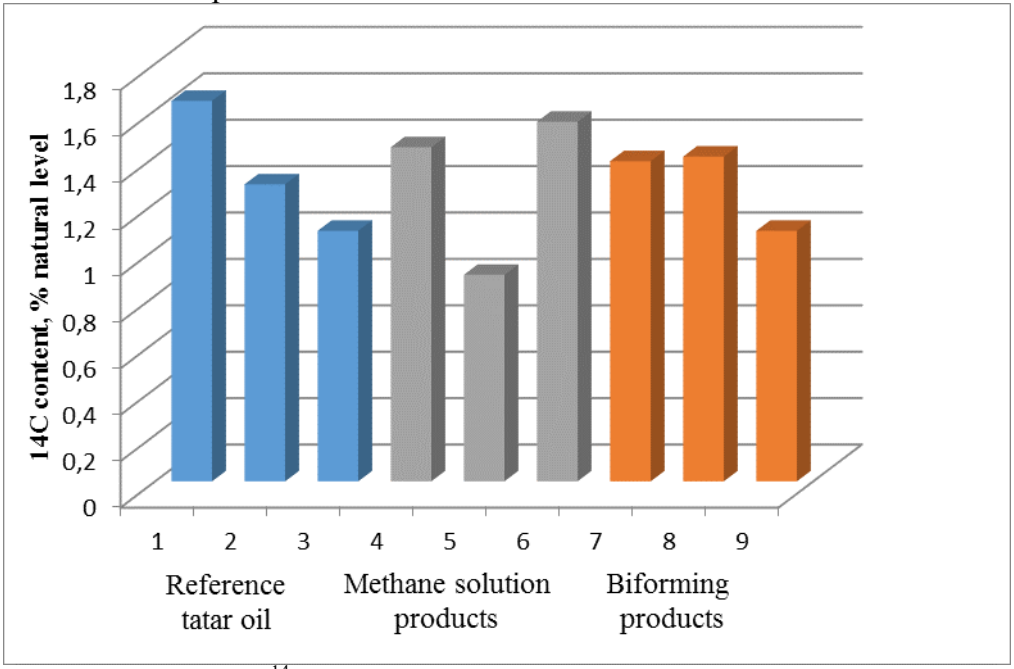

Fig 1. ^{14}C content in tatar oil and biforming products.

4 Conclusions

Method of ^{14}C analysis in oils have been set. Namely the carbon probe preparation for AMS analysis. The carbon probe preparation has level of ^{14}C contamination no more than 2% of ^{14}C natural content. The carbon yield is 85% from the carbon quantity in a liquid probe. The minimal volume of liquid probe is 30µl.

Biforming process do not proceed with parameters used in experiment : 420°C, 15MPa, LHSV $1h^{-1}$, CoMoNi mesoporous catalyst. Further studies should be conducted in this field. In the first instance, some experiments with other catalysts and hydrogen addition should be carried out.

Synthesis of Alcohols and their Conversion in Reactive and Inert Gases on Alkali Modified Molybdenum Disulphide Catalysts

Dorokhov V.S.*, Permyakov E.A., Kogan V.M.

Zelinsky Institute of Organic Chemistry RAS, Moscow, Russia

* viktor.s.dorokhov@yandex.ru

Keywords: molybdenum, disulphide, alcohols, synthesis, oxygenates, synthesis-gas, mechanism

1 Introduction

Molybdenum-based sulphide catalytic systems are promising for production of alcohols from CO and H_2. The model of interlayer dynamic nature of the active sites of transition metal sulphide catalysts was taken as a conceptual basis for the work [1].

2 Results and discussion

We conducted investigations of structure and functioning mechanism of potassium modified MoS_2-based catalysts active phase in oxygenates synthesis reaction. We found out that potassium forms a single phase with molybdenum disulphide and substantially changes its structure. Addition of potassium increases average number of layers and average linear size of MoS_2 crystallites. As it follows from our catalytic experiments, both Co and K increases selectivity of alcohols formation [2].

It was assumed that the formation of alcohols and hydrocarbons from CO and H_2 is caused by the formation of active sites containing potassium in the active phase of the (Co)MoS catalyst. The mechanism was proposed for the formation of alcohols from synthesis-gas on the KCoMoS catalysts [3].

The addition of ethanol or ethylene to syngas substantially changes the reaction rate and composition of the products [3]. The reaction products of syngas in the presence of ethanol and ethylene contain alcohols and also ethers and esters, aldehydes, ketones, and organic acids. Therefore, the use of ethanol and ethylene additives to syngas makes it possible to obtain a wide range of compounds of different classes.

Is was also established that alcohol molecules are able to disproportionate with formation of olefins, alkanes and different oxygenates on KCoMoS-catalyst under inert atmosphere (N_2, Ar, He). We proposed mechanism for conversion of alcohols to different oxygenates on KCoMoS catalysts.

3 Conclusions

The application of the interlayer concept as a generalized approach to synthesis of alcohols makes it possible to explain the experimental structure-properties correlations and to optimize the catalyst composition for these processes. The principles were developed for the preparation of efficient sulphide catalysts based on molybdenum promoted with cobalt and modified by potassium for the synthesis of alcohols from syngas.

Keywords: carbon support, IR spectroscopy, phenol, hydrodeoxygenation, X-ray absorption,spectroscopy

1 Introduction

Effective utilization of biomass as a renewable source of energy and feedstock for conversion to useful chemicals hinges upon designing highly active and stable catalysts. [1] A one-step efficient conversion of lignin-derived phenolic oil, such as lignin waste from industrial paper production, [2] has yet to be developed. This approach requires multifunctional catalysts that have sufficient contact with reactants and high stability of the active sites under process conditions.

In this contribution, we report a novel dual-functional Ni/C-SO_3H catalyst that exhibits remarkably high activity towards phenol hydrodeoxygenation (HDO) in liquid hexadecane at mild reaction conditions (473 K, 4 MPa H_2). An in-depth *ex situ* and *in situ* characterization of sulfonated carbon supports, and Ni incorporated carbon catalysts permitted correlating catalyst properties and catalytic activity. Mutual influences of metal and acid sites anchored either on one (Ni/C-SO_3H) or physically mixed (C-SO_3H + Ni/C-SO_3H) carbon sheets have been investigated with respect to the model reaction of phenol HDO.

2 Methodology

High surface carbon materials were produced by pyrolysis of two carbon precursors, glucose and cellulose, resulting in graphitic respectively graphene like structures. The dual functional catalyst synthesized by grafting as-synthesized nickel nanoparticles supported on SO_3H-carbon was designed to fulfil a cascade reaction of four subsequent reactions of phenol hydrodeoxygenation (HDO).

The nano-sized Ni particles grafted onto sulfonated carbon support were studied in greater detail using *ex situ* transmission electron microscopy (TEM) and *in situ* X-ray absorption fine structure (XAFS) techniques.

Additionally using in situ IR spectroscopy, the rate determining step of the liquid phase phenol HDO was evaluated. Thus, phenol HDO catalysis was further improved by admixing C-SO_3H with the Ni/C-SO_3H catalyst to balance the two catalytic functions and achieving nearly quantitative conversion of phenol towards cyclohexane in 6h, at temperatures as low as 473 K.

3 Results and discussion

The representative TEM image of the Ni particles grafted on the sulfonated carbon support is shown in Figure 1a, along with the particle size distributions obtained from statistical analysis of at least 300 Ni particles from the TEM images. Ni nanoparticles on sulfonated high surface carbon (Ni/C-SO_3H) exhibited an average size of 4.2 ± 1.2 nm.

The state of Ni and its particle size in the Ni/C-SO_3H catalyst were investigated by XAS

during phenol HDO. Figure 1b contains the near-edge (XANES) portion of the spectra of the 10 wt. % Ni/C-SO_3H during HDO of 0.56 M phenol/water solution at 473 K and a total pressure of 5 MPa. To determine the concentration of both the Ni(0) and Ni(II) phase as a function of time, we simulated the XANES spectra as linear combinations of Ni foil (473 K), NiO and α-$Ni(OH)_2$ standards. Initially, the Ni particles were 100 % in the Ni(II) state, or specifically, a 20:80 mixture of NiO and $Ni(OH)_2$. The reduction to Ni(0) started after 12 min, i.e., when the temperature of 473 K was reached, and proceeded to completion within 50 min. The metallic state of Ni dominated after 30 min following the start of the reaction.

The figure 1c shows the time-resolved in situ IR spectroscopy study during phenol HDO over Ni/C-SO_3H catalyst. With increasing reaction time, the intensity of IR peaks of phenol (1224 cm^{-1} aromatic CO stretch) declined, while cyclohexanol (1067 cm^{-1} alicyclic CO stretch) increased first and then slowly dropped to a low value, indicating that cyclohexanol was still present after 180 minutes of reaction. The sharp increase of the C-H_x stretching vibration peaks (2928 cm^{-1} representing the CH_x peaks) demonstrates the high hydrogenation rates on the nano-sized Ni particles. Thus, the rate-determining step is concluded shown to be the dehydration of cyclohexanol.

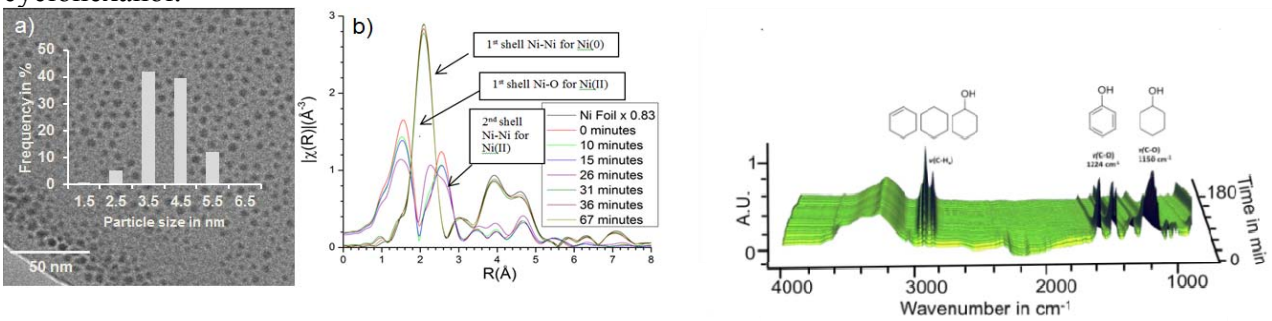

Figure 1 a) TEM image of Ni/C-SO_3H and b) Ni K-edge spectra of the χ(R) magnitude of Ni foil (black line) to that of Ni/C-SO_3H as a function of time at 473 K and 5 MPa P_{H2} and c) time-resolved *in situ* IR spectroscopy study during phenol HDO over Ni/C-SO_3H in hexadecane as solvent at 473 K and 3 MPa H_2.

Based on the insight from in situ IR studies, we attempted to accelerate the rates of cyclohexanol dehydration, the limiting step in phenol HDO in hexadecane, by adding sulfonated carbon (C-SO_3H) with the supported Ni/C-SO_3H catalyst. Interestingly, the additional amounts of sulfonated carbon influenced not only the dehydration of cyclohexanol but also the hydrogenation of phenol. The results suggest that the sulfonic acid groups interact with Ni directly or indirectly, reducing its availability for hydrogenation.

4 Conclusions

Bifunctional, highly active, and stable catalysts have been developed that combine metallic Ni nanoparticles (3–5 nm) with acidic sulfonated HS carbons derived from glucose and cellulose. *In situ* XAFS measurements demonstrate that the active metallic Ni phase in the Ni/C-SO_3H catalysts is stable in the aqueous phase under HDO conditions. The rate-determining step is shown to be the acid-catalyzed dehydration of cyclohexanol. Thus, the catalysis of HDO could be optimized by mixing additional C-SO_3H with the Ni/C-SO_3H catalyst to provide the subtle balance required for the two synergistic catalytic functions.

Keywords: propane ammoxidation, MoVTe(Nb) catalyst, M1 phase, M2 phase

1 Introduction

To date, the problem of oil gas utilization and industrial processing of its components (methane, ethane and propane) is very actual. This issue is closely connected with the need to develop new power saving technologies in petrochemical industry. In light of this, the development of relevant manufacturing process of acrylonitrile from inexpensive and abundant propane instead propylene is challenging and economically is attractive. MoVTeNbO catalysts are reported [1, 2] to be the most efficient catalysts for the ammooxidation of propane to acrylonitrile. The role of Nb in the formation of the structure of these catalysts is still under debate. The work object is to elucidate of Nb effect on the phase composition and catalytic function in selective conversion of propane.

2 Experimental

The $Mo_1V_{0.3}Te_{0.23}O_n$ and $Mo_1V_{0.3}Te_{0.23}Nb_{0.12}O_m$ catalyst were synthesized from aqueous slurry using ammonium heptamolybdate, ammonium metavanadate, telluric acid and niobium oxalate. Thereafter, a lab spray-dryer (Buchi-290, T_{inlet}= 220°C and T_{outlet}= 110°C) was used for rapid drying of the crude precursors. The resulting orange solid precursors (220°C) were treated by step in interval 250–550°C under the flow of He.

XRD, IR-spectroscopy and HRTEM have been used for characterization of final catalysts.

The propane ammooxidation was carried out in a fixed-bed tubular reactor with on-line chromatographic analysis at 420°C with the feed consisting of 5% C_3H_8, 6% NH_3, 89% air.

3 Results and discussion

Mixing solutions of the initial components result to the formation of heteropoly compounds (HPC) with Anderson-type structure in MoVTe and MoVTeNb systems. These structures are preserved after spray-drying. A nanostructured M1 phase is formed after the decomposition of the HPC.

In MoVTe sample the increase in the heat treatment temperature to >450°C leads to destruction of the M1 domains and crystallization of the M2 phase, a number VMo oxides and individual oxide phases. The heat treatment of MoVTeNb results to the transformation of nanostructured particles to phases M1 and M2 (Fig.1).

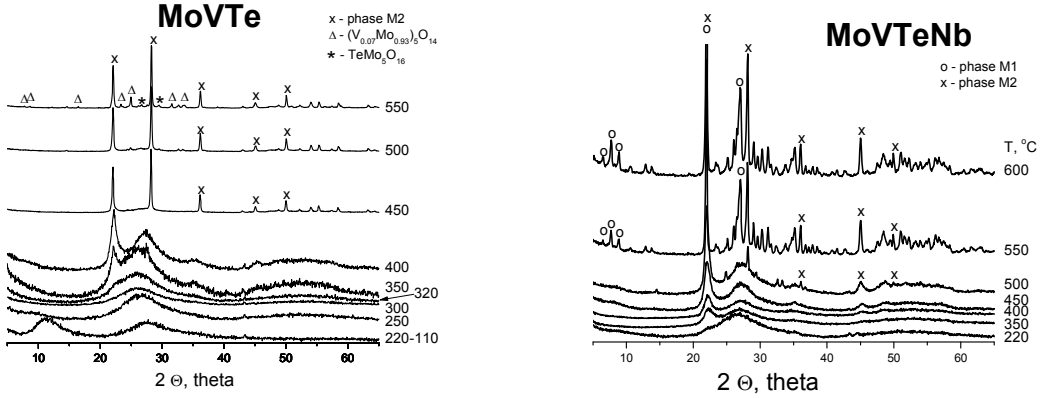

Fig. 1. XRD patterns of MoVTe and MoVTeNb catalysts

Table 1. Effect of the phase composition of $Mo_1V_{0.3}Te_{0.23}O_n$ and $Mo_1V_{0.3}Te_{0.23}Nb_{0.12}O_m$ catalyst on the catalytic properties.

Compound	T, °C*	X, %	S C_3H_3N, %	S C_3H_6, %	S CO_x, %	Phase composition
MoVTe	450	23.7	35.3	15.8	34.6	Nanostructured phases
MoVTeNb	450	28.6	36.8	13.1	37.6	Nanostructured phases
MoVTe	550	4.1	33.7	40.0	17.0	M2 (80%), $V_{0.97}Mo_{0.95}O_5$, $V_xMo_{5-x}O_{14}$, $TeMo_5O_{16}$
MoVTeNb	550	57.0	68.8	4.7	15.3	M1 (80%), M2

* Temperature of heat treatment, X - the conversion of propane, S – selectivity, τ - 2s.

Table 1 demonstrates catalytic properties and phase composition of the catalysts. It exhibits comparable behavior relating activity and selectivity of nanostructured three- and four-component catalysts.

Changing phase composition under heat treatment results to strong distinction of catalytic behavior. The activity of ternary-component catalysts containing mainly the phase M2 decrease, at this time high selectivity is preserved. In contrast to the ternary system, the four-component system transits from the low-temperature state containing highly dispersed crystallites of M1 to the well-crystallized M1 phase. This process is accompanied by an improvement of the catalytic properties as compared with ones of nanostructured sample.

4 Conclusions

So, catalytic activity is determined by the phase composition of the catalysts. Phase transformation in the ternary system result in decreasing catalytic characteristics. Contrary, in the four-component system, the transformation of nanostructured M1 phase to well-crystallized M1 phase enhances the catalytic properties. Our results provide evidence of the key role of niobium in the stabilization of orthorhombic structure of M1 phase.

$CuFe_2O_4$ Magnetic Nanoparticles: An Efficient, Recyclable Catalyst for N-arylation of Indole and Imidazole with Aryl Halide under Mild Reaction Conditions

Yadav G. D.*, Nakhate A.V.

Department of Chemical Engineering, Institute of Chemical Technology, Mumbai, India

* gdyadav@yahoo.com

Keywords: spinel ferrite nanospheres, hydrothermal synthesis, magnetic separation, N-arylation, heterogeneous catalyst

1 Introduction

The C–N bond formation is one of the most important chemical reactions in organic synthesis and represents an important step in the production of nitrogen containing heterocyclic molecules which play vital role in natural products, industrial polymers, agrochemical and biologically active pharmaceutical products [1-2].

Herein, we report a simple, effective and environmentally greener protocol for synthesis of different spinel ferrite microspheres which is highly efficient, stable, well-dispersed and magnetically recyclable catalyst. The resulting catalyst was applied for *N*–aryaltion reaction of indole and imidazole with different aryl halide. The reaction afforded good to excellent yields with $CuFe_2O_4$ MNPs as catalyst under ligand-free conditions. In addition, $CuFe_2O_4$ MNPs could be reused at least six times showing no loss of catalytic activity (scheme 1). A comprehensive investigation of various parameters was accomplished for indole and a kinetic model developed and validated against experimental results. The studies were extended to other heterocycle.

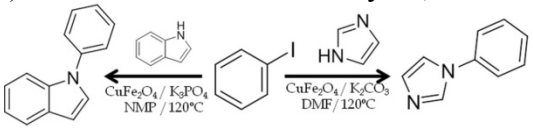
2 Experimental

2.1 Preparation of $CuFe_2O_4$ particle

MFe_2O_4 (M = Cu, Co, Mg, Mn, Ni) MNPs were prepared by hydrothermal method. A mixture of the $MCl_2.2H_2O$ (5mmol), $FeCl_3.6H_2O$ (10mmol), polyethylene glycol 400 (2g) and sodium acetate (7g) in ethylene glycol was used to form a stable transparent solution. The mixture was sealed in teflon lined SS autoclave. The autoclave was maintained at 200ºC for 24 h and allowed to cool to room temperature. The black products were washed several times with ethanol and dried at 60ºC for 6 h.

2.2 General procedure for N-arylation of nitrogen nucleophiles and substrate study.

All experiments were performed in high pressure reactor. Predetermined amounts of reactants and the catalyst were charged into the autoclave and the temperature raised to the set value. Once the temperature was attained, a zero hour sample was withdrawn and sampling was done periodically. The control experiment was: iodobenzene (3 mmol), indole (2 mmol), K_3PO_4 (3 mmol), NMP (30 mL made up volume) as solvent and 0.001 g/ml catalyst. The reaction was carried out at 120 ºC with a speed of agitation (400 rpm). Products were confirmed by ^1H, ^{13}C NMR and GC-MS analyses.



Scheme 1. Copper catalyzed *N*-arylation

3 Results and discussion

The XRD patterns of MFe_2O_4 agreement with the standard XRD patterns of JCPDS data except some pure metal impurity peak were observed [Figure 1. (a)]. TEM and SEM images,

clearly showing that the as prepared MFe_2O_4 is usually in a spherical shape with smooth surface, and has a narrow size distribution, EDXA confirmed the chemical composition of ferrite complex [Figure 2 (b-c)]. The FT-IR spectra of MFe_2O_4 showed a strong band associated with the Fe-O stretching vibration at 620-650 cm^{-1}. TGA spectra confirmed that catalyst was thermally stable. The isotherm of the MFe_2O_4 MNPs nanosphere exhibited type IV isotherm depicting characteristics of the mesoporous solid with hysteresis loops, indicating that the adsorption process was completely irreversible. In order to optimize the reaction conditions, initial studies were conducted using $CuFe_2O_4$ as a choice of catalyst for N-arylation of indole with iodobenzene as a model reaction. Different reaction parameters such as catalyst screening, solvent, base, speed of agitation, catalyst loading, molar ratio and temperature using $CuFe_2O_4$ as catalyst were studied [Figure 1(d-e)] [Figure 2 (a-e)]

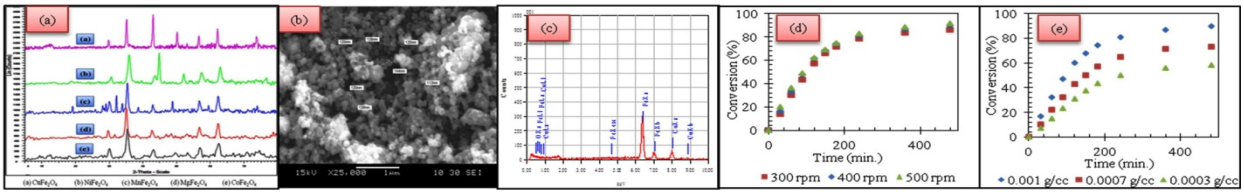


Fig.1. (a) XRD patterns of MFe_2O_4 (b) SEM image of $CuFe_2O_4$ (c) EDXA of $CuFe_2O_4$. (d) Effect of speed of agitation (e) Effect of catalyst loading

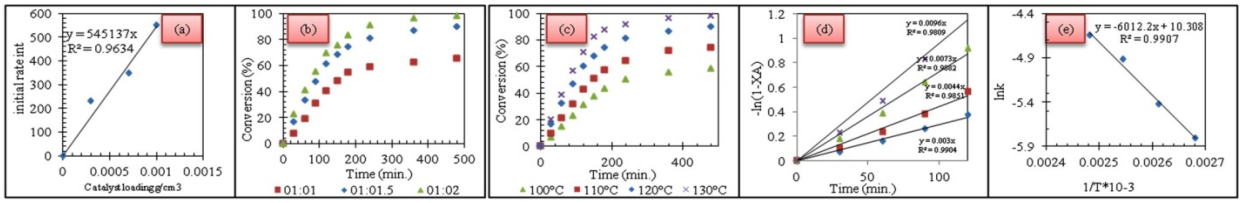

Fig.2. (a) Plot of initial rate vs. catalyst loading (b) Effect of mole ratio (c) Effect of temperature (d) plot of $\ln(1-X_A)$ vs. time (e) Arrhenius plot lnk vs $1/T*10^{-3}$

4 Conclusions

A series of ferrite complex oxides MFe_2O_4 (M = Mg, Cu, Ni, CO, Mn) microspheres were prepared by a simple and effective hydrothermal approach and characterized by using SEM, TEM, XRD, FT-IR, TGA and BET. The $CuFe_2O_4$ magnetic microsphere exhibited impressive catalytic activity under ligand free conditions producing desired products in moderate to excellent yield. . The catalyst can be reused six times with minor changes in the catalytic activity. We have reported a kinetic model for this reaction system. The reactions were found to be intrinsically kinetically controlled. The LHHW type model with weak adsorption of all species fits our data well and the system follows first order kinetic equation. The activation energy was found to be 13.06 kcal mol^{-1}.

Keywords: Ti-Mg, supported catalyst, multi-wall carbon nanotubes, polypropylene

1 Introduction

Multi-wall carbon nanotubes (MWCNTs) have been widely regarded as an attractive candidate for the use as a fillers in the composite materials. Incorporation of carbon nanotubes into the polymer matrix results in significant improvement of polymer properties – mechanical strength, electrical and thermal conductivity, fracture toughness, electromagnetic shielding properties [1-3]. These improvements can be achieved in case of the uniform distribution of the filler in the polymer matrix. The common methods for the preparation of MWCNT/polymer composites include mechanical mixing with extrusion, solution mixing, melt blending, coagulation precipitation technique and in situ polymerization. In the present work the *in situ* polymerization technique was applied for preparation of MWCNT/polypropylene (MWCNT/PP) composites with various MWCNTs loading. Original preparation procedure of catalytic species TMC/MWCNT with uniform distribution of TMC on the MWCNT surface was proposed.

2 Experimental/methodology

In this study MWCNTs (d ~ 9 nm) as produced and after oxidation pre-treatment (denoted as MWCNT-ini and MWCNT-ox, correspondingly) were used [4]. Carbon nanotube oxidation was performed by reflux of 1–2 g of MWCNTs in the excess of concentrated nitric acid (90 min). This procedure provides formation 0.8 carboxylic groups per 1 nm^2.

Catalysts preparation was carried out by (1) impregnation and precipitation of organomagnesium compound as alkoxy magnesium compounds using magnesium-titanium alkoxide complex $(Mg(OEt)_2 \cdot Ti(OEt)_4$ or $(EtMgBu + Si(OEt)_4)$ and (2) subsequent titanation of surface alkoxy magnesium compounds with titanium tetrachloride in the presence of an electron donor compound (dibutyl phthalate – DBP). The obtained catalytic systems were denoted as TMC/MWCNT - $(TiCl_4/DBP/MgCl_2)$/MWCNT).

Propylene slurry polymerization was performed in heptane; triethyl aluminum (18 mmol/L) and propyl trimethoxy silane was used as the cocatalyst (mole ratio Al/Si was 30); concentration of H_2 2 vol. % and temperature 70°C. Propylene pressure (1-6 atm) and polymerization time were selected for obtaining the desired amount of PP. The resulting product was washed with heptane and ethanol, and dried to the constant weight.

Structure and morphology of initial and oxidized MWCNTs were studied using TEM, BET surface measurements, and titrimetric analysis. TEM, XRD, DSC were used for characterization of the structure of MWCNT/PP composites.

3 Results and discussion

Using both types of MWCNTs the catalysts TMC/MWCNTs with different TMC content (from 1 to 10 wt. %) were prepared. Polymer composites were prepared with desired content of

PP using these catalysts and various polymerization conditions. Based on the catalyst active component is observed some decrease in the catalytic activity (per Ti atom) compared to a sample without the MWCNTs. At the same time we didn't observe the influence of the MWCNTs nature on the catalytic activity in polymerization. The structure of the MWCNT/PP composites was studied using TEM. The propylene polymerization results in the formation of polymer powder with MWCNT homogeneous distributed in PP matrix (Fig.1A); PP molecules demonstrate high wetting ability of nanotube surface. We succeeded to observe Ti-Mg – containing catalyst particles in the form of 2-3nm dark spots (Fig.1B).

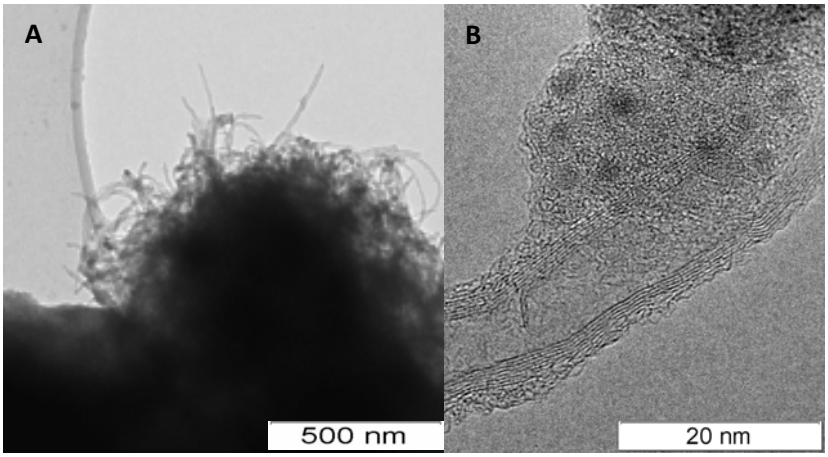

Fig. 1. TEM images of 20 wt.% MWCNT-ox/PP composite.

According to the DSC data the introduction of the nanotubes in the polymer results in the decrease of polymer's melting point (3-4°C). However, the values of the melting temperature (160-163°C) and the degree of crystallinity (50-55%) are rather high. This indicates insignificant changes in the crystal structure of the composites in comparison to pure polypropylene. According to XRD data the introduction of two types of MWCNT into polypropylene matrix does not lead to significant changes in the crystalline structure of polypropylene.

4 Conclusions

The concentrate MWCNT/PP with a uniform distribution in the polypropylene matrix of MWCNTs was obtained. PP molecules demonstrate high wetting ability of nanotube surface.

For the first time we have observed the Ti-Mg – containing catalyst species of the size 2-3 nm on the MWCNT surface, stabilized in polymer matrix. The results suggest promising directions for composite MWCNT/PP preparation via the catalyst distribution on the surface of MWCNTs followed by polymerization of propylene. MWCNT/PP composites with high concentration of homogeneously distributed nanotubes are perspective as polymer carbon nanotubes conductive masterbatches.

Keywords: metal oxides, nanoparticulate, matter, magnetite, clay, composites, peroxidase enzyme, radioiodination, reaction, BSA

1 Introduction

The intrinsic enzyme-like activity of nanoparticles (NPs) or nanostructured solids has become a growing area of interest. Compared with natural enzymes, these enzyme-like NPs are stable against denaturing, low in cost, and highly resistant to high concentrations of substrate [1].Several recent studies have investigated different metal oxides and composites solid compounds in order to design new heterogeneous Fenton-like system for catalysis, clinical and technological applications. Some of the metal containing solids investigated was goethite, anatasa, clay minerals, manganese oxide and metal ferrites among others [2,3, 4]. Typical metal oxides such as anatasa, ZnO, and MnO_2 showed interesting catalytic properties on some pollutant green degradation systems. On the other hand, metallic iron, Fe^0, has been studied as a low cost and innocuous reductant in different environmental remediation processes, e.g. permeable reactive barriers [5] reduction of organochloro[6], dyes [7] .

In this work, metal oxides (MnO_2, ZnO, Fe_3O_4, and $MnFe_2O_4$) obtained by (co)-precipitation method in presence of surfactant direct micelles were evaluated as catalyst using Fenton UV heterogeneous model against methylene blue using TiO_2 as reference catalyst. These oxides were additionally evaluated for thermal degradation efficiency of methyl orange dye. Additionally, composites like Fe^0/ clay-Fe_3O_4 and Fe^0/ clay- $MnFe_2O_4$, obtained by mixed *in situ* coprecipitation and grinding methods were evaluated as peroxidase enzyme-like catalyst using radioactive iodination method of bovine serum albumin (BSA).

2 Experimental

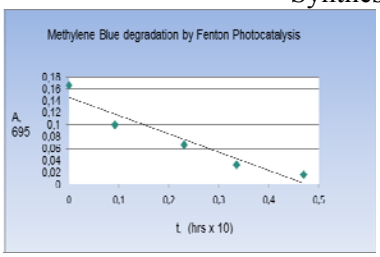
Catalyst Preparation. In a pure water were prepared 0.02 mol/L solutions of $ZnSO_4$ or $MnSO_4$ (MercK). Pure cethyltrimethyl ammonium bromide (CTAB) was added to both reaction vessels (300 mL volume) in order to obtain 0.5 g/L surfactant solution. The mixture was vigorously stirred at room temperature for 60 minutes. To the reaction vessel were added 15 mL of diethanolamine and the system was carefully heated until 70 ^{0}C and maintained under stirring for two hours. The precipitated solids were separated (pH 10) and washed twice. After drying at 105 ^{0}C for 12 hours, the precipitated solids were heated at 600 ^{0}C for 6 hours. Using a ultrasound treated water, by which was passed a nitrogen gas flow during 2 hours was prepared a sample of pure magnetite by adding a stoichiometric mixture containing $FeSO_4 \cdot 7\ H_2O$ and $FeCl_3 \cdot 6H_2O$ (MercK) at ratio 1:2 , 1g/L of CTAB solution and 30 mL of diethanolamine. The mixture was vigorously stirred during two hours at 70 ^{0}C, pH 10. The precipitated magnetite was washed twice and dried at room temperature. The preparation of $MnFe_2O_4$ follows the same pathway and conditions but $MnSO_4$ was collocated on the initial mixture.

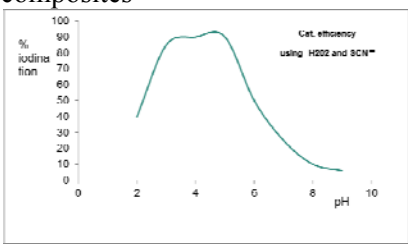
Magnetite and ferrite clay composites were prepared by adding prior to the before described synthesis a momtmorillonite type national clay, previously purified and micrometer sized.

Catalytic Measurements. Catalytic evaluation measurements were carried out using three models. The first one was the degradation of Methylene Blue (MB) under UV lamp in the presence of H_2O_2. In a 100 mL reaction vessel were collocated 70 mL of 0.002 mol/L solution of MB and 500 mg of each evaluated oxide. The suspension was stirred for 5 hours and the color change was determined spectrophotometrically at 695 nm. The efficiency of MB degradation was calculated. Thermal degradation of methyl orange (MO) dye was the second model in catalytic properties measurement. Arrhenius plots for MO oxidation as a function of reciprocal temperature (25, 50, 75 and 95 ^{0}C) allows calculating activation energy (Ea) for each evaluated oxide. In order to evaluate the peroxidase enzyme like activity magnetite and heterogeneous composites like Fe^0/ clay-Fe_3O_4 and Fe^0/ clay- $MnFe_2O_4$ recently mixed (0.1 mg) were putted on 2 mL Eppendorff vial. 500 µL of buffer pH 4, 200 µL of BSA solution (0.01mg/mL), 50 µL of substrate (H_2O_2 or KSCN solution) and 10 µL of radioactive solution of NaI (0.01mCi) were incubated for 30 minutes. The iodination efficiency was calculated by radioactivity measurements ratio of protein native fraction over total fractions counts after size exclusion chromatography over Sephadex G200.

3 Results and discussion

Synthesed Clay-magnetite composites





Degradation efficiency: TiO2 (anatasa) > MnO2> ZnO> $MeFe_2O_4$ (Mn, Ce)

High efficiency iodination over clay systems, Fe^0/ clay-$MnFe_2O_4$, Fe^0/clay-Fe_3O_4 were achieved.

4 Conclusions

A simple core-shell approach yields metal oxide-composite materials with catalytic and/or magnetic properties with peroxidase activity against aromatic rest of BSA. The successful radioisotope iodination substrates in absence of experimental enhancing factors such as temperature and UV radiation and with the use of rare substrate for experimental research SCN^- ion, allows affirming that oxidation mechanism can be considered artificial peroxidase enzyme activity.

Keywords: Metal-Organic Framework, gold nanoparticles, HKUST-1, ZIF-8

1 Introduction

Metal-Organic Frameworks (MOFs) are porous hybrid organic-inorganic materials with a large surface area. Their structures can be described in terms of secondary building units (SBU) forming a characteristic topology for any given coordination network of metal ions and organic ligands [1]. This class of materials has wide range of potential applications in gas storage [2], in bio-medical studies [3], and in catalysis [4].

MOFs are typically produced by hydrothermal or solvothermal techniques. The resulted product still contains solvent molecules inside the pores. After respective activation procedure, the coordinately unsaturated metal sites inside the SBU acquire catalytic activity as Lewis acids [5]. Gold particles of 3-10 nm range are found to show remarkable catalytic activity [6], and being hosted in porous material like MOF, constitute a promising heterogeneous catalyst [7].

MOF powder can be further treated with a gold precursor looking for formation of metal nanoparticles on external surfaces of crystallites or in pores of framework. Alternatively, a gold precursor can be added already during the synthesis of MOF, allowing for growth of metal nanoclusters inside the MOF pores [8] along the formation of crystalline framework.

Present investigation is focused on development of a microwave-assistant solvothermal synthesis in order to grow gold nanoparticles inside the MOF structures – $Cu_3(BTC)_2$ [9] and Fe(BTC) [10] (BTC – benzene-1,3,5-tricarboxilic acid), and inside the ZIF-8 (zeolitic imidazolate framework) [11].

2 Experimental

The $Cu_3(BTC)_2$ (HKUST-1) MOF samples were produced in our laboratory by solvothermal technique [12] and by using microwave irradiation [13], starting from copper acetate and H_3BTC in DMF/water solutions. The commercially available Basolite C300 ($Cu_3(BTC)_2$) and its isostructural counterpart Basolite F300 (Fe(BTC)) were also used for functionalizing experiments. The ZIF-8 was produced in a microwave oven from zinc acetate and 2-methylimidazole in DMF/water solutions. The activation procedure consisted in heating in dynamic vacuum at 200 °C for 6 hours and cooling down to room temperature with finally being fluxed with dry air.

The functionalization with gold was performed on activated dry MOF powder. The water solution of 6 mg/ml $HAuCl_4$ was poured on MOF powder and the mixture has been kept under magnetic stirring for various period of time from several minutes to several days. After that, water solution of 16 mg/ml sodium citrate was added and the mixture was placed into the microwave oven to react at 100 °C for 16 minutes. After centrifugation the resulting powder was dried at 50 °C in air.

3 Results and discussion

The structures of obtained MOFs were confirmed by powder XRD measurements. For studies of gold-functionalized MOFs the TEM images were acquired, and variety of spectroscopic methods

(UV-Vis, Mid-IR, X-Ray absorption at Au L_3-edge) was used. The representative TEM images of functionalized MOFs $Cu_3(BTC)_2$ and ZIF-8 are presented in Figure 1 (marked as HKUST-1@Au and ZIF-8@Au). In the case of HKUST-1@Au the gold particles of 6-8 nm are observed to decorate the external surfaces of MOF crystals without clear evidence of penetration inside the voids. Instead, the gold particles of 5-13 nm are found to be embedded in ZIF-8 matrix as can be seen from respective TEM image.

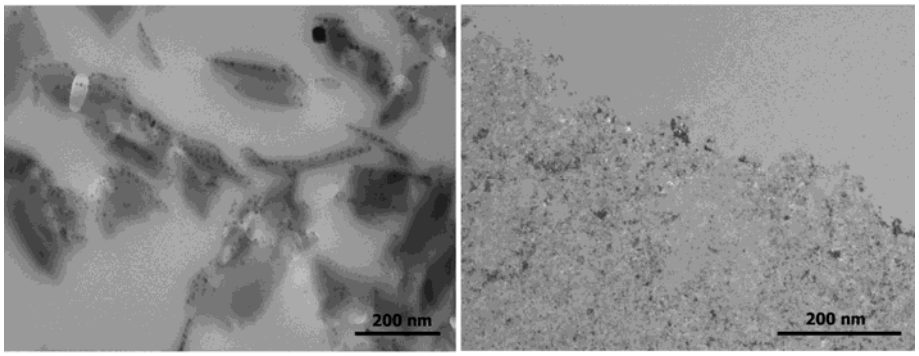

Fig. TEM images of HKUST-1@Au (left) and ZIF-8@Au (right) samples

By changing synthesis parameters, the dependence of penetration depth of gold particles inside the MOF structure with time of stirring was found. Both diffusion problems arising from pore size of MOFs and chosen conditions for formation of gold nanoparticles (interplay between gold precursor and reducing agent) might lead to different situation with MOFs functionalization. However gold nanoparticles supported on MOF crystals and embedded inside the pores are preserved against aggregation and rather stable in time.

In conclusion, we have developed the microwave-assistant solvothermal synthesis, which allowed as to functionalize three MOFs - $Cu_3(BTC)_2$, Fe(BTC), and ZIF-8 with gold nanoparticles with diameters in 5-13 nm range. Variations in time of mixing of the reagents allowing to optimize the penetration depth of gold into the porous matrix. Obtained materials have good stability and may be applied for catalytic tests.

On the Origin and State of Ni and Fe Species as Catalysts for the Initiation of Metal Dusting Corrosion

Gunawardana P.V.D.S.[1], Hwang J.[1], Walmsley J.C.[2], Svenum I.H.[2], Venvik H.J.[1*]

Keywords: natural gas, conversion, carbon formation, metal dusting, carbon activity, carbon filament

1 Introduction

Metal dusting corrosion constitutes a serious issue in a range of chemical industries [1–3], where a mixture of CO, CO_2, H_2, steam and hydrocarbons meets metals and alloys at elevated temperatures (T>400 ˚C) and low oxygen/steam partial pressures (P_{O_2}/P_{Steam}). The first stages of carbon formation that initiate metal dusting are analogous to carbon formation issues on heterogeneous catalysts used in the petrochemical industry. The thermodynamic driving force is hence given by the activity for carbon formation (aC), and metal dusting is prevailing for aC>1. The formation of solid carbon is nevertheless strongly controlled by kinetics; it rarely forms in the gas phase, even at very high aC. Ni and Fe are excellent catalysts for carbon formation. Unfortunately, they are also the main constituent elements of common industrial alloys. Hence their stability in alloy matrix is critical for metal dusting.

The overall objective of this study is to advance the understanding of the initiation of metal dusting corrosion. In our recent work, improved understanding of the initial carbon formation and the role of the protective surface oxide layer was obtained through a comprehensive experimental investigation, including advanced surface and bulk characterization. We have established that the surface oxide layer composition, thickness and structure, as affected by pretreatment temperature, oxidant partial pressure and sample preparation procedure, strongly affects the susceptibility to form solid carbon [4–6]. Here, we further proceed to study the nature and localization of Ni/Fe phases at the surface within and/or below the surface oxide layer formed as a result of the pre-oxidation and how they are accessed by the reducing atmosphere during syngas exposure.

2 Experimental

A set of coupon-like alloy (INCONEL® 601) samples were subjected to oxidation at different temperatures for 6 h under 10% steam/inert (at 1 bar). Then some of the pretreated samples were exposed to carburizing syngas mixtures with either *infinite* (10%CO in Ar, 1 bar) or *finite* (20% or 50% CO in H_2/CO_2/steam/Ar, 20 bar) carbon activity (aC>>1 or aC>1). The duration of the syngas exposure was also varied.

The resulting surfaces and carbonaceous products were characterized by means of optical imaging and light-optical microscopy, scanning electron microscopy (SEM), depth profile analysis by Auger Electron Spectroscopy (AES) under ion-sputtering, transmission electron microscopy (TEM) equipped with energy dispersive X-ray spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS).

3 Results and discussion

Pre-oxidation at 540 ˚C produced samples covered by a Cr and Al rich, thin oxide layer. SEM reveals carbon formation on all such samples subjected to CO exposure at *infinite a*C, increasing with exposure time as expected. The amount of carbon formed during 1 h CO exposure treatment could not be detected by visual inspection, but thin carbon filaments could be observed in high magnification covering part of the initial surface. The formation of filaments and complementary TEM/EDS results indicated the presence of metal nanoparticles containing Ni and/or Fe, and such short exposures represent a basis for an accelerated experimental protocol to reveal the origin of these particles within the surface oxide layer. Higher pre-treatment temperature under oxidizing conditions lowers the susceptibility to carbon formation, and the critical factors to and durability of this effect will be further discussed and investigated.

Under *finite a*C conditions, thick carbon deposits were obtained at 650 ˚C and 750 ˚C while no (20%CO) or little (50%CO) carbon was found after syngas exposure at 550 ˚C. Hence, under different CO concentration but a constant level of H_2, CO_2 and steam, the amount of carbon formed is clearly a function of exposure temperature and gas composition. The former clearly demonstrates the kinetic control of the (exothermic) reactions. Removal of carbonaceous deposits revealed that material degradation had taken place at higher temperatures (either '*pitting*' or '*spallation*'). As shown by Auger depth profile analysis, oxidation of the alloy matrix had proceeded alongside the reducing reactions leading to carbon formation under exposure to the 20%CO containing gas mixture at higher temperatures, while this was not the case under 50%CO. The TEM and EDS results show that the formation of filamentous carbon deposits under *finite a*C conditions was also catalyzed by metallic particles containing Ni and Fe.

XPS is currently being used to examine the oxidation states of the different species that exist in the near surface region. A next step will be detailed TEM/EDS analysis of the near surface region by a combination of carefully prepared cross-sections and micro/nano-scale samples obtained via Focused Ion Beam (FIB).

4 Conclusions

We have established protocols to investigate the catalytic properties of high temperature alloy surfaces, and factors leading to (*unwanted*) carbon formation and subsequent metal dusting, under both simplified (aC>>1, low pressure) and more industrially relevant (syngas, aC>1, high pressure) conditions. The experiments verify the kinetic nature of these phenomena and point to the importance of the structure and composition of the protective surface oxide layer that depends on the conditions of the preceding oxidative treatment. The metal dusting hence appears to be strongly linked to the inclusion of Ni/Fe species in the oxide surface layer, which subsequently reduce to facilitate carbon formation.

Keywords: SMPO, transfer, hydrogenation, phosphinites, ruthenium

1 Introduction

There is a huge demand in petrochemical industries in non-gaseous hydrogen donors for hydrogenation of organic compounds (so called transfer hydrogenation). Basically, standard industrial equipment can be used in the transfer hydrogenation process, rather than the pressurized equipment necessary when using hydrogen gas. The use of hydrogen in gas form is a much more expensive endeavor than using non-gaseous hydrogen donors, such as iso-propanol, and will make the industrial process more cost effective [1].

The popular petrochemical processes used by companies such as Shell, ARCO Chemical, Sumimoto and others more than 30 years is SMPO (styrene monomer propylene oxide) process of conversion of styrene and propene to styrene and propylene oxide that is shown in figure 1:

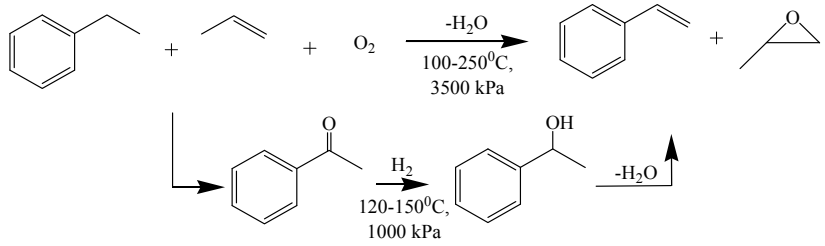

Fig. 1. SMPO process

Herein we report about significantly more mild reaction conditions (82^{0}C, atm. pressure) for the transfer hydrogenation of ketones using Ru/IL catalysts.

2 Experimental/methodology

Procedure for the catalytic hydrogen transfer reaction: a solution of complexes [Ru((Ph$_2$PO)-C$_7$H$_{14}$N$_2$Cl)(η^6-arene)Cl$_2$]Cl and [Ru((Cy$_2$PO)-C$_7$H$_{14}$N$_2$Cl)(η^6-arene)Cl$_2$]Cl (arene: benzene 1,2; *p*-cymene, 3,4) (0.005 mmol), KOH (0.025 mmol) and the corresponding ketone (0.5 mmol) in degassed iso-PrOH (5 mL) were refluxed until the reactions were completed.

3 Results and discussion

The results collected from the catalytic test reactions are listed in table 1.

At room temperature no considerable formation of 1-phenylethanol was observed. Furthermore, the precatalysts, as well as the presence of KOH, are necessary to observe appreciable conversions. The base facilitates the formation of ruthenium alkoxide by abstracting proton of the alcohol and subsequently alkoxide undergoes β-elimination to give ruthenium hydride, which is an active species in this reaction. This is the mechanism proposed by several workers on the studies of ruthenium catalyzed transfer hydrogenation reaction by metal hydride intermediates [2]. Increasing the substrate-to-catalyst ratio does not damage the conversions of

the product in most cases.

Table 1. Transfer hydrogenation of acetophenone with 2-propanol catalyzed by [Ru((Ph2PO)-C7H14N2Cl)(η6-benzene)Cl2]Cl, 1, [Ru((Cy2PO)-C7H14N2Cl)(η6-benzene)Cl2]Cl, 2, [Ru((Ph2PO)-C7H14N2Cl)(η6-*p*-cymene)Cl2]Cl, 3 and [Ru((Cy2PO)-C7H14N2Cl)(η6-*p*-cymene)Cl2]Cl, 4

4 [a]	10min	97	582
4 [b]	48h	<5	....

[a] Refluxing in 2-propanol; [b] At room temperature; [c] Substrate:catalyst:KOH=100:1:5 [d] Determined by GC (three independent catalytic experiments); [e] The reaction time shown in column; TOF= (mol product/mol Ru(II)Cat)*h^{-1}.A prototypical reaction using acetophenone indicated that the reaction rate not depend on the arene moieties (benzene and *p*-cymene) bound to metal center, conversely depend on the alkyl substituents on the phosphorus atom.

Encouraged by the activities obtained in these preliminary studies, we next investigated hydrogenation of substituted acetophenone derivatives (R = F, Cl, Br, 2-MeO) for the needs of petrochemistry and polymer chemistry. The introduction of electron withdrawing substituents, such as F, Cl and Br to the para position of the aryl ring of the ketone decreased the electron density of the C=O bond and the activity was improved giving rise to easier hydrogenation [3].

4 Conclusions

Results obtained from optimization studies indicate clearly that both complexes, [Ru($Cy_2POC_7H_{14}N_2Cl$)(η6-benzene)Cl_2]Cl, 2 and [Ru($Cy_2POC_7H_{14}N_2Cl$)(η6-*p*-cymene)Cl_2]Cl, 4 including Cy moiety on phosphorus atom are active and more efficient catalysts leading to nearly quantitative conversions. The catalytic activities dependent on the groups (phenyl and cyclohexyl) on the phosphorus atom, conversely not to depend on the arene moieties bound to metal center. The catalytic performance shown by both of these complexes is generally higher than that of recently reported for the related half-sandwich complexes bearing heterodifunctional P,N-ligands [4], P,O- ligands [5], and NHCs ligands [6].

1 Introduction

At the international level, the concern about the global warming and the depletion of fossil fuels has attracted much attention. Thus, several environmentally friendly technologies have been developed in the recent years. One of them is the production of high valuable syngas (a mixture of H_2 and CO) by dry reforming of CH_4 (DRM). Using CO_2 and CH_4 as reactants, gases largely involved in the global warming, is attractive in the approach of getting green processes [1]. To this purpose, Ni based catalysts are very promising candidates [2].

Following the green pathway, we report in this study the CH_4 dry reforming activity and the H_2/CO formation over Ni-based catalysts. The influence of different parameters has been studied such as the Ni loading, reaction temperature and partial pressure of the reactants.

2 Experimental/methodology

Two different series of Ni-based catalysts (Ce-Ni-O and Ni-Mg-Al-O) were prepared by coprecipitation method [3, 4]. The solids were calcined in air at 500 °C. The catalytic performance (10 – 200 mg) was conducted under the atmospheric pressure in a fixed-bed quartz reactor fitted in a programmable oven. The gas stream of CH_4/CO_2/He/Ar (5-20/5-20/x/y %v) was fed to the reactor (F_T = 100 ml/min). The stoichiometric molar ratio CH_4/CO_2 was maintained at 1 while varying the reactants concentration. The outlet gases were analyzed online by a mass spectrometer (MS).

3 Results and discussion

Very different types of Ni based composites were successfully developed and applied to syngas production from methane and carbon dioxide ($CH_4 + CO_2 \rightarrow 2\ CO + 2\ H_2$). As an example *Fig.1* shows the influence of the nickel content of cerium based compounds on CH_4 and CO_2 conversions measured at 600°C using a 5% initial concentration of each reactant. The conversion of CH_4 increases with the Ni loading, while the conversion of CO_2 presents an optimum on the catalyst with 19 wt% Ni. On this compound, the CH_4 and CO_2 conversions are about 54 and 57% respectively with the formation of about 43% (mol.) of H_2, 52% of CO and 5% of H_2O with the formation of a small amount of carbon. When Ni content increases up to 24 wt % the conversion of CH_4 is higher than the one of CO_2 which probably means that at such loading, it is easier to promote the $CH_4 \rightarrow C + 2\ H_2$ reaction. *Fig.2* presents the conversions of CH_4 and CO_2 obtained at 600ºC on a Ni-Mg-Al-O compound (10 mg) using higher concentration of the reactants (20%). In such conditions, the conversions of CH_4 and CO_2 are 58% and 66%, close to the DRM thermodynamic limitation, evidencing the high efficiency of the catalyst. The conversions remain quite stable along all the experiment, and the H_2/CO

obtained is close to 0.8. For this low temperature of 600°C, relatively good efficiency of the catalysts is observed, when comparing to recent results reported on Ni based mixed oxides catalysts [5-8] or on noble metal based catalyst [9]. The results obtained here are quite promising due to the easy catalysts preparation, the low mass of catalyst used, the low working temperature, and the relative high concentrations of the reactants used.

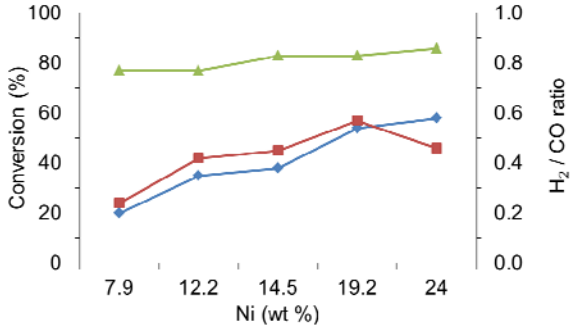

Fig. 1. CH_4 (●) and CO_2 (■) conversions and H_2/CO (▲) ratio at 600°C on Ce-Ni-O catalysts in gas stream of CH_4/CO_2/He/Ar: 5/5/10/80. (Each point after 5h).

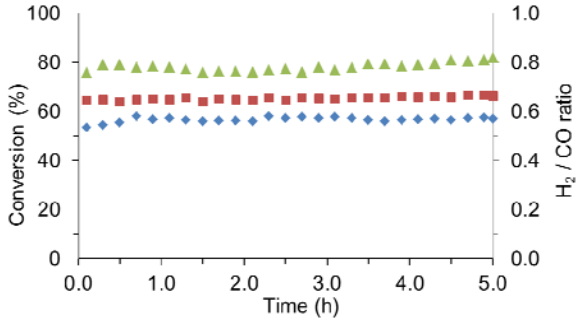

Fig. 2. CH_4 (●) and CO_2 (■) conversions and H_2/CO (▲) at 600°C on Ni-Mg-Al-O catalyst in gas stream of CH_4/CO_2/He/Ar: 20/20/20/40.

4 Conclusions

Well tuning Ni based catalysts formulation and preparation allows obtaining promising conversions of methane and carbon dioxide at mild conditions with a high selectivity for the formation of syngas (H_2 and CO).

Keywords: catalyst, speciation, resting states, olefin polymerization, UV-vis, NMR, spectroscopy

1 Introduction

The structural characterization of reactive intermediates, which arise in the course of a catalytic reaction, and the kinetic tracing of their concentration profiles are ongoing tasks in all fields of catalysis research. Magnetic resonance methods – such as NMR and EPR spectroscopy – can generally provide superb structural information concerning catalyst species present in solid or in homogeneously dissolved catalyst systems, but the time resolution of these methods is often insufficient to follow the time-course of a rapidly proceeding catalyst reaction. UV-vis spectroscopic methods, on the other hand, can generally provide only very limited structural information but these methods can, in principle, be tuned so as to provide an almost unlimited time-resolution. To elucidate catalytic processes in structural as well as kinetic terms, it would thus appear desirable to combine both of these complementary spectroscopy methods. In the following, we describe the application of this approach toward full characterization of several zirconocene-based catalyst systems used for the polymerization of α-olefins.

2 Experimental/methodology

All operations were carried out in an argon-filled glovebox or in vacuo by break-seal techniques. Solvents and liquid reagents were degassed and dried over molecular sieves (4Å) or distilled from sodium. Zirconocene complexes were obtained from MCAT Co., Konstanz, and trimethylaluminum and methylalumoxane from Aldrich Chemical Co. and used as such. Solutions for NMR experiments were prepared by dissolving ca. 1 μmol of the zirconocene dimethyl complex studied, directly in a 5-mm OD glass NMR tube, in 0.4 mL of a solution of $AlMe_3$ in C_6D_6 and then dissolving the appropriate amounts of $[Ph_3C][B(C_6F_5)_4]$ or of solid methylalumoxane in the reaction mixture. The NMR tube was transferred from the glovebox, inside an Ar-filled Schlenk vessel, to the cavity of the NMR spectrometer. After adding 1-hexene through the PTFE-lined septum closure from a PE syringe, which had also been kept inside an Ar-filled Schlenk vessel, ^1H NMR spectra were recorded on a Bruker AV 400 spectrometer, with 2.7 s acquisition time and 1 s delay time. Solutions for UV-vis experiments were similarly prepared in small (5-10 mL) sample vials. Portions of 2-2.5 mL were transferred to 1-cm UV-vis cuvettes equipped with a double-septum closure. After recording initial UV-vis spectra, 50-100 μL quantities of 1-hexene were added via a syringe through the double-septum closure and the ensuing spectral changes were recorded with a Cary 60 spectrometer, first in intervals of 12 seconds, later in 0.5- and 1-min intervals.

3 Results and discussion

In previous studies on the polymerization of 1-hexene or propene with various zirconocene-based catalysts by means of parallel ^1H NMR and UV-vis spectroscopy, we have shown that the initially predominant pre-catalyst species $[LZr(\mu\text{-}Me)_2AlMe_2]^+$ (with L = Me_2Si-bridged and/or substituted bis-indenyl ligand) is almost completely converted to cationic complexes with Zr-bound allylic chain ends, $[LZr\text{-}\eta^3\text{-}CH2CRCHR']^+$ (with R,R' = alkyl, polymeryl) [1, 2]. These polymer-carrying cationic Zr-allyl complexes, which constitute the dominant catalyst species

during ongoing polymerization catalysis, give rise to a UV-vis absorbance at ca. 560 nm. More recent kinetic studies on such a catalyst system by fast UV-vis spectroscopy provide evidence that – in addition to the two cationic complexes mentioned above and to a slowly forming decay product – an additional, short-lived intermediate arises during the first few minutes of the catalysis reaction, at the stage where most of the olefin is consumed. Since the concentration of this short-lived species appears to be proportional to the rate of olefin consumption, as obtained by parallel NMR measurements, it is likely to represent the hitherto elusive rate-determining catalyst intermediate [LZr(η^2-olefin)-polymeryl]$^+$. Its concentration appears to amount to ca. 5-10% of the total catalyst concentration.

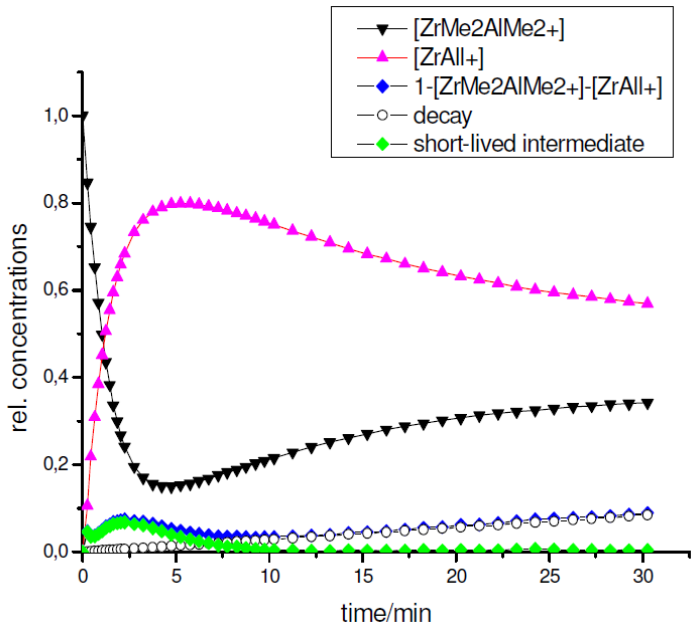

Figure 1. Concentration profiles of the pre-catalyst species [LZr(μ-Me)$_2$AlMe$_2$]$^+$ (black), of the main resting state [LZr-η^3-allyl-polymer]$^+$ (magenta), of a decay product (open circles) and of a short-lived catalyst intermediate (green), during polymerization of 1-hexene by a trityl-activated Me$_2$Si(ind)$_2$ZrMe$_2$ catalyst, determined by parallel ^{1}H NMR and UV-vis spectroscopy.

Further corroboration of the catalyst kinetics based on these UV-vis data is to be derived from ongoing NMR studies, which are aimed at a quantitative structural characterization of the polymer products with regard to internal and to chain-end unsaturations, known to arise from Zr-allyl species by olefin insertion and by their chain transfer to an alkyl-aluminum co-catalyst, respectively. Together, these spectroscopic results are expected to yield a detailed description of all relevant reaction steps involved in these catalytic polymerization reactions.

4 Conclusions

By parallel NMR and UV-vis studies, a thorough structural characterization of catalyst intermediates can be combined with a detailed kinetic elucidation of elementary reaction steps, which are responsible for the overall rate and the product distribution of a catalytic process.

Density Functional Theory Study of Alcohol Amination Reaction on Monoclinic Zirconia Surfaces

Martin L.[1,2], Paul J.-F.[1,2*]

Keywords: DFT, calculations, oxide, surface, coadsorption, effect, alcohol amination, ethanol, ammonia

1 Introduction

In the actual environmental awareness, it is essential to develop eco-efficient processes for the synthesis of highly valuable diamine monomers (either new or already existing) using molecules obtained from biomass upgrading. Among the various processes to prepare amines, the N-alkylation of alcohols with ammonia or amines over is particularly attractive because of the availability of various types of alcohols (which can be bio-sourced diols) and the fact that water is the main by-product.

Metal-Supported Oxide catalytic family offers promising properties for alcohols amination with amines and ammonia [1]. However, the role played by the support in this amination process is not precisely understood. As the oxide supports have specific properties like Bronsted and/or Lewis acido-basic and/or redox properties, the interaction of molecules like water, ammonia, amines and alcohols with these oxide surfaces can lead to a large range of reaction.

In our study, we are interested in the catalytic reactions of ammonia and ethanol over bare and partially hydrated ZrO_2 surfaces using the Density Functional Theory (DFT). Particularly, we wanted to determine the energy barriers for different mechanisms of alcohol amination reaction and alcohol dehydrogenation process on a ZrO_2 catalyst.

2 Computational details

All calculations were performed using the plane wave DFT code VASP using the PBE functional. The electronic wave-functions were described in the Projected Augmented Wave (PAW) formalism. Reaction paths have been studied with the Nudge Elastic Band procedure (NEB) and all structures were minimized until the forces acting on each atom were less than 0.03 eV/Å.

3 Results and discussion

First, we have compared the adsorption on the exposed ZrO_2 surfaces (the (-111), (111), (011) and (001) facets were considered for the monoclinic zirconia phase [2]) of three different molecules: water, ammonia and ethanol. From our calculations, the isolated ethanol or water molecules prefer to dissociate at the zirconia surfaces due to the presence of Lewis acid Zr(s) sites and sufficiently strong Bronsted basic O(s) sites. On the contrary, ammonia is always adsorbed associatively on the Zr(s) sites. Moreover, the thermodynamic study of adsorption competition have indicated that the reactants (ammonia and ethanol) can substitute the initially adsorbed water molecules on ZrO_2 surfaces in the gas-phase conditions of the amination reaction (method proposed by Lemaire et *al.* [3] for oxide catalyst ($T_{reaction}$=200-300°C)).

Then, several possible reaction mechanisms for alcohol amination and dehydrogenation were investigated on the ZrO_2(111) plane. We demonstrated that similar catalytic behaviour was obtained for different ZrO_2 facets due to their comparable acido-basic properties. For the N-alkylation of ethanol with ammonia over zirconia, a nucleophilic substitution has been proposed

from a configuration in which the two reactants are coadsorbed on the ZrO_2(111) facet. In this Langmuir-Hinshelwood (LH) scheme (figure 1), a carbocation intermediate is formed from the adsorbed ethanol. Then the dissociated NH_3 molecule reacts with this intermediate to form the product $C_2H_5NH_2$.

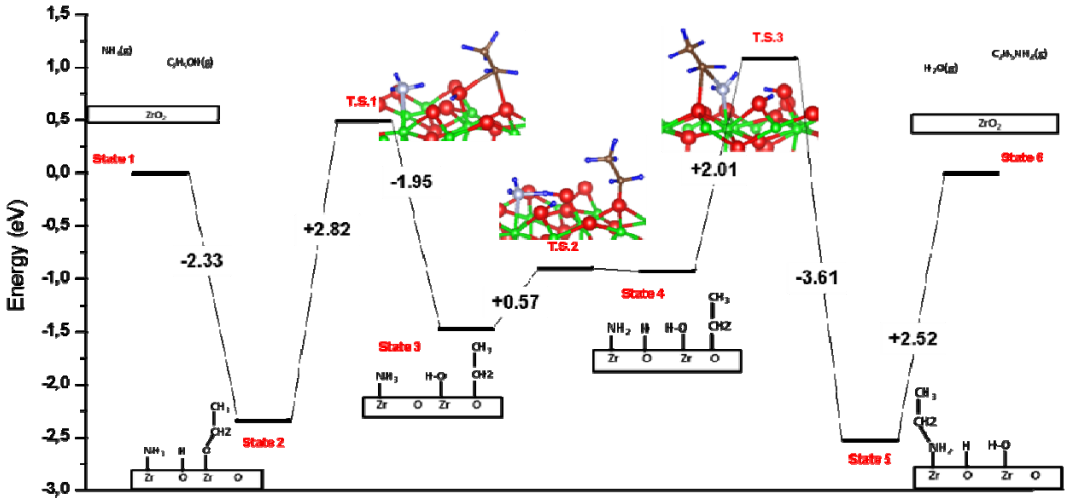

Fig. 1. An example of catalytic cycle calculated for the amination reaction in the LH case

In the Eley-Rideal (ER) mechanism, the nucleophilic NH_3 molecule does not adsorb on the surface and directly reacts on the adsorbed ethanol. In this case, we demonstrated the importance of water molecule coadsorption in a favourable configuration (hydrogen-bonded to NH_3(g) and adsorbed ethanol). Indeed, the adsorbed base [OH^-] assists the alcohol amination on ZrO_2 catalyst as it facilitates the N-H bond scission. For the ER type reaction, the calculated energy barrier is around 1.6 eV which is much smaller than those calculated for the LH mechanism (figure 1).

Finally, we also demonstrated that coadsorption of ethanol and water molecules in a specific configuration at ZrO_2(111) surface efficiently assists the ethanol dehydrogenation as it can strongly influence the C-H and O-H bonds activation.

4 Conclusions

The adsorption and reactivity of ammonia and ethanol at ZrO_2 surfaces revealed a relatively poor catalytic activity of the bare ZrO_2 surfaces for amination reaction and evidenced the crucial role played by the coadsorbed water molecule in the acide-base reactions. From our DFT calculations, we can conclude that the alcohol amination requires temperature activation to be efficient on oxide catalyst which is in agreement with previous experimental results [3]. These theoretical results highlight the importance of adding metallic particles to make this amination process more efficient.

Keywords: EU-1 zeolite, multivalent surfactant capping agent, Ethylbenzene Hydroisomerization

1 Introduction

EU-1 (EUO topology) is a medium-pore ICI proprietary zeolite featuring deep side-pockets connected at regular distances to a tubular pore system. This intriguing microporous architecture has resulted in the industrial application of EU-1 based catalysts in the industrially relevant ethylbenzene hydroisomerization. During an initial period of fast deactivation, following the blockage by carbonaceous deposits of the access to the inner sites of the EUO micropores, solely the outer surface sites remain active and relatively insensitive to deactivation. Over the stabilized catalysts, for which only the protonic sites of large side pockets can be active, the selectivity to isomers is particularly high [1]. The quasi isolation of these acid sites is believed favorable to monomolecular one-step reactions at the expense of bimolecular reactions (e.g. ethylbenzene disproportionation and transalkylation) or of multi-step reactions (e.g. secondary cracking). As only a reduced fraction of the protonic sites can effectively participate in the acid-catalyzed reactions, up to date the challenge has been to prepare EU-1 based catalysts with a larger and easily accessible outer surface. Over the years, exploratory work has led to the synthesis of hierarchical zeolites using both top-down and bottom-up approaches. The synthesis of nanocrystalline zeolites using multi-ammonium surfactants through a capping effect has been recently reported [2]. Multivalent cationic surfactants were witnessed to be able to synthesize FAU, MOR, CHA, and MFI-type zeolite nanocrystals. In this paper, the surfactant-capping strategy was applied to the EU-1 zeolite and the resulting nanocrystalline zeolite tested in the hydroisomerization of ethylbenzene and compared with a bulk counterpart.

2 Experimental/methodology

Bulk EU-1 zeolite with Si to Al molar ratio equal to 30 was synthesized at 423 K, following a synthesis procedure described elsewhere [3]. Hexamethonium bromide (TCI) was used as the SDA. In the synthesis of the hierarchical EU-1 zeolite, $C_{18}H_{37}$-$N^+(CH_3)_2$-C_6H_{12}-$N^+(CH_3)_2$-C_6H_{12}-$N^+(CH_3)_2$-$C_{18}H_{37}$ was added to the conventional synthesis composition of EU-1 zeolite. The use of seed was pondered to reduce the necessary hydrothermal time. The obtained gel had a molar composition 60 SiO_2:1 Al_2O_3:10 SDA:1 C_{18}-N_3-C_{18}:10 Na_2O:1500 H_2O:3 seed. The bifunctional catalysts were prepared by milling the zeolite samples with 1.0 wt.% Pt/Al_2O_3, prepared by ionic exchange of □-Al_2O_3 with a hexachloroplatinic acidic solution. A corresponding weight proportion of 10:90 was used. The ethylbenzene hydroisomerization was conducted in a fixed bed stainless steel reactor at 683 K, 10 bar and a H_2/ethylbenzene=4 mol/mol. 1.0 g of catalyst with a particle size between 0.200-0.355 mm was loaded into the reactor. The catalyst was activated *in situ* at 753 K for 4 hours under H_2 flow (5 K/min, at 10 bar). The reaction was firstly carried out, at a fixed weight hourly space velocity (WHSV=15 g of ethylbenzene h^{-1} g^{-1} of catalyst), until a virtually stable conversion was obtained with increasing time-on-stream. At this point, conversion was then

determined in function of the WHSV, varied in a 2-60 h^{-1} range, by changing the reactant flow. The obtained products were analyzed online by flame ionization detector gas chromatography.

3 Results and discussion

XRD patterns of both as-synthesized EU-1 samples were in agreement with those reported in the literature. Representative scanning electron microscopy (SEM) photographs illustrated the presence of agglomerates of small granular crystals in the 20-50 nm range. The agglomerates exhibited dimensions up to 3-4 μm. SEM images confirmed the successful appliance of the surfactant-capping agent through the presence of granular crystals with decreasing particle diameters. Following nitrogen assessment, the *t*-plot method revealed an external surface of the EU-1 nanocrystals obtained in this manner of 152 m^2 g^{-1}, whereas the bulk counterpart exhibited only 62 m^2 g^{-1}. With both samples, the activity of EU-1 based catalysts was observed to decrease with TOS up to a certain extent, after which solely the outer surface sites remained active and relatively insensitive to deactivation. The results presented hereafter were obtained at the aforementioned steady state. The conversion rates of ethylbenzene were plotted for both EU-1 based catalysts as a function of the contact time, taken as the reverse of the corresponding WHSV values (Figure 1). In each case, the obtained results reveal a continuous increase of ethylbenzene conversion with the contact time. More importantly, given the significant increase of the external surface area, the catalytic activity was remarkably shifted to higher values at *iso*-WHSV values. Despite the significant increase in the catalyst activity, no detrimental effect was observed in the obtained isomerisation yields.

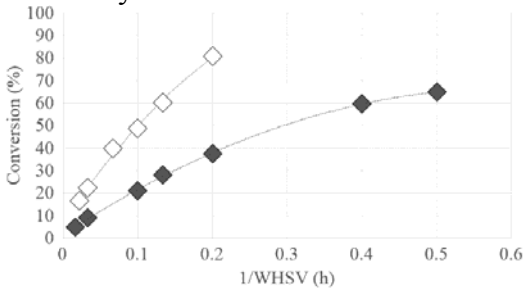

Fig. 1. Ethylbenzene conversion against contact time (taken as the reverse of WHSV) over EU-1 zeolite synthesized in presence (open diamond) and absence (closed diamond) of a capping agent.

4 Conclusions

The capping effect of a multivalent cationic surfactant was successfully used in the synthesis of EU-1 zeolite nanocrystals. Whereas the conventional template, hexamethonium bromide, was still confirmed to direct the synthesis of the zeolite crystals, the nanocrystals formation was attributed to the strongly binding effect of the surfactant molecules on the substrate surfaces. The surfactant capping was confirmed to effectively determine the crystal size in a passive manner. Preliminary catalytic results demonstrated the remarkable impact of generating an EU-1 zeolite with a larger and easily accessible outer surface, exhibiting a higher concentration of active acid sites. Current works intend to study the continuous increase of the external surface area that would allow to decrease the density of acid sites responsible for secondary and undesired bimolecular reactions.

Catalytic Oxidation of α-Alkenes C8-C12 to Carboxylic Acids

Oleneva P.V., Berdnikova P.V., Pai Z.P.*

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

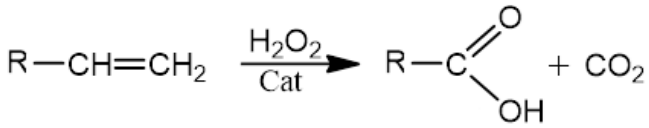
* zpai@catalysis.ru

Keywords: oxidation, ofterminal, alkenes, phase-transfer, catalysis, hydrogen, peroxide, peroxotungstate

1 Introduction

Monocarboxylic acids are useful products in various industries: chemical (for the production of lubricants, hydraulic fluids, paints, plastics), agrochemical (for the production of pesticides, herbicides, acaricides), food and perfume (preservatives, fragrance precursors), and pharmaceutical (drugs or their precursors).

C8-C10, C10-C12 alkene fractions and pure C8, C10 and C12 alkenes are available in oil refineries (for example, Neftekamsk Oil refinery). But effective ways of processing these fractions are limited [1]. Generally speaking, alkenes can be converted to alcohols or carboxylic acids. The results of C8-C12 terminal alkenes oxidation in two-phase system (organic phase/water phase) with phase-transfer catalysts to aliphatic carboxylic acids are shown in this study:



,

where R = C_4H_9, C_6H_{13}, C_8H_{17}.

2 Experimental/methodology

The available and environmentally friendly 30% aqueous hydrogen peroxide is used as an oxidant. The reaction is performed in the presence of bifunctional catalytic systems based on peroxocomplexes of tungsten in combination with quaternary ammonium cations – $Q_3\{PO_4[WO(O_2)_2]_4\}$, where Q^+ is quaternary ammonium cation [2].

The phase-transfer catalysis allows the oxidation reactions of various organic substrates to be carried out under mild conditions – at low temperature (up to 100 °C) and atmospheric pressure. The important advantage of this catalytic method is the possibility of process implementation in the absence of hazardous organic solvents. Therefore, the phase-transfer catalytic reactions can be related to the "green" chemistry. The problem of a homogeneous catalyst separation from the reaction mixture in this case is solved by separating the phases since the catalyst and the final product are in different phases – organic and aqueous, respectively.

3 Results and discussion

As shown in Figure 1, the yield of heptanoic acid (C7) in the 1-octene oxidation in the presence of $[Bu^n_4N]_3\{PO_4[WO(O_2)_2]_4\}$ catalytic complex was 18%, in the presence of $[CetPy]_3\{PO_4[WO(O_2)_2]_4\}$ catalytic complex – 90%, and in the presence of $[MeOct^n_3N]_3\{PO_4[WO(O_2)_2]_4\}$catalytic complex – 92%. The lowest activity is observed in the presence of tetra-*n*-butylammonium salt of $\{PO_4[WO(O_2)_2]_4\}^{3-}$. It is accounted for the influence of cation type on the catalytic activity as reported in [2b]. The yields of nonanoic acid (C9) in the 1-decene oxidation and the yields of undecanoic acid (C11) in the 1-dodecene oxidation in the presence of $[Bu^n_4N]_3\{PO_4[WO(O_2)_2]_4\}$ did not exceed 17-18% (Fig. 1).

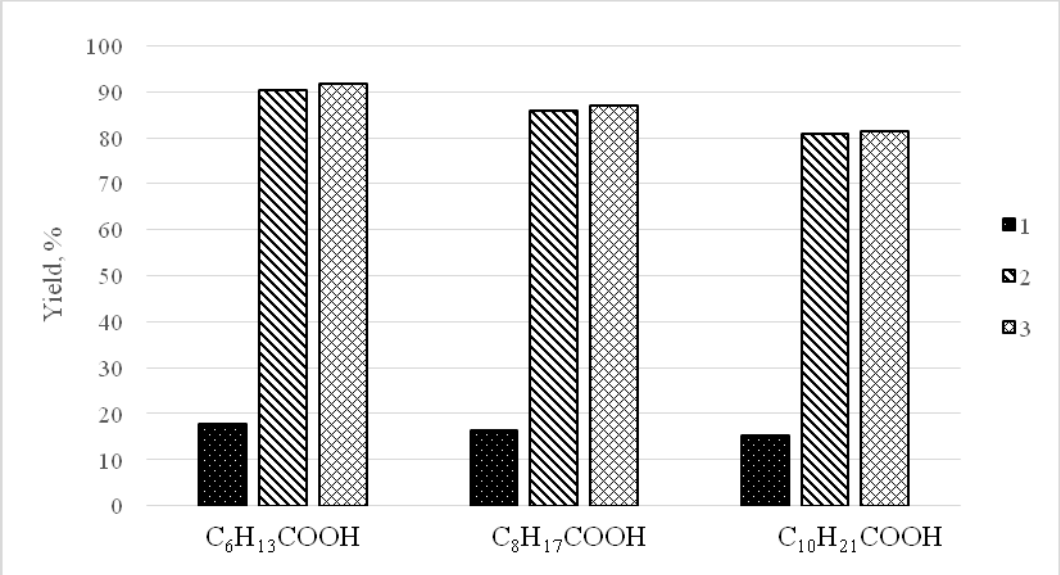


Fig. 1. Yields of carboxylic acids in α-alkenes oxidation with 30% aqueous hydrogen peroxide in the presence of catalytic complexes **1-3**.
Conditions: T = 90 °C, [Sub] / [Cat] = 200, $[H_2O_2]$ / [Sub] = 5, τ = 4 h.
1 – $[Bu^n{}_4N]_3\{PO_4[WO(O_2)_2]_4\}$
2 – $[CetPy]_3\{PO_4[WO(O_2)_2]_4\}$
3 – $[MeOct^n{}_3N]_3\{PO_4[WO(O_2)_2]_4\}$

4 Conclusions

The data obtained in the α-alkenes oxidation with 30% aqueous hydrogen peroxide in the presence of peroxopolyoxophosphotungstates $Q_3\{PO_4[WO(O_2)_2]_4\}$ demonstrate the possibility for obtaining valuable carboxylic acids (heptanoic, nonanoic and undecanoic) with high yields (more than 90%) under mild conditions (temperature < 90 °C, atmospheric pressure).

The most active catalysts are *tris*cetylpyridinium- and *tris*methyl-*n*-trioctylammonium tetrakis(oxodiperoxotungsto)phosphate.

Keywords: structured catalyst, wash coating, ZSM-5, methanol-to-olefins, robocasted catalyst

1 Introduction

Present-day catalytic research focusses often on enhancing the economic and environmental properties of existing processes. In order to do so process intensification is implied, the energy-efficiency, activity, selectivity and stability of catalysts need to be improved. By replacing packed beds of catalyst pellets or powders by a structured catalyst, the performance of the reactions that suffer from mass and heat transfer limitations can be significantly improved. However the architecture of the porous support material will have an impact on the catalytic properties of the final catalyst.

2 Experimental/methodology

By using a rapid prototyping technique the porous support was build up layer by layer [1, 2] (Figure 1). Robocasting is a solid free forming technique for the manufacture of metallic or ceramic porous structures. In this way periodic and highly reproducible support structures, with high mechanical properties and low pressure drop were synthesized [3, 4]. This technique allows to control the porosity, size of the unit cell and design of the support material. The support structures were coated by a wash coating procedure (Figure 2). After drying and sintering of the coated supports the adhesion of the coating was evaluated using ultrasonic treatment. Methanol-to-olefins (MTO), a highly economically relevant that suffers from mass and heat transfer limitations was chosen as demonstration reaction. In the present work, 3DFD support structures with different architectures were coated with ZSM-5 catalyst and compared with a packed bed of zeolite and traditional honeycomb monoliths for the conversion of methanol to olefins.

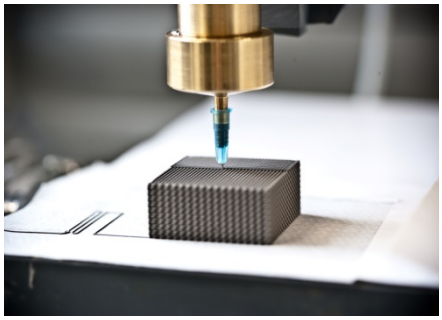

Figure 1. Synthesis of support by 3DFD

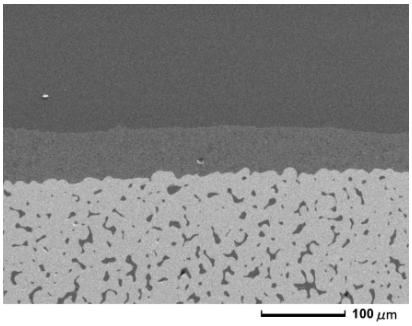

Figure 2. SEM image of coated 3DFD support

3 Results and discussion

The results of catalytic tests show an increase in activity and selectivity to the desired light

olefins (Figure 3) in case of using structured catalysts. Interestingly the 3DFD sample with zigzag channels in the direction of the gas flow shows the highest selectivity towards the desired products. It is suggested that the more tortious pathway of the reagents and products through the structure leads to the improved mass and heat transfer properties of the support resulting in better catalytic performance. Pressure drop measurements have already confirmed that the flow behaviour in the structures with different architectures is significantly different.

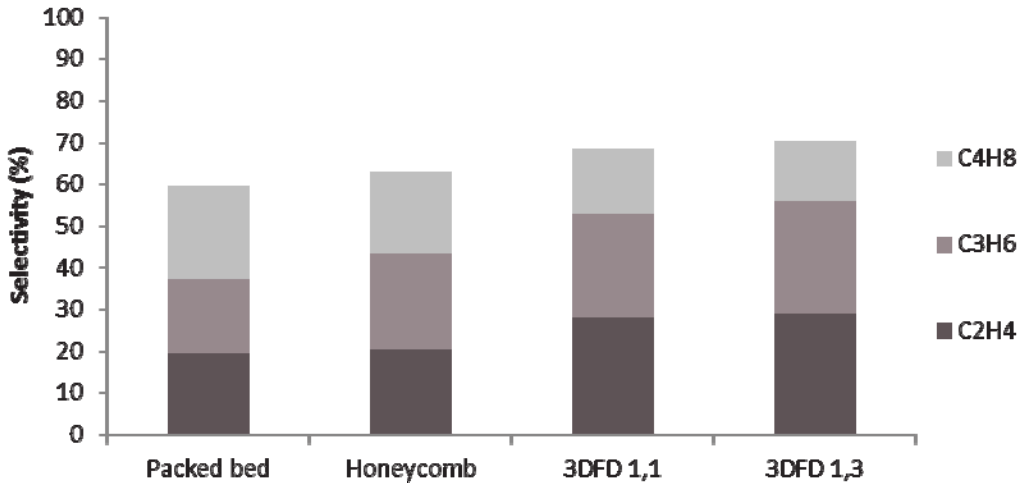

Figure 3. Selectivity to light olefins of different catalytic systems.

4 Conclusions

Robocasting could become an interesting tool for the development of innovative catalytic structures with improved mass and heat transfer properties. Further improvement can be made by optimizing the porosity, unit cell size and further design of the channels of the structures. However this implies a very large freedom of design and the input from modelling will lead to faster optimization of the design of the catalytic structure. Moreover the design of the catalyst can be altered as a function of the reaction and the desired properties of the catalyst.

Keywords: oxide, catalyst, hydrocarbons, carbon, dioxide, toluene, deep oxidation

1 Introduction

The problem of chemical safety and air protection is particularly relevant due to increased emissions of industrial enterprises, which have toxic effects on the fauna and flora. Emissions of the industrial enterprises (paint, furniture, cable, pharmaceutical, printing) and transport are the main pollutants. Many chemical compounds (toluene, xylene, styrene, phenol, tricresol, white spirit, etc.), which have a negative impact on living organisms, are also harmful toxic emissions from industrial plants [1]. In this regard, the development of new-generation catalysts for deep cleaning of industrial emissions and motor vehicles which do not contain precious metals or low their content in the catalysts is relevant for the Republic of Kazakhstan.

2 Experimental/methodology

Polyoxide catalysts were prepared by incipient wetness impregnation of alumina modified by cerium with mixed aqueous solution of metal salts nitrate followed by drying at 453-473 K (4-5 h) and calcination at 873 K (1-1.5 h) in air. The spherical θ-Al_2O_3 (made at Boreskov Institute of Catalysis, Novosibirsk) with a diameter of 3-4 mm and specific surface area of 100 m^2/g, bulk weight of 0.80 g/cm^3, the mechanical strength of 150 MPa and pore volume of 0.48 cm^3/g was used as a carrier for polyoxide catalysts [2]. θ-Al_2O_3 was modified by cerium oxide, which forms the surface $CeAlO_3$ of perovskite type with alumina resistant up to 1373 K.

Deep oxidation of toluene as a model object was carried out on the flow installation. Toluene content before and after reaction was analyzed on a chromatograph Crystal-2000M with flame ionization detector on a capillary column. Column temperature - 160°C, evaporator temperature - 240°C, the hydrogen flow - 25 mL/min, air flow - 250.0 ml/min. The catalyst activity was measured in the oxidation of toluene, a substance frequently present in industrial gas emissions. The test of Ni-Cu-Cr/2% Ce/θ-Al_2O_3 catalyst was carried out at space velocity W = 5×10^3 h^{-1} in the temperature range 523-773 K and toluene concentration of 320 mg/m^3 [3].

3 Results and discussion

The obtained data showed that the nickel-copper-chromium-containing polyoxide catalysts in deep oxidation reaction of toluene at 723 K and space velocity 5×10^3 h^{-1} are arranged in the following order on the activity:

NiCuCr/2%Ce/θ-Al_2O_3(98,8%) > NiCuCr/θ-Al_2O_3 (93%) > Ni-Cu/2%Ce/θ-Al_2O_3(85%) > Ni-Cr/2%Ce/θ-Al_2O_3(76%) > Ni/2%Ce/θ-Al_2O_3(57%)

Comparison of the activity of multicomponent nickel-copper-chromium-containing catalyst supported on alumina modified by cerium with a catalyst supported on alumina without cerium showed that the conversion of toluene on the Ni-Cu-Cr/2% Ce/θ-Al_2O_3 catalyst is more high (98.8%) than on the Ni-Cu-Cr /θ-Al_2O_3 (93%) catalyst. The highest degree of conversion (up to 98.8%) of toluene was achieved on a multi-component Ni-Cu-Cr/2% Ce/θ-Al_2O_3 catalyst, and

the lowest - on the Ni/2% Ce/θ-Al_2O_3 contact.

Methods of entering the active components in composition of the nickel-copper-chromium catalyst for deep oxidation of toluene to CO_2 and H_2O were investigated. Methods for supporting of active phase indicated that sequential entering of components does not contribute to improving the effectiveness of nickel-copper-chromium catalyst. The best result was obtained at simultaneous introduction of all components in the impregnating solution. Modification by small additions of basic compounds which are introduced into impregnation solution (Na_2CO_3, KOH, NH_4HCO_3) is one of the methods for obtaining of catalysts with uniform distribution of components.

Thus, the conversion of toluene to CO_2 reaches 97.5-98.8% on the Ni-Cu-Cr/2% Ce/θ-Al_2O_3 catalyst at the temperature of 723-773 K and space velocity 5×10^3 h^{-1}.

4 Conclusions

Polyoxide Ni-Cu-Cr/2% Ce/θ-Al_2O_3 catalyst with desired properties on carriers for deep oxidation of hydrocarbons - toluene, xylene, styrene, ethyl acetate, butyl acetate, isobutanol, formaldehyde, acetone, ethanol, etc., which have a toxic effect on living organisms and flora, was developed. It has been shown that the synthesized polyoxide Ni-Cu-Cr catalyst supported on 2% Ce/θ-Al_2O_3 provides 98.8% toluene conversion up to CO_2 at space velocity 5×10^3 h^{-1}, temperature 723-773 K and content of toluene 320 mg/m^3 in the initial mixture.

Keywords: asphaltenes, deposit, crude oil, SAXS

1 Introduction

One of the most intractable problems of recovery and processing of heavy oils and their components is the formation of asphaltene deposits inside the equipment used for transport and processing of heavy oils, which lead to inefficient heat transfer, loss of energy and raw materials during the process up to a few percent of each barrel of crude oil (energy equivalent) [1]. Asphaltenes that are defined as the heaviest fractions of crude oil insoluble in normal alkanes (n-pentane, n-heptane, etc.) have the complex molecular structure. Besides alkyl-substituted aromatic structures and aliphatic chains, asphaltenes can incorporate functional groups containing heteroatoms, including sulfides and nitrogen-containing saturated structures and some carbonyl, ether, or ester groups [2]. These complex structures of asphaltenes are known to deactivate and shorten the operational lifetime of hydrotreating catalysts used for heavy oil processing because of the deposition and coke formation onto the active catalytic sites [3, 4]. This provided motivation for finding new ways for the conversion of asphaltenes into valuable chemicals.

The typical asphaltene concentrations in the heavy oils lay in the range from 1 to 15%. The asphaltene molecules can form aggregates with sizes varied from 5 to 50 nm depending on the oil type and asphaltenes structure. Asphaltene aggregates can take different shape and morphology – from disks and cylinders to the fractal-like objects [5]. The essential factor that affects the processes of asphaltene aggregation is related to the asphaltene local environment in crude oil. The composition of the surrounding fluid along with pressure and temperature play an important role in the asphaltene stability. For example, an addition of paraffin solvent changes the solubility of asphaltenes in the bulk oil because paraffin solvent properties affect interactions among asphaltenes and resins [1, 5]. The high temperatures and pressures can also change the local environment of asphaltene molecules, resulting in either an increase or decrease of asphaltene solubility in crude oil. Thus, the prediction and control of oil stability and asphaltene solubility under certain conditions requires fundamental studies of the intermolecular interactions between asphaltenes and their local environment and investigation of local rheological properties of crude oil and molecular dynamics of asphaltenes in different surroundings.

Here we report the investigation of the asphaltene aggregation process influenced by some chemical additives based on the analysis of the Small Angle X-ray Scattering (SAXS) data. The SAXS method allowed us to investigate the kinetic of the asphaltenes aggregation *in situ* and analyze the key factors that influence the aggregation processes and asphaltenes stability.

2 Experimental

The behavior of asphaltene extracted from crude heavy oil [6] according ASTM method D6560-005 [7] has been investigated. Asphaltenes density measured by He pycnometer is 1.178 g/cm^3. The asphaltenes were dissolved in toluene followed by the introduction of certain

additives into the solution. The asphaltene and the additive concentrations in solutions were 5 mass % and 20 mass % respectively. The S3 MICRO (HECUS) small angle diffractometer (Cu Kα, 50W) with a point collimation of primary beam was used for measuring scattering patterns of all samples. The scattering vector magnitude $h = 4\pi*\sin(\theta)/\lambda$ (where 2θ is the scattering angle, and $\lambda = 1.541$ Å is the radiation wavelength) was used as the scattering coordinate. The scattering intensity was measured in the range of the scattering vector magnitudes $0.01 < h < 0.6$ $Å^{-1}$. The asphaltene solutions were placed in a quartz or glass capillary with 1.5 mm external diameter. The numerical calculation of the particle size distributions based on the scattering data obtained was made via GNOM program from the ATSAS package [8].

3 Results and discussion

It was found that the asphaltene aggregates in the toluene solution without any additives have elongate shapes and wide sizes distribution with characteristic size about several nm. The influence of more than 30 chemical additives and asphaltene aggregation process has been studied. It was shown that such additives as cyclohexane, methanol, formic acid, heptane, TBAF, acetonitril, decane, hexanol-1, furfural, octen-1 tend to increase the sizes of asphaltenes aggregates. At the same time acetone, glycerol, ethylacetate, dioxane, benzyl alcohol, limonene, pinene, cycloheptatriene and ionic liquid (t-butyl imidazole tetrafluoroborate) practically do not affect the aggregates sizes. It was shown that some polar compounds (e.g. DMSO) can lead to the disaggregation of the asphaltenes.

Keywords: hydrodeoxygenation, sulfide catalyst, aliphatic ethers, rapeseed oil

1 Introduction

Hydrodeoxygenation (HDO) of triglyceride-based feedstocks such as vegetable oils and animal fats produces a mixture of C_{13}-C_{18} paraffins and is considered now as an important commercial route for the production of diesel range bio-fuels. Hydroprocessing of such feedstocks may be performed in stand-alone units or via the co-hydrotreatment of renewable feeds with petroleum-derived distillates in the existing HDS units. In both cases conventional hydrodesulfurisation catalysts (CoMo or NiMo) may be used to convert triglycerides into linear alkanes. The reaction pathways of triglyceride molecules conversion involve the elimination of oxygen through several competing routes: hydrodeoxygenation (HDO) or decarboxylation/ decarbonylation ($HDeCO_X$). The critical challenge in the developing of the new energy-efficient processes for the triglyceride-based feedstock conversion is the elucidation of peculiarities of sulphide catalyst's behaviour depending on their chemical composition.

The current work presents the results of the comparative study of MoS_2/Al_2O_3, $CoMoS/Al_2O_3$ and $NiMoS/Al_2O_3$ catalysts in the aliphatic ethers hydro conversion as well as in the hydrotreating of rapeseed oil (RSO) and its mixtures with the straight-run gasoil (SRGO). Our efforts are concentrated on the selectivity of aliphatic ether transformation depending on the active phase chemical composition and the reaction conditions; the influence of RSO content on the HDS and HDN activity of catalysts in the SRGO hydrotreating was also analyzed.

2 Experimental/methodology

The catalysts were prepared by impregnation of Al_2O_3 granules with a solution of active metals precursors, phosphoric and citric acids. The HDO of methyl heptanoate (MH) and methyl palmitate (MP) were performed in a batch reactor at 300°C and hydrogen pressure of 3.5 MPa. The reaction products were identified by GC/MS technique and quantified by gas chromatography system (Agilent 6890N) equipped with atomic emission detector (GC-AED). The hydroprocessing of RSO, SRGO and blended feeds (5-15 wt.% of RSO) was carried out in trikle-bed reactor at 3.5-7.0 MPa, 300-360°C, LHSV 1-2 h^{-1}, H_2/feed ratio 300-1000. The total S and N content in the products were determined using ANTEK 9000NS, the total oxygen content – by means of CHNSO analyzer Vario EL Cube. The quality of produced fuels (boiling range distribution, density and cetane number) was checked using the corresponding ASTM methods.

3 Results and discussion

Characterization of the catalysts in the sulfide state by means of XPS, XRD and HRTEM confirmed that the applied preparation and sulfidation procedures provide the formation of highly dispersed MoS_2, CoMoS and NiMoS nanoparticles (3-5 nm) on the alumina surface.

The comparison of catalyst's performance in MP hydroconversion let us to conclude, that the sulfided Mo/Al_2O_3, $CoMo/Al_2O_3$ and $NiMo/Al_2O_3$ catalysts revealed the same rate of the methyl palmitate conversion but the rate of the intermediate oxygenates conversion decreased in order: $CoMoS/Al_2O_3 > NiMoS/Al_2O_3 > MoS_2/Al_2O_3$. A mixture of linear saturated and unsaturated C_{15} and C_{16} hydrocarbons was produced when the oxygen-containing compounds were fully consumed. The main products obtained over the Mo/Al_2O_3 were C_{16} hydrocarbons (about 95 mol. % selectivity at 100% conversion), while $CoMo/Al_2O_3$ and $NiMo/Al_2O_3$ catalysts gave C_{16} hydrocarbons with the selectivity of 72 and 40%, respectively. So, the chemical compositions of sulphide phase effects on the contributions of the hydrodeoxygenation (HDO) and decarboxylation/decarbonylation ($DeCO_x$) pathways during the hydroconversion of methyl palmitate. The investigation of listed above catalysts in RSO hydrotreating confirmed this conclusion and elucidate the influence of reaction condition on selectivity: the rising of temperature and decrease of hydrogen pressure enhance the contribution of $DeCO_x$ pathways.

Comparing HDS rate constants for the SRGO feeds with the different RSO content showed that RSO addition (up to 15 wt. %) markedly decreased the activity of $CoMoS/Al_2O_3$ catalysts but had no effect on the activity of $NiMoS/Al_2O_3$ one. The same dependencies were observed in HDN reaction. In accordance, over $NiMoS/Al_2O_3$ catalyst ULSD can be produced from SRGO and RSO-SRGO blend at the same conditions, while the temperature increase is needed if the $CoMoS/Al_2O_3$ catalyst is used for ULSD production from RSO-SRGO blends. The hydrodeoxygenation of RSO over sulfide catalysts gave paraffins, propane, water, CO, and CO_2. It was observed in the special experiments that addition of CO to the hydrogen flow had the same effect on the HDS activity of the $CoMo/Al_2O_3$ and $NiMo/Al_2O_3$ catalysts as the addition of RSO to the SRGO feed. Thus, CO molecules formed as a result of RSO hydroconversion can be considered as a main reason of decrease of $CoMoS/Al_2O_3$ catalyst's activity. This assumption was supported by the observation that addition of benzofuran giving only water in HDO reaction had a minor influence on the activity of $CoMoS/Al_2O_3$ catalyst in HDS of SRGO. Taking into account the discovered peculiarities the reactor with multi-bed loading was proposed for the hydrotreating of RSO-SRGO mixture. The use of MoS_2/Al_2O_3 in front layer for the RSO conversion diminished the CO formation and allowed to use the $CoMoS/Al_2O_3$ catalyst in the second layer without significant decrease of HDS activity. The feasible reasons of the observed differences between $CoMo/Al_2O_3$ and $NiMo/Al_2O_3$ catalyst behavior were also discussed.

4 Conclusions

The behaviour of MoS_2/Al_2O_3, $CoMoS/Al_2O_3$ and $NiMoS/Al_2O_3$ catalysts was investigated in the HDO of aliphatic ethers and in the hydrotreating of RSO and its mixtures with the SRGO feed. It has been shown that the selectivity of aliphatic ether and RSO transformation depends on the composition of sulphide phase and the reaction conditions. The un-promoted MoS_2/Al_2O_3 catalyst turns the reaction to HDO route, avoiding the formation of C_{15} hydrocarbons and CO/CO_2 molecules. It was observed that RSO addition decreased markedly the activity of $CoMoS/Al_2O_3$ catalysts but had no effect on the activity of $NiMoS/Al_2O_3$ one in the HDS and HDN reaction. The CO molecules formed as a result of RSO hydroconversion can be considered as a main inhibitor of $CoMoS/Al_2O_3$ catalyst's activity. So, the chemical composition of sulphide phases effects strongly on the behaviour of sulfided catalysts in the hydrotreating of triglyceride-based feedstocks.

Keywords: heteropolyacid, mesoporous silica, isopropanol decomposition

1 Introduction

Heteropolyacids (HPAs), $H_{3+x}PMo_{12-x}V_xO_{40}$ (x =1-3) having Kigging structure have attracted increasing interest especially for the selective oxidations of hydrocarbons. The strong Brönsted acidity of such compounds is well known to be favourable to selective oxidation reactions. However, their low surface area (<10m^2/g) is always the main drawback. In order to overcome this problem, some recent works pointed out the use of suitable supports such as mesoporous silicates (MCM-41, HMS, CMI-1, SBA-15 …), providing high thermal stability, large surface area and high pore volume.

The objective of this work is to support $H_{3+x}PMo_{12-x}V_xO_{40}$ acid (x=1) on the silicate mesoporous (HMS). These materials present the advantage to have large surface area and pore volume with uniform mesopores and high thermal stability.

2 Experimental

HPAs were supported on silicate mesopourous HMS by dry impregnation method with 3wt.% loading. Various techniques including: Elemental analysis, XRD, FT-IR-DRIFT, N_2 physisorption, TG-DTA and SEM analysis were used to characterize the fresh catalysts. Catalytic performances of supported HPAs were compared to those of HPAs bulk in the isopropanol decomposition reaction to propene, diisopropylether and acetone products at 75°C.

3 Results and discussion

The supported HPAs showed better dispersion of heteropolyacids on the HMS surface. A sensitive decrease of the HMS support surface area was observed in the presence of $H_4PMo_{11}VO_{40}$ clusters. By TG-TDA analysis, HPA-HMS catalyst showed a higher thermal stability than pure HPA.

4 Conclusion

High catalytic performances were obtained for HPA-HMS catalyst. These results could be related to the high dispersion of HPA on the support.

Keywords: CO_2 hydrogenation, iron-based catalyst, N-doped carbon, nanotubes, promoter

1 Introduction

Rising concentrations of CO_2 may contribute to the increase in global temperature due to the greenhouse effect. In addition, depletion in crude oil resources and the continuous increase of its price have raised the research interest in CO_2 hydrogenation. CO_2 hydrogenation to hydrocarbons is a modification of Fischer-Tropsch synthesis (FTS), where CO_2 is used as reactant instead of CO. Recently, carbon nanotubes (CNTs) have been claimed as a promising support for catalysts used in FTS [1], because CNTs have a large outer surface area and are able to increase the dispersion of the catalytically active nanoparticles [2]. Promoters such as potassium are well known to increase the surface basicity of the catalyst. Consequently, they increase olefin selectivity and chain growth probability and suppress methane formation [2,3]. Hence, this work describes CO_2 hydrogenation to short-chain hydrocarbons over K- and Mn-promoted iron nanoparticles supported on nitrogen-functionalized CNTs (NCNTs).

2 Experimental/methodology

CNTs with inner diameters of 20-50 nm from Applied Sciences lnc. (Ohio) were subjected to nitric acid vapour treatment at 200°C for 24 h to create oxygen-functionalized CNTs (OCNTs). The OCNTs were treated at 400°C for 6 h in flowing ammonia (10 vol% NH_3 in He) to obtain NCNTs. NCNTs were added to an aqueous solution of ammonium ferric citrate to achieve a 40 wt% Fe loading. To obtain Mn-promoted iron catalyst, NCNTs were added to a mixture aqueous solution of ammonium ferric citrate and manganese (II) nitrate hydrate to achieve 10 wt% Mn and 40 wt% Fe. The mixtures were dried at 50°C overnight and calcination of the mixtures was carried out in air at 300°C for 90 min. Subsequently, the calcined samples were suspended into an aqueous solution of potassium carbonate aiming at a theoretical K loading of 1.5 wt%. CO_2 hydrogenation experiments were conducted in a fixed-bed U-tube reactor. The catalyst was first reduced in pure H_2 at 380°C and 25 bar for 5 h. Subsequently, the hydrogenation reaction was performed at 360°C and 25 bar using a mixture of 22.5% CO_2, 67.5% H_2 and 10% Ar at a total flow rate of 3.1 – 50 L g^{-1} h^{-1}. Online gas analysis was performed with a GC-TCD-FID using Ar as internal standard.

3 Results and discussion

The iron catalysts promoted with K and/or Mn showed higher degrees of conversion and more stable performance as compared to the unpromoted Fe/NCNT catalyst (Fig. 1). Potassium is known to increase the degree of carburization of iron catalysts during reaction to Hägg carbide, which is known to be the active phase in FTS [3]. It has been reported that a Mn-rich surface acts as a protective shell for an inner Fe-rich core, preventing oxidation by water formed as co-product leading to a higher stability [4]. After doping with small amounts of K, it was already possible to lower the methane selectivity from 39.9% to 5.6% and simultaneously to

enhance C_{3+} selectivity (Table 1).

Moreover, the addition of K increased the olefin selectivity significantly up to 80%. The product distribution over Mn/Fe/NCNT was almost similar to Fe/NCNT demonstrating that Mn acted as structural promoter. By increasing the residence time in the reaction zone, the selectivity towards hydrocarbons was increased while the selectivity of CO was decreased (Table 1) suggesting that CO is an intermediate being favoured at short residence times.

Table 1. Product selectivities, chain growth probabilities, olefin selectivities and CO_2 conversion.

Catalyst	Product selectivity (%)					$C_{2=}$-$C_{5=}$/C_2-C_5	α	X (CO_2) %
	CO	C_1	C_2	C_{3+}	Alcohol			
Fe/NCNT[a]	38.4	39.9	12.1	9.4	0.2	0.09	0.29	25.4
K/Fe/NCNT[a]	74.9	5.6	5.3	12.2	2.0	0.87	0.41	31.8
Mn/Fe/NCNT[a]	48.5	35.6	9.3	6.5	0.0	0.11	0.34	27.6
K/Mn/Fe/NCNT[a]	72.1	5.9	5.2	14.5	2.4	0.89	0.43	30.3
K/Mn/Fe/NCNT[b]	45.5	12.0	11.5	28.4	1.4	0.90	0.45	31.0
K/Mn/Fe/NCNT[c]	30.4	14.5	13.1	35.7	3.0	0.90	0.47	34.9

[a] total flow of 50 L g^{-1} h^{-1}, [b] total flow of 12.5 L g^{-1} h^{-1}, [c] total flow of 3.1 L g^{-1} h^{-1}.

4 Conclusions

CO_2 hydrogenation over unpromoted iron catalyst resulted in a high methanation tendency combined with a low olefin selectivity. By adding K, it was possible to suppress methane formation and to increase the olefin selectivity significantly. The stability of catalysts was improved by doping with Mn, which acts as structural promoter. The addition of both K and Mn enhanced the catalytic activity and stability of iron catalysts in CO_2 hydrogenation.

Combining Operando Spectroscopy and Chemometrics to Understand Changes in the Active and Deactivating Species during the Methanol-to-Olefins Reaction over H-SSZ-13

Ruiz-Martínez J.[1], Borodina E.[1], Meirer F.[1], Lezcano-González I.[1], Mokhtar M.[2], Asiri A.M.[2,3], Al-Thabaiti S.A.[2], Basahel S.N.[2], Weckhuysen B.M.[1*]

Keywords: operando spectroscopy, methanol-to-olefins, zeolite, UV-Vis, H-SSZ-13, multivariate analysis

1 Introduction

In most of the zeolite-catalysed reactions, deposition of discrete hydrocarbon species, also known as coke, causes loss of the catalytic activity and subsequent deactivation. Understanding catalyst deactivation by coke formation, especially when catalysts are working under real reaction conditions, is highly needed for the improvement of our current zeolite catalysts. This is notoriously difficult in relevant zeolite-catalysed reaction, for example the methanol-to-olefins (MTO) reaction, where discrete hydrocarbon species are believed to be the real active sites and therefore beneficial for the catalytic reaction [1]. Methods to discriminate between deactivating coke and active coke are therefore critical to understand catalyst functioning. In this research work, we report a method to determine the role of the hydrocarbon species during the MTO reaction over zeolite H-SSZ-13. Operando UV-Vis spectroscopy in combination with a multivariate analysis allow us to reveal that the reaction temperature affects to a great extent the nature of both the hydrocarbon species active in the MTO reaction and the hydrocarbon species deactivating the catalyst material.

2 Experimental/methodology

An Al-containing H-SSZ-13 was synthesized and characterized by N_2 physisorption, scanning electron microscopy, inductively coupled plasma optical emission spectrometry, X-ray diffraction, temperature-programmed desorption of NH_3 and CO adsorption at 77 K followed by IR spectroscopy. Operando tests were performed in a fixed bed reactor coupled with an UV-Vis optical probe. The analysis of the reaction products were performed with on-line gas chromatography (GC) and UV-Vis data were analyzed with the aid of a non-negative matrix factorization method. The nature of the compounds retained after MTO reactions was determined by dissolution of the zeolite sample and analysis of the extracted hydrocarbons by GC/MS.

3 Results and discussion

Catalytic activity data show that within the range of reaction temperatures studied (i.e., 573-723 K) the induction period decreases and catalyst stability increases with the reaction temperature. During the catalytic tests, the zeolite H-SSZ-13 was continuously monitored by operando UV-Vis spectroscopy in order to obtain detailed insight into the hydrocarbons formed inside of the pores during the MTO reaction. Interestingly, the UV-Vis data show that the reaction temperature affects the dynamics and position of the characteristic UV-Vis bands. This

can be related to a change in the rate and nature of the hydrocarbon species formed inside of the zeolite micropores. For an accurate chemical assignment of the UV-Vis bands, we have combined those experiments with the analysis of the retained hydrocarbons, determined by GC-MS, after a dissolution-extraction procedure.

Due to the complexity and dynamics of the spectra, a NNMF chemometrical method was applied for the analysis of the data. Two main groups of bands (I and II) with different kinetic behaviour were identified, as shown in Figures 1a and 1c during the MTO reaction at 573 and 723 K, respectively. Figures 1b and 1d clearly show that the group I is strongly linked to the activity of the material, whereas group II increases until the catalyst is completely deactivated. These results point out that each group of bands corresponds to species responsible for the activity and deactivation of the catalyst.

Interestingly, the reaction temperature affects the nature of both groups of species, as can be observed by the different UV-Vis features in Figures 1a and 1c. More specifically, the majority of active hydrocarbon pool species at low reaction temperatures (i.e., 573-598 K) are methylated benzene carbocations, while methylated naphthalene carbocations are determined as dominant active hydrocarbon pool species at high reaction temperatures (i.e., 623-723 K). Furthermore, at low reaction temperature deactivation occurs because of pore filling with methylated naphthalene carbocations and when the temperature is higher the deactivation is related to bulkier species, such as phenanthrene, pyrene and more poly-aromatic species, blocking the porosity of the catalytic material.

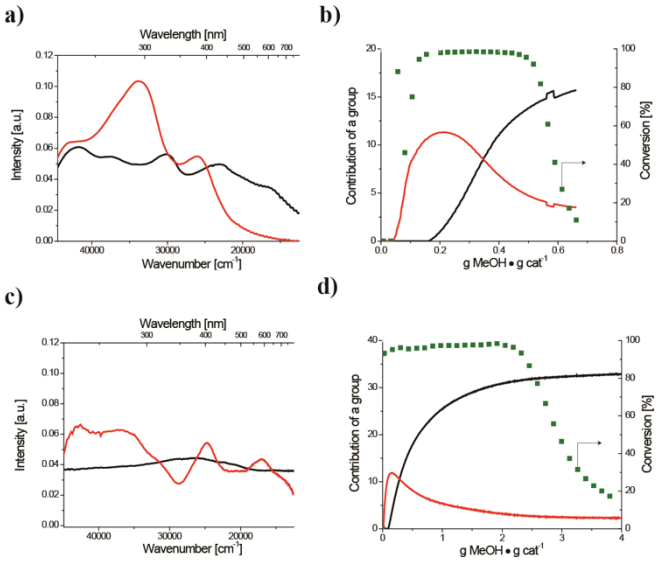

Figure 1. Deconvolution of the in-situ UV-Vis spectra collected during MTO reactions at 573 (a and b) and 723 K (c and d) on a H-SSZ-13 catalyst. The groups of bands (Eigen-spectra) for the species with different kinetics (a and c) and the evolution of every group of species as a function of methanol load on the catalyst material (b and d) were calculated by a non-negative matrix factorisation method. The red curve represents group I (active species), while the black curve corresponds to group II (deactivating species).

4 Conclusions

In this contribution we present a powerful approach to discriminate between the hydrocarbon species, which are contributing to the activity and deactivation of a H-SSZ-13 catalyst during the MTO reaction. This combines an operando UV/Vis spectroscopy setup with a chemometrical analysis of the spectroscopic data. This methodology reveals that the nature of the active and deactivating species change with the MTO reaction temperature. These results provide important fundamental insight into the MTO reaction and deactivation mechanisms.

Keywords: zeolites, hydrothermal synthesis mechanism, *in situ*, MAS, NMR

1 Introduction

Synthesis under hydrothermal conditions is the main synthetic route leading to wide variety of catalysts such as zeolites, zeotypes, mesoporous and micro-mesoporous materials, hybrid inorganic-organic frameworks and others. The improvement of existing catalytic materials and rational design of novel ones require the profound understanding of the mechanism of their synthesis.

The traditional approach for the investigation of the mechanism of hydrothermal synthesis is based on the interruption of the synthesis at different stages, isolation of the intermediate products and their analysis by a complex of physicochemical methods. The mechanism proposals are usually made on the basis of the information about structure and composition of intermediate products. This approach is named «*ex situ*», since intermediate products are analyzed outside of the reaction system. However this method does not always provide reliable results, since the state of the reaction system during synthesis can change significantly after the interruption of the reaction and isolation of intermediate products. To obtain full and, what is the most important, reliable information about the processes occurring during the synthesis, the techniques of direct observation "*in situ*" are required. But the "in situ" studies of hydrothermal synthesis of molecular sieve catalysts are connected with a lot of experimental difficulties concerned with severe synthesis conditions (temperatures up to 220 °C, pressure up to 20 atm, alkaline media) and with the complexity of the studied system, which is usually composed of various phases: true solutions, colloid solutions, gels, amorphous precipitates nanosized crystalline intermediates and final products.

This contribution is aimed at the development of the new techniques for the investigation of the mechanism of hydrothermal synthesis based on the application of NMR spectroscopy *in situ* and at the elucidation of the mechanisms of synthesis of Al-, Zr- and Sn-BEA zeolites.

2 Experimental/methodology

The synthesis of zeolites Al-, Zr- and Sn-BEA was carried out at 140 °C under hydrothermal conditions according the procedures described in [1-3]. For the investigation of the mechanisms of synthesis two approaches were used: traditional *ex situ* approach and novel *in situ* method based on MAS NMR spectroscopy. The first approach included the investigation of the structure, the composition and properties of stable intermediates recovered during the synthesis of molecular-sieve catalysts by means of wide range of physico-chemical methods, including XRF, XRD, IR spectroscopy, low-temperature N2 adsorption, TGA-DSC analysis, SEM and TEM. The amount, strength and nature of the active sites of catalysts was investigated by means of temperature-programmed desorption and IR spectroscopy of adsorbed probe molecules. The second approach was based on the direct observation of the state of atomic nuclei, which compose the frameworks of reagents, products and intermediates, during the synthesis using solid-state NMR spectroscopy in situ. The measurements were carried out in specially

constructed autoclave-type MAS NMR cell adapted for Bruker AVANCE II 400WB spectrometer. The spectra were recorded every 4 hours for ^{1}H, ^{23}Na, ^{27}Al, ^{29}Si and ^{119}Sn nuclei. The duration of experiments was from 1 hour to several days.

3 Results and discussion

The results obtained showed that the application of *in situ* MAS NMR approach provides unique information on the dynamics of various nuclei in reagents, intermediates and final products directly during the hydrothermal synthesis. It was found out that the spectral data for ^{1}H nuclei allow to follow the changes in pH and to study the kinetics of organic templates' transformations. At the same time, ^{29}Si MAS NMR permits detecting various mobile and rigid inorganic species, gives insight into the formation of intermediate unstable phases, including protozeolitic phases, and allows to follow their transformation into solid zeolitic structures. ^{29}Si MAS NMR HPDEC spectra allows detecting mobile and disordered siliceous species, whereas CPMAS technique provides the information about silicon atoms in solids. ^{27}Al and ^{119}Sn MAS NMR spectroscopy gives detailed information about the creation of zeolite active sites. Thus, the formation of different Al and Sn sites was detected and the kinetics of their transformation during synthesis was investigated. To summarize, it has been demonstrated that the spectral data give insight into the mechanism of the main steps of synthesis, including, gel formation, gel aging, crystal nucleation, growth and recrystallation; provide information on the kinetics of each reaction step; enable detection intermediate species stable only under hydrothermal conditions. The technique can be used without interrupting the synthesis and perturbing the crystallization process, it reduces the time and minimizes the amount of sample required for mechanistic studies by several orders of magnitude and allows for isotopic labelling of specific nuclei.

The comparison of the results of *in situ* MAS NMR experiments with *ex situ* studies performed using XRD, SEM, TEM, IR and adsorption techniques outlined that the kinetic parameters obtained using both approaches are in good agreement and pointed to full identity in structure and morphology of final products. The main benefit of the *ex situ* approach is the possibility to apply the whole complex of modern physicochemical techniques, which allows to obtain comprehensive information on the structure and properties of stable intermediate products. The *in situ* MAS NMR approach makes it possible to follow the nuclei dynamics directly during the synthesis and to get additional information about the unstable intermediate products. Combination of these two approaches will lead to fast progress in understanding the mechanisms of synthesis of different solids and therefore will facilitate the development of novel advanced materials.

4 Conclusions

The potential of the *in situ* MAS NMR techniques for the unravel of the mechanism of hydrothermal synthesis of zeolite catalysts has been fully demonstrated. The technique can be used without interrupting the synthesis and perturbing the crystallization process and provides unique information on the main steps of synthesis, including, gel formation, gel aging, crystal nucleation, growth and recrystallation.

Optimizing Catalytic Performances of Oxide Catalysts via Morphology Engineering

Huang W.*

Department of Chemical Physics, University of Science and Technology of China, Hefei, China

* huangwx@ustc.edu.cn

Keywords: oxide nanocrystal catalysts, propylene partial oxidation, structure-activity, relation, reaction, mechanism

1 Introduction

Selective oxidation of propylene with molecular oxygen is of great importance and oxides are used as the catalysts. The morphology of oxide nanoparticles decides the exposed crystal planes and thus strongly affects their catalytic performances. Recently uniform oxide nanocrystals predominantly exposing one or two types of crystal planes have been successfully prepared. In this talk I will report two examples to demonstrate the morphology effect of oxide catalysts on their catalytic performances in selective oxidation of propylene: one is propylene oxidation with O_2 catalyzed by Cu_2O nanocrystals [1], the other is propylene epoxidation with O_2 and H_2 catalyzed by Au/TiO2 catalysts [2].

2 Experimental/methodology

Uniform cubic (c-Cu_2O), octahedral (o-Cu_2O) and rhombic dodecahedral (d-Cu^2O) Cu_2O nanocrystals were synthesized, characterized and used as the catalysts for propylene oxidation with O_2. 0.2 g catalyst was used and heated in a reaction gas mixture (C_3H_6 /O_2/N_2 = 4/2/44 with flow rates of 50mL/min) from RT to reaction temperature in 6 h. The products were analyzed online using a gas chromatograph (Shimazu GC-2014) equipped with a flame ionization detector and a thermal conductivity detector, attached, respectively, to a FFAP capillary column (0.32 mm×60 m) and a Porapak Q compact column (3 mm×3 m).

1wt%-Au/TiO_2 catalysts employing P25 (Au/P25), anatase TiO_2 nanocrystals predominantly exposing the {001} facets (Au/TiO_2(001)), anatase TiO_2 nanocrystals predominantly exposing the {100} facets (Au/TiO_2(100)) as the supports were synthesized, characterized and used as the catalysts for propylene oxidation with O_2 and H_2. 0.25 g catalyst was used and heated in the reaction gas mixture (C_3H_6/O_2/H_2/Ar = 1/1/1/7, GHSV = 8000 $mlh^{-1}g^{-1}_{catalyst}$) to 50 ºC at a rate of 2 ºC/min. All reaction products were analyzed using an online Shimazu GC-2014 gas chromatograph equipped with both flame ionization detectors (FID) and thermal conductivity detector (TCD). One FID was attached to a Stabilwax-DA capillary column (0.53 mm × 60m) to detect propylene and oxygenates (acetaldehyde, PO, acetone, propionaldehyde, acrolein, acetic acid, and isopropanol), and the TCD was attached to a Porapak Q (3mm × 3m) and C13x compact column (3 mm × 3m) to detect H_2 and O_2.

Propylene conversion was calculated by moles of (oxygenates + CO_2/3)/moles of propylene in feed, PO selectivity was calculated by moles of PO/moles of (oxygenates + CO_2/3), acrolein selectivity was calculated by moles of acrolein/moles of (oxygenates + CO_2/3), and CO_2 selectivity was calculated by moles of CO_2/moles of (oxygenates + CO_2/3).

3 Results and discussion

Figure 1 shows the catalytic performances of different Cu_2O nanocrystals in in propylene oxidation with molecular oxygen. Cu_2O nanocrystals exhibit distinct morphology-dependent catalytic activities. The specific reaction rate normalized to the specific surface area over various

Cu_2O nanocrystals follows the order of o-Cu_2O > d-Cu_2O > c-Cu_2O. Very interestingly, we observed that the catalytic selectivity of Cu_2O nanocrystals in propylene oxidation with molecular oxygen is also sensitively dependent in their morphology. c-Cu_2O is highly selective in catalyzing the propylene combustion reaction with the CO_2 selectivity above 80% under investigated reaction temperatures. o-Cu_2O exhibits the highest selectivity towards the partial oxidation of propylene to acrolein. d-Cu_2O exhibits comparable selectivity towards propylene oxide (20%), acrolein (40%) and CO_2 (40%). Combining operando DRIFTS results demonstrate the formation of different surface species during the propylene chemisorption and oxidation on meansurements and DFT calculations, C_3H_6(a) on Cu_{CUS} of Cu_2O(111), bridging C_3H_6(a) on neighboring Cu_{CSA} and three-coordinated O_{CUS} of Cu_2O(110) and bridging C_3H_6(a) on two neighboring two-coordinated O_{CUS} of Cu_2O(100) were identified as the active species respectively producing acrolein, PO and CO_2.

Table 1 summarizes catalytic performances of Au/TiO_2 catalysts in propylene oxidation with O_2 and H_2 at 50 ºC. The results demonstrate a distinct TiO_2-morphology-dependent catalytic performances of Au/TiO_2 catalysts. Au/P25 gives a C_3H_6 conversion of 0.50%, a PO selectivity of 98.36% and a PO formation rate of 18.1 $mmol_{PO}/h/g_{Au}$. These data are comparable to previous reported results of Au/P25. Au/TiO_2(001) is more active than Au/P25 and meanwhile keeps the similar selectivity toward PO. The C_3H_6 conversion reaches 0.69% and the PO selectivity is 97.64%, giving a PO formation rate of 25.4 $mmol_{PO}/h/g_{Au}$. However, Au/TiO_2(100) is much less active than Au/P25 and its selectivity toward PO is also poorer than that of Au/P25. The C_3H_6 conversion is only 0.14%. Besides the PO production with a selectivity of 89.44%, acetone and CO_2 were observed to form with the selectivity of 5.58% and 4.98%, respectively. Thus PO formation rate over Au/TiO_2(100) is as low as 4.2 $mmol_{PO}/h/g_{Au}$. Therefore, the PO formation rate of various Au/TiO_2 catalysts follows the order of Au/TiO_2(001) > Au/P25 >> Au/TiO_2(100), and the PO formation rate over Au/TiO_2(001) is higher than that of Au/P25 by more than 40%. The ensemble consisting of intimately-contacting $Au^{\delta-}$ species and Ti^{4+} species with weak chemisorption strength is active to catalyze propylene epoxidation with O_2 and H_2 to propylene oxide.

Above results reveal a morphology-engineering strategy of oxide catalysts not only for the innovation of both active and selective catalysts but also for the fundamental understanding of complex heterogeneous catalytic reactions at the molecular-level.

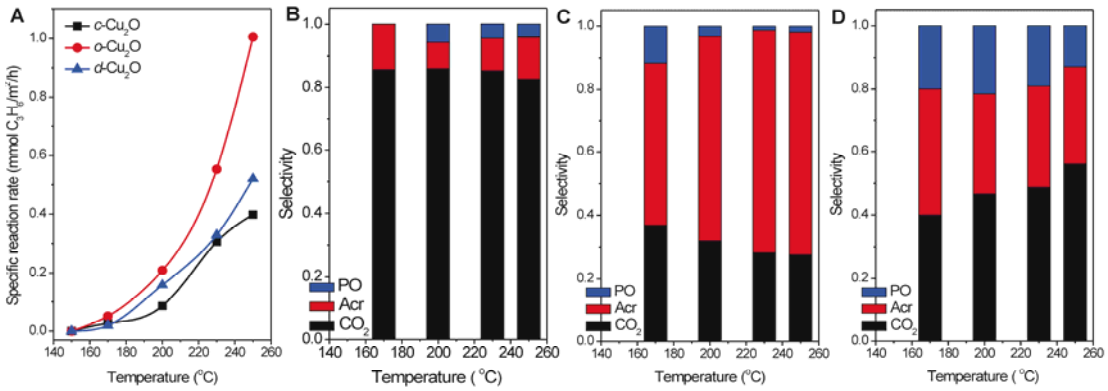

Fig. 1. (**A**) Specific reaction rate of C_3H_6 oxidation catalyzed by Cu_2O cubes (c-Cu_2O), octahedra (o-Cu_2O) and rhombic dodecahedra (d-Cu_2O). Selectivity of C_3H_6 oxidation catalyzed by (**B**) c-Cu_2O, (**C**) o-Cu_2O and (**D**) d-Cu_2O.

Catalyst (250mg)	Conversion (%)			C_3H_6 selectivity (%)			PO formation rate ($mmol_{PO}/h/g_{Au}$)	O_2 selectivity	H_2 efficiency
	C_3H_6	H_2	O_2	PO	Acetone	CO_2			
Au/P25	0.50	2.96	1.61	98.36	0.76	0.88	18.1	30.3%	16.5%
Au/TiO_2(001)	0.69	2.54	1.63	97.64	0.80	1.56	25.4	41.1%	26.5%
Au/TiO_2(100)	0.14	3.20	1.66	89.44	5.58	4.98	4.2	7.4%	3.8%

Keywords: methane activation, In/H-ZSM-5, zeolite, surface species, characterization, NMR, *in situ*

1 Introduction

In-modified zeolites are promising catalysts for methane transformation to aromatic hydrocarbons. It has been revealed that methane reacts with ethylene or benzene yielding propylene or toluene on In/H-ZSM-5 [1,2]. However, the pathways of methane activation and transformation to the surface species, which evolves further to final reaction products still unclear.

In this paper, we have analyzed in situ the kinetics of H/D exchange of methane with Brønsted acid sites of zeolite H-ZSM-5 modified with indium (In^+/H-ZSM-5 and InO^+/H-ZSM-5) by ^{1}H MAS NMR and compared this kinetics with the kinetics on the pure acid form of zeolite H-ZSM-5. Surface species formed from methane at elevated temperatures have been monitored with ^{13}C CP/MAS NMR spectroscopy. This approach to the study of methane activation on heterogeneous catalysts allowed us to establish some peculiarities of methane activation by Brønsted acid sites and by indium species of In^+/H-ZSM-5 and InO^+/H-ZSM-5 zeolites and clarify the pathway of methane involvement in the reaction with ethylene and benzene.

2 Experimental

Details of the synthesis and characterization of In-modified zeolites ZSM-5 are described in refs. [3,4]. Kinetics of the H/D exchange was analyzed in situ in a closed microreactor, representing a sealed glass tube of 5 mm diameter and 10 mm length. The reactor could be tightly inserted in 7 mm zirconia rotor to perform the reaction monitoring with ^{1}H MAS NMR at 450-570 K. The surface hydrocarbon species formed from methane in the course of the reaction at elevated temperature (300–670 K) were analyzed by ^{13}C CP/MAS NMR spectroscopy at room temperature (296 K). NMR spectra were recorded at 9.4 T on a Bruker Avance-400 spectrometer equipped with broad-band double-resonance MAS probe. 7 mm zirconia rotors for ^{1}H MAS NMR 4 mm rotors for ^{13}C MAS NMR with the inserted sealed glass tube were spun at 3-10 kHz by dry compressed air. Details of NMR experiments are provided in refs. [3,4].

3 Results and discussion

Analysis of the kinetics of hydrogen (H/D) exchange between methane-d_4 and Brønsted acid sites (BAS) for both the pure acid form zeolite (H-ZSM-5) and In- modified zeolites (In^+/H-ZSM-5 and InO^+/H-ZSM-5) has shown that the rate of exchange is two order of magnitude larger on InO^+/H-ZSM-5 than that on H-ZSM-5. The activation energy (E_a=74 kJ mol^{-1}) for the

reaction of the exchange on InO^+/H-ZSM-5 is lower than that on H-ZSM-5 (E_a=127 kJ mol^{-1}). The significant change of the kinetic parameters of the exchange for InO^+/H-ZSM-5 is rationalized in terms of involvement of both InO^+ species and BAS in activation of methane molecules on this In-modified zeolite. The shape of the kinetics (Fig. 1a) shows that besides H/D exchange methane-d_4 is involved in chemical transformation on InO^+/H-ZSM-5 to form some surface species. ^{13}C CP MAS NMR shows that this surface species exhibits the chemical shift of -29 ppm, which indicates that indium-methyl ($OIn-CH_3$) is formed from methane (-6 ppm) (Fig. 1b). H/D exchange kinetics data presume that some transient intermediate complex of methane with the zeolite InO^+ species and BAS is formed within the void of zeolite pore. This complex is either involved in the reaction of H/D exchange with BAS of the zeolite or evolves further to offer indium methyl species.

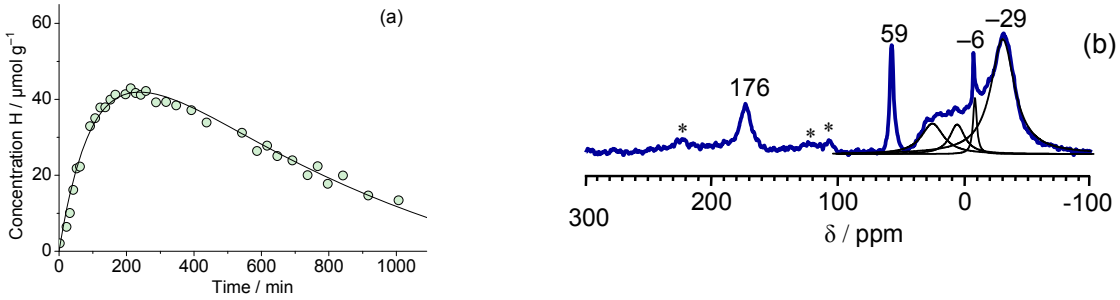

Fig. 1. (a) Kinetics of H/D exchange of methane-d_4 with BAS of InO^+/H-ZSM-5 at 445 K. (b) ^{13}C CP MAS NMR spectrum of the products of interaction of methane-^{13}C with InO^+/H-ZSM-5 at 523 K.

Further interaction of InO^+ with $OIn-CH_3$ gives methoxy species (CH_3-O-InO) with the signal at 59 ppm. Methoxy evolves to formate species (176 ppm). Acetaldehyde is further formed by interaction of the formate with $OIn-CH_3$. The interaction of methoxy with benzene produces toluene. The latter reaction can represent a pathway of methane involvement in co-aromatization with ethylene, which is transformed to aromatics itself on this zeolite catalyst.

4 Conclusions

The pathways of methane activation and transformation to surface species on In/H-ZSM-5 were characterized by solid-state NMR. The intermediate surface species were identified. The mechanism of methane involvement in the reaction of its co-aromatization with ethylene was established.

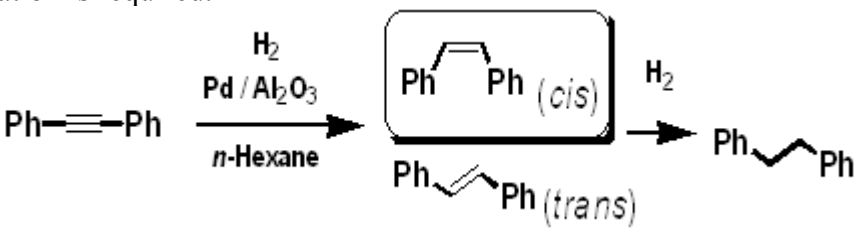
1 Introduction

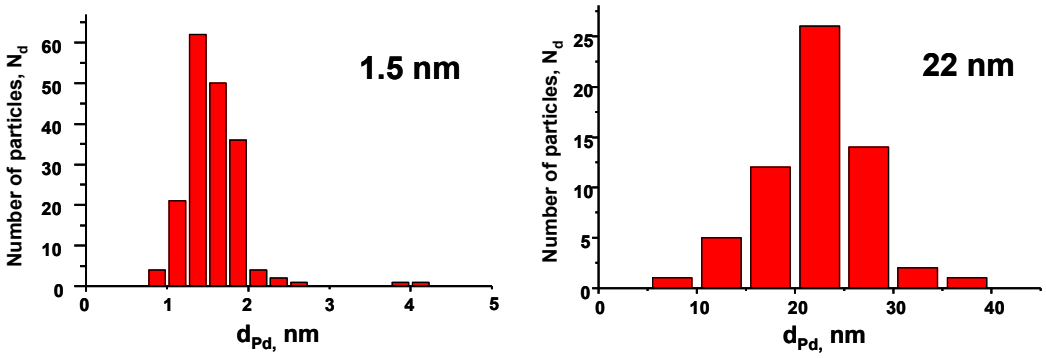
Alkynes are versatile reagents in organic synthesis since C≡C group can be easily transformed to a cis-alkene through stereoselective addition of hydrogen molecule on Pd catalyst. This so called semihydrogenation is often an important step in industrial processes as well as in laboratory-scale reactions. However, careful selectivity control and minimization of over-hydrogenation is required.



In this work we studied a relationship between the size of Pd nanoparticles (ranging from 1.5 to 22 nm) in 1%Pd/Al_2O_3 catalyst and the activity/selectivity in liquid-phase diphenylacetylene (DPA) hydrogenation.

2 Experimental/methodology

Series of Pd/Al_2O_3 catalysts was prepared by impregnation of alumina with Pd nitrate solutions followed by air calcination at 400-600°C for 3 hours and reduction in flowing H_2 at 400°C. Variation of Pd/NO_3^- ratio during impregnation and the calcination temperature enabled variation of Pd particle size from 1.5 to 22 nm with narrow particle size distribution (see below).



Hydrogenation was carried out in autoclave at 5 atm H_2 and room temperature. The reaction kinetics was monitored by the rate of H_2 uptake, and the reaction products were analyzed using ^{1}H-NMR.

3 Results and discussion

Catalytic data reveal a significant increase in turnover frequency (calculated per surface Pd atom) and pronounced improvement of the selectivity as Pd particle size increases from 1.5 to 22 nm (Fig. 1, (a) and (b) respectively). The observed relationship can be explained by a strong adsorption of bulky DPA molecule on low-coordinated surface atoms of small Pd nanoparticles. Strong absorption reduces TOF_{DPA} due to competition between adsorbed DPA molecules and hydrogen. As Pd particles grow in size, the percentage of low-coordinated palladium surface atoms rapidly decreases thus increasing TOF_{DPA}.

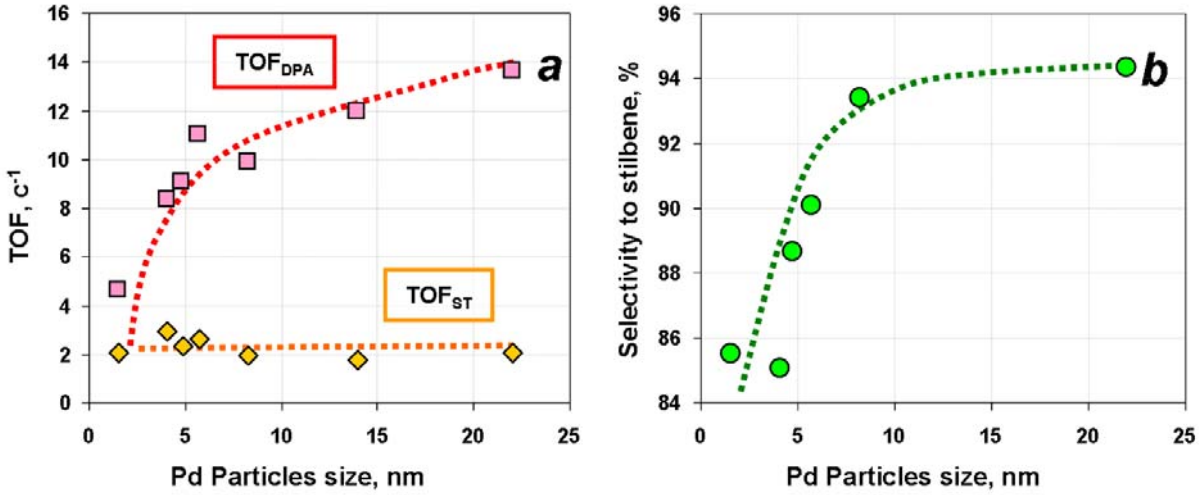


Fig. 1. Effect of Pd particle size on TOF [n(DPA)/n(Pd_{surf})*s^{-1}] (a) and selectivity toward stilbene formation (b) in the course of DPA hydrogenation over 1%Pd/Al_2O_3. Reaction conditions: P_{H2} = 5 bar, T_{react} = 25°C, [DPA]/Pd ~ 4000, n-C_6H_{14} as solvent

The strong increase in TOF_{DPA} with increasing Pd particle size indicates structure sensitivity of triple bond hydrogenation. On the other hand, $TOF_{stilbene}$ of the second hydrogenation stage (double bond hydrogenation) remains essentially independent on Pd particle size. This implies structure-insensitivity of the second stage. We suggest that the different structure sensitivities stem from the differences in rate-limiting steps: activation of triple the π-bond on the 1-st stage, vs. formation of C-H □-bond on the 2-nd stage [1].

As a result of different structure sensitivities of the 1-st and 2-nd hydrogenation stages, the ratio $TOF_{DPA}/TOF_{stilbene}$ increases with increasing Pd particle size thus improving the selectivity in alkene (stilbene) formation.

4 Conclusions

Variation of Pd particle size provides the effective tool for tuning activity-selectivity parameters in selective semihydrogenation of substituted alkynes due to different structure sensitivity of triple bond hydrogenation vs double bond hydrogenation.

Dispersion and Orientation of Zeolite ZSM-5 Crystallites within a Fluid Catalytic Cracking Catalyst Particle

Sprung C.*, Weckhuysen B.M.

Utrecht University, Department of Chemistry, Inorganic Chemistry and Catalysis, Utrecht, The Netherlands

* sprung@fhi-berlin.mpg.de

Keywords: zeolite ZSM-5, fluid catalytic cracking, polarisation, dispersion and orientation

1 Introduction

Fluid catalytic cracking (FCC) is of great industrial importance in crude oil refinery. The FCC catalyst particles are a complex mixture of various components (such as boehmite, kaolinite, silica, and zeolite) to ensure the catalytic performance and its resistance to chemical and mechanical deactivation. Locating the various components in a catalyst particle is challenging and may involve the degradation of the particle [1]. Confocal fluorescence microscopy (CFM) is non-destructive and has been proven to selectively image zeolite crystals within the matrix of FCC particles by selective staining [2].

The Brønsted acid catalyzed oligomerisation of 4-fluorostyrene was chosen, since their dimeric carbocationic products form elongated species, which are trapped inside the zeolite channel architecture, and, furthermore are fluorescent after excitation in the visible spectrum. Well characterized large coffin-shaped ZSM-5 crystals served as a model system to prove the principle of orientation/polarization dependent interaction of light with such anisotropic crystals [3]. This knowledge was translated for the investigation of the location, orientation, dispersion, and quantification of the zeolite component of 1-3 μm in size inside a real industrial FCC catalyst particle [3].

2 Experimental

Large coffin-shaped ZSM-5 crystals and FCC catalyst particles were impregnated at 30°C with excess of 4-fluorostyrene (the probe molecule) before the oligomerisation reaction of the probe molecule was initiated by increasing the temperature rapidly to 180°C.

An upright optical microscope from Olympus (BX 41) was employed in reflectance mode, equipped a 30 W halogen lamp. The incoming light was plane-polarized through a U-90 PO3 polarizer and the reflected light was analysed with a rotatable analyser U-AN360 from Olympus. Fluorescence microscopic investigations were performed with a Nikon ECLIPS 90*i* confocal microscope in reflectance mode. Excitation light was provided by a 561 nm laser and plane polarized by an internal polarizer/analyzer, the emission range recorded was 580 – 750 nm. FCC particles were investigated by a rotation sequence in steps of 5° [3].

3 Results and discussion

Both absorption and emission of light of elongated molecules are, of course, oriented. In preliminary experiments on large coffin-shaped ZSM-5 crystals, this principle was proven and investigated. Elongated molecules entrapped inside the zeolite channels do absorb/emit light of a certain polarisation plane, which distinguishes it from an area/volume with the same molecules, but randomly oriented.

Figure 1 shows the fluorescence images of a fresh FCC catalyst particle, containing small zeolite ZSM-5 crystallites (and the oligomerised carbocationic species of the probe molecule). The FCC catalyst particle was rotated with respect to the horizontally oriented polarisation plane

of excitation light. Depending on the orientation of the catalyst particle, hence, the zeolite component inside this catalyst particle, the fluorescence of entrapped oligomerised carbocationic species was observed or absent (exemplified highlighted by the white arrows in Figure 1). The polarisation dependence of the observed fluorescence confirms its origin from a crystalline (anisotropic) material, hence, the zeolite component. A single orientation did amount to only 20-40% of the total fluorescence observed when all images of the 5°-rotation sequence were considered.

The emitted fluorescence light was statistically analysed with respect to its intensity and dispersion. A large number of fluorescence light was observed for domains of 0.015-0.25 μm^2, which represents single zeolite crystallites or small aggregates thereof and a fairly high degree of zeolite dispersion. However, the highest amount of crystalline material was aggregated into larger domains (ca. 1–5 μm^2) with more or less similarly oriented zeolite crystallites.

A typical composition of an FCC catalyst particle was assumed, consisting of boehmite, kaolinite, and silica as binder material (composition 1:1:1), and zeolite ZSM-5 as the zeolite component. The amount of detected fluorescence light originating from the stained zeolite ZSM-5 aggregates corresponds to about 15 wt% [3].

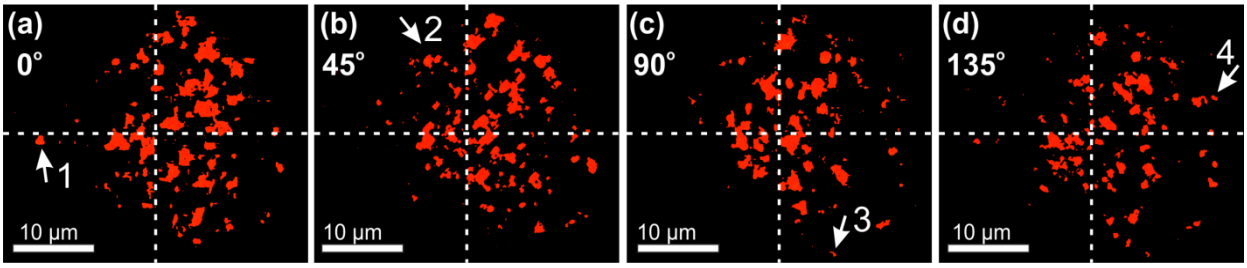

Fig. 1. Fresh FCC catalyst particle containing ZSM-5 at 180°C after 4-fluorostyrene oligomerisation; the images, which belong to an image sequence of full circumference in 5° steps, show a FCC particle rotated to orientations of (a) 0°, (b) 45°, (c) 90°, and (d) 135° with respect to the allowed vibrational path of the polarizer. The images were rotated back to the initial position for better comparison. The arrows/pointer 1 - 4 highlight exemplified areas where fluorescence signal appears/disappears.

4 Conclusions

The anisotropic nature of absorption and emission of elongated molecules entrapped inside zeolite channels was employed to selectively visualize the zeolite component within the matrix of an industrial FCC catalyst particle. Confocal fluorescence microscopy views the inner volume of the intact catalyst particle and is selective to (anisotropic) crystalline material and allows its location, size distribution, and orientation in three dimensions. This selective visualization may serve as a post-synthesis quality control on the dispersion and quantity of zeolite ZSM-5 crystallites inside a single FCC particle.

Keywords: heterogeneous hydrogenation, parahydrogen, mechanism evaluation, MRI, NMR

1 Introduction

Parahydrogen-induced polarization of nuclear spins provides enhancements of NMR signals for various nuclei of up to four to five orders of magnitude in magnetic fields of modern NMR spectrometers and even higher enhancements in low and ultra-low magnetic fields. It is based on the use of parahydrogen in catalytic hydrogenation reactions which, upon pairwise addition of the two H atoms of parahydrogen, can strongly enhance the NMR signals of reaction intermediates and products in solution. A recent advance in this field is the demonstration that PHIP can be observed not only in homogeneous hydrogenations but also in heterogeneous catalytic reactions. The use of heterogeneous catalysts for generating PHIP provides a number of significant advantages over the homogeneous processes, including the possibility to produce hyperpolarized gases, better control over the hydrogenation process, and the ease of separation of hyperpolarized fluids from the catalyst. The latter advantage is of paramount importance in light of the recent tendency toward utilization of hyperpolarized substances *in vivo* spectroscopic and imaging applications of NMR. In addition, PHIP demonstrates the potential to become a useful tool for studying mechanisms of heterogeneous catalytic processes and for in situ studies of operating catalytic reactors.

2 Experimental/methodology

Pure (>99.99%) hydrogen gas was used for the preparation of >90% p-H2 using a Bruker Parahydrogen Generator BPHG 90. High-resolution high-field NMR spectroscopy was conducted on a Bruker Avance NMR spectrometers. For ALTADENA experiments, the hydrogenation reaction was performed in a temperature-controlled reaction chamber at Earth magnetic field, and the resulting gas was transferred for detection to the NMR spectrometer via Teflon tubing. For PASADENA experiments, a small quantity (a few milligrams) of supported metal catalyst was placed at the bottom of a standard NMR tube, and the gas:p-H2 mixture was delivered to the catalyst via Teflon tubing.

High-field 3D MRI studies were conducted using a 4.7 T Varian MRI scanner (Varian, Palo Alto, California) and a custom-built 38 mm ID dual-channel MRI coil tuned to 1H frequency of 200.25 MHz. All low-field studies were carried out using a Kea2 NMR spectrometer (Magritek, Wellington, New Zealand) with a custom-built frequency optimized dual-channel RF 1H-X probe. The flow rate was not controlled in low-field MR experiments due to experimental limitations.

3 Results and discussion

Several supported metal catalysts were synthesized, characterized and tested in heterogeneous hydrogenation of propene with parahydrogen to maximize nuclear spin

hyperpolarization of propane gas using Parahydrogen Induced Polarization. The Rh/TiO_2 catalyst with 1.6 nm Rh metal particle size was found the most active and effective in pairwise hydrogen addition and robust, demonstrating reproducible results with multiple hydrogenation experiments and stability for ≥1.5 years. 3D ^1H magnetic resonance imaging (MRI) of 1% hyperpolarized flowing gas with micro-scale spatial resolution (625x625x625 μm^3) and large imaging matrix (128x128x32) was demonstrated using pre-clinical 4.7 T scanner and 17.4 s imaging scan time [1]. Moreover, propene-d_6 gas was efficiently hyperpolarized using PHIP technique and Rh/TiO_2 catalyst allowing for preparation of pure HP propane-d_6 gas. PHIP of propane-d_6 provides significant advantages for the mechanistic studies of the catalytic hydrogenation reaction, showing in particular that propene gas is hydrogenated to yield propane, which can be subsequently dehydrogenated by the catalyst studied. Propene-d_6 can also be useful for high-resolution high-field MRI of flowing HP propane-d_6 gas as demonstrated here by 3D MRI with 0.5×0.5×0.5 mm^3 and 17.7 s spatial and temporal resolution. Importantly, low-field NMR at 0.0475 T enabled efficient direct detection of PHIP hyperpolarized propane-d_6 in contrast to non-deuterated PHIP polarized propane. The feasibility of high-resolution MRI should pave the way to biomedical use of PHIP hyperpolarized propane-d_6 as an inhalable contrast agent for pulmonary imaging using proton MRI hardware and pulse sequences [2]. In the case of mechanism evaluation very recent results show that PHIP may be succesfully utilized for studying the heterogeneous hydrogenation of several unsaturated (acrolein, crotonaldehyde) and saturated (acetone, propanal) carbonyl compounds. PHIP effects were successfully observed in liquid and gas phase hydrogenations of C=C bond of acrolein and crotonaldehyde over several supported metal catalysts and bulk metals and oxides. These observations confirm the existence of the route of pairwise hydrogen addition to the C=C bond in the reaction mechanism [3,4].

4 Conclusions

Therefore, the concept of PHIP in heterogeneous hydrogenations has clearly proven its viability. While this sub-field of hyperpolarization in magnetic resonance is still in its infancy, at this point the demonstration that many types of heterogeneous catalysts have an intrinsic ability to produce PHIP is quite an important and encouraging achievement. Heterogeneous processes may have certain limitations, but they also have many advantages over their homogeneous counterparts. In particular, while it is possible in principle to remove a dissolved catalyst from solution of a hyperpolarized molecule, practical attempts to do this lead to a dramatic reduction in the levels of signal enhancement by several orders of magnitude. In this respect, PHIP appears to be a more direct way to catalyst-free hyperpolarized liquids and solutes, and quite likely the only way to utilize parahydrogen to produce hyperpolarized gases. It is also expected that PHIP could become a useful tool in the mechanistic studies of heterogeneous catalytic processes.

Keywords: fiberglass, palladium, nanoparticles, acetylene, hydrogenation, 13C, labeling

1 Introduction

Non-porous fiberglass (FG) textile materials of silicate origin are widely used as perfect heat and electric insulators. However, these materials are much less known in catalysis in spite of their obvious advantages, such as chemical inertness, improved hydrodynamics and ability to make the structured beds of any shape. The capability of FG to stabilize highly dispersed metals (clusters) in the bulk is responsible for excellent performance of FG based catalysts in various oxidation reactions in spite of extremely low noble metal content (0.01-0.02 wt.%) [1]. Here, we present new data on the Pd/FG catalysts preparation, their performance in selective hydrogenation of acetylene, as well as kinetic and mechanistic studies using SSITKA technique. The STEM-HAADF, XPS and HS-LEIS were used to characterize the size, charge and location of Pd species.

2 Experimental

Leached FG silicate materials modified with Al, Zr or rare earth metals were used for the catalyst preparation. Pd(II) cations were introduced into the bulk of glass via ion exchange from its amine complex. The small metal clusters Pd(v) were formed and confined in the bulk of glass by redox treatments at elevated temperatures. The ratio of metal clusters to the Pd remaining on the external surface of the fibers was controlled by the heating rate or by selective removal of surface particles. In addition, the catalyst where metal is deposited mainly on the external surface of the fibers was prepared using anionic palladium precursor (H_2PdCl_4). FG catalysts were tested in selective hydrogenation of acetylene under reaction conditions close to the tail-end process and studied by SSITKA technique using $^{13}C_2H_2$ at acetylene conversion close to 100 %.

3 Results and discussion

The key stages of FG catalyst synthesis are i) the ion exchange of Pd amine cations with the strong protons to anchor them in the bulk of glass and ii) the redox treatment at elevated temperature to decompose the Pd complexes and to form the 1 nm $Pd^{\delta+}$ clusters located in the bulk of glass at a depth of 10-20 nm. In order to increase their number at the expense of Pd particles remaining on the external surface of the fibers, the decomposition of the Pd amine complexes was carried out at a higher heating rate. Indeed, the fraction of clusters grows substantially with the heating rate, so that the catalyst calcined at 50 K/min contained mostly the $Pd^{\delta+}$ particles. In the case of Pd(s)/FG when anionic precursor was used, big palladium particles were deposited only on the external surface of the fiberglass.

The FG catalysts showed high performance in acetylene hydrogenation and their activity did not change after removal of metal particles from the external surface of the fibers. Moreover,

the Pd(v)/FG catalyst containing only $Pd^{\delta+}$ clusters showed the highest catalytic activity. These data clearly indicated that small $Pd^{\delta+}$ clusters were mainly responsible for the catalyst performance, while contribution of the surface particles to the activity was insignificant. The subsurface location of active sites did not limit the reaction rate due to fast diffusion in the bulk of glass.

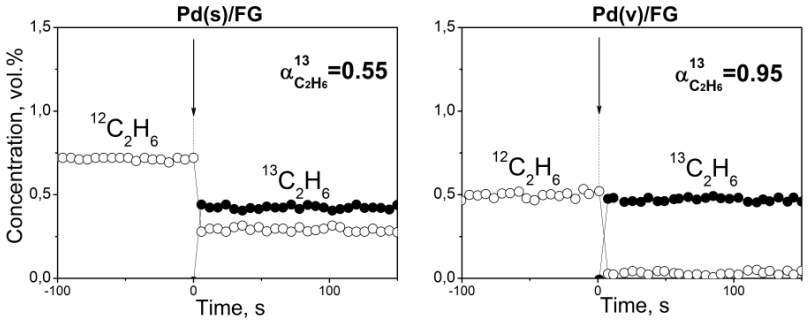

Fig. 1. ^{13}C label transfer from acetylene to ethane observed after replacement of $^{12}C_2H_2$ by $^{13}C_2H_2$ under steady state conditions. Feed gas (vol.%): 2.0 C_2H_2 + 2.0 C_2H_4 +7.0 H_2 + He for balance. Here, α^{13}_{C2H6} is the ^{13}C isotopic fraction in ethane. Arrows show the switching of isotope composition.

Unlike conventional Pd-supported catalysts, an unusual kinetics of selective acetylene hydrogenation over FG catalyst was observed: the reaction selectivity decreases very slowly with the conversion remaining quite high (*ca.* 60%) until a complete conversion of acetylene. At the same time, over Pd(s)/FG containing only metal particles on the external fiber surface, the selectivity drops sharply with acetylene conversion as for conventional monometallic catalysts [2,3]. To clarify the plateau-like dependence of selectivity *vs* conversion, the SSITKA study using double labeled $^{13}C_2H_2$ at a very high acetylene conversion of 97-99 % was carried out (Fig. 1). Surprisingly, over Pd(v)/FG ethane was produced mainly from acetylene despite a 100-fold excess of ethylene, while over Pd(s)/FG nearly half of ethane was produced from gas-phase ethylene. So, it was concluded that gas-phase ethylene was not involved in hydrogenation over the catalyst where active sites were confined in the glass bulk. This fact is related to the capability of glass to absorb selectively the polarizable molecules like acetylene, but not ethylene.

Within the proposed reaction mechanism, the turnover frequencies (TOFs) were measured and compared with the literature data. It was concluded that the reaction rate referred to the number of active sites slightly depends on Pd particles dispersion.

4 Conclusions

The effective methods of confining highly dispersed Pd particles (clusters) in the subsurface layers of glass and the increase in their concentration have been developed. These small clusters demonstrated high activity in selective acetylene hydrogenation. It was clearly shown that gas-phase ethylene was not involved in the reaction even at its very high excess and ethane, being the main by-product, was formed from acetylene only. This is caused by the ability of glass to absorb predominantly the readily polarizable molecules like acetylene (but not ethylene). As a result, high selectivity (the ethylene increment of 60 %) can be achieved at a complete conversion of acetylene, which is even higher than that of the commercial bimetallic catalyst.

Keywords: nanoparticles palladium, phosphonium, ionic, liquids, Suzuki reaction, size, distribution, stabilization, mechanism

1 Introduction

Palladium nanoparticles (PdNPs) are widely used as the catalyst in cross-coupling reactions such as Suzuki reaction [1, 2]. Nanoscale catalysis combines the advantages of homogeneous and heterogeneous processes, i.e., possesses high activity and recyclability. The problem of nanoparticles aggregation could be effectively solved by using sterically hindered phosphonium ionic liquids (PILs) as stabilizers [3].

ILs are not clear homogeneous solvents but could be considered as "supramolecular" fluids [4]. Therefore, the influence of stabilizer on the catalytic reaction is crucial. Modelling of NP's stabilization process admits to find out the optimal reaction conditions.

2 Experimental

PILs with a bulky cation containing three *tert*-butyl groups and alkyl chain on the phosphorus atom were synthesized. For comparison, we have obtained similar known in the literature phosphonium salts. A number of physical chemical methods such as NMR spectroscopy, elemental analysis, ESI, TG-DSC was used for characterization of new compounds.

The range of phosphonium salts was used for stabilization of PdNPs. The size distribution of nanoparticles was evaluated by transmission electron microscopy. More over it was mentioned that nature both of anionic and cationic part of phosphonium salt has influence at size distribution. The resulting catalytic systems were tested in Suzuki cross-coupling reaction under mild condition with low palladium loading (0.36 mol%).

3 Results and discussion

We have observed the formation of aggregates of PdNPs as well as individual nanoparticles (Fig. 1).

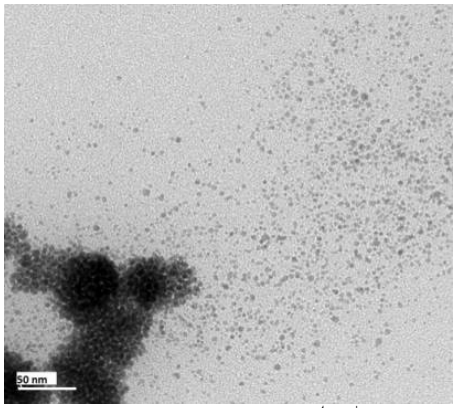

Fig. 1. PdNPs stabilized by $Bu^t_3P^+C_{10}H_{21}BF_4^-$.

PdNPs stabilized with PILs containing linear substituents were less active than sterically hindered ones. It was also found that concentration of stabilizer in the reaction mixture along with its structure has a significant effect on the catalytic activity of stabilized palladium nanoparticles. The latter is connected with represented stabilization models (Fig. 2).

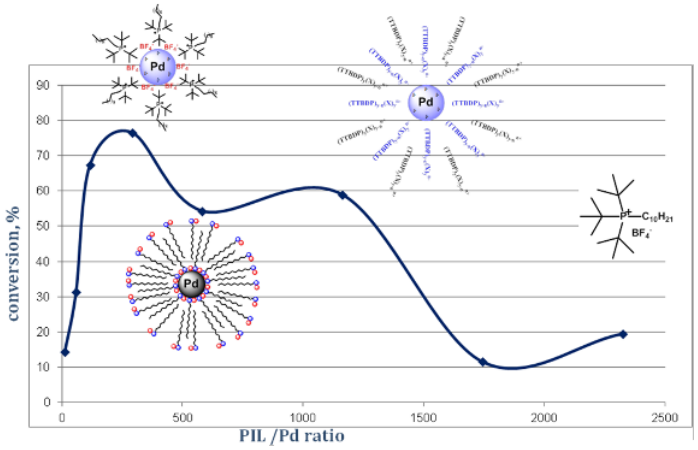

Fig. 2. Dependence of conversion on PIL/PdNPs ratio and supposed models of stabilization.

4 Conclusions

A number of synthesized PILs was tested as the stabilizers of PdNPs in Suzuki cross-coupling of 1,3,5-tribromobenzene and phenylboronic acid. Size distribution and arrangement of PdNPs are determined by nature of the coating agent as well as its concentration in reaction mixture. Rational design and concentration control of these salts allows to separate the contribution of steric and electrostatic factors in PdNPs stabilization.

Keywords: ethylene, trimerization, NMR, EPR, active, species, mechanism

1 Introduction

Linear α-olefins 1-hexene and 1-octene are important comonomers utilized in the copolymerization with ethylene to generate linear low-density polyethylene. They are produced predominantly via nonselective oligomerization of ethylene. This oligomerization generally yields a broad range of olefins that obey a Schulz–Flory distribution (SHOP process or the Sablin process)[1]. Therefore, catalyst systems that are selective for particular target alkenes would be of great industrial and academic interest.

In 2010 Fujita, Kawamura and coworkers prepared a titanium(IV) complex $LTi^{IV}Cl_3$ bearing a phenoxy-imine ligand with a pendant aryl-OCH_3 donor for selective ethylene trimerization (Chart 1). This complex when activated by MAO produced 1-hexene with exceptionally high activity (up to 132 kg 1-hexene (g Ti)$^{-1}$ h^{-1} bar^{-1}).[2]

The main disadvantage of titanium selective trimerization catalysts is the formation of 2-5 wt. % of high molecular weight polyethylene (PE), which can result in reactor fouling. The nature of the titanium species, responsible for the undesirable PE formation, was unclear.

The hypothetical metallacyclic mechanism of ethylene selective trimerization by the titanium catalysts is depicted in Scheme 1.[3] Unfortunately, previous attempts to isolate or spectroscopically observe Ti(IV) or Ti(II) species, responsible for ethylene trimerization, have not thus far been successful.

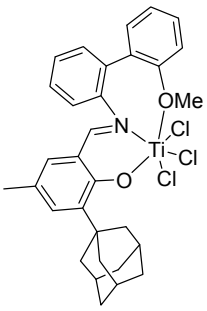

Chart 1.

This work is aimed at using NMR and EPR spectroscopic monitoring of the Ti(IV), Ti(III) and Ti(II) species formed upon the activation of titanium(IV) phenoxy-imine pre-catalyst $LTi^{IV}Cl_3$ with various activators (MAO, MMAO, $AlR_3/[CPh_3]^+[B(C_6F_5)_4]^-$, R = Me, Et, ^{i}Bu) to elucidate the possible role of the observed titanium species in ethylene trimerization and polymerization reactions.

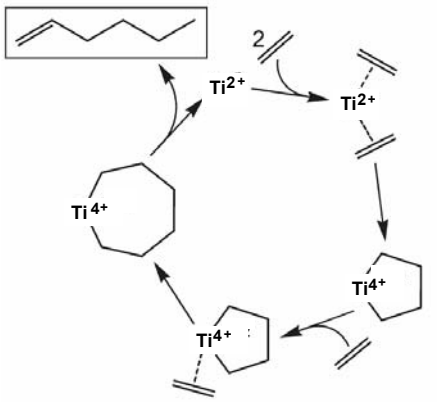
2 Experimental/methodology

All solvents were dried before used. Complex $LTi^{IV}Cl_3$ (Chart 1) was synthesized according to published procedures.[2] Co-catalysts for the catalytic and spectroscopic experiments were purchased from Crompton, AKZO, and Aldrich and used as is.

Samples for NMR and EPR experiments were prepared in the glovebox. For the NMR-tube ethylene trimerization experiments, the break-sealed technique was used. ^{1}H and ^{13}C NMR spectra were measured on a Bruker Avance 400 MHz NMR spectrometer at 400.130 and 100.613 MHz, respectively, using 5 mm o.d. glass NMR tubes. Chemical shifts were referenced to residual solvent peak, 2.09 ppm for CD_2H proton resonance of toluene. EPR spectra were measured on a Bruker ER-200D spectrometer at 9.3 GHz.

3 Results and discussion

Using NMR and EPR spectroscopy, we have monitored transformations of the Ti species in the ethylene trimerization catalyst systems. At the initial stage of the reaction between $LTi^{IV}Cl_3$ with co-catalysts $AlMe_3/[Ph_3C]^+[B(C_6F_5)_4]^-$, MAO or MMAO, diamagnetic outer-sphere Ti(IV) ion pairs of the type $[LTi^{IV}Me_2]^+[A]^-$ ($[A]^- = [B(C_6F_5)_4]^-$, $[MeMAO]^-$ and $[MeMMAO]^-$) are formed. These ion pairs are fairly stable and gradually transform into paramagnetic Ti(III) and Ti(II) species upon storing at room temperature.



Scheme 1. Proposed metallocyclic mechanism of the selective ethylene trimerization.[3]

In the catalyst systems $LTi^{IV}Cl_3/AlMe_3/[Ph_3C]^+[B(C_6F_5)_4]^-$ and $LTi^{IV}Cl_3/MAO$, complexes with proposed structures $LTi^{III}Me_2$, $LTi^{II}Cl$ and $[LTi^{II}][A]^-$ ($[A]^- = [B(C_6F_5)_4]^-$ or $[MeMAO]^-$) were observed using EPR (Ti(III), S = ½) and NMR spectroscopy of the paramagnetic molecules (Ti(II), S = 1). According to our quantitative measurements the concentration of Ti(III) species in both systems was significantly smaller than that of Ti(II) species, and did not exceed 10 % of the overall titanium content.

In contrast, in the catalyst system $LTi^{IV}Cl_3/MMAO$, a major part of titanium (more than 50%) exist in the reaction solution in the trivalent state (complexes with proposed structures $[LTi^{III}(\mu\text{-}H)(\mu\text{-}Cl)Al^iBu_2]^+[MeMMAO]^-$ and $[LTi^{III}(\mu\text{-}Me)(\mu\text{-}Cl)Al^iBu_2]^+[MeMMAO]^-$). The system $LTi^{IV}Cl_3/MMAO$ demonstrates a lower ethylene trimerization activity than the system $LTi^{IV}Cl_3/MAO$, and produces higher amounts of polyethylene; this behavior correlates with the higher concentration of Ti(III) species in the former system. On the basis of the data obtained we propose that Ti(III) species promote undesirable PE formation.

4 Conclusions

The catalyst systems $LTiCl_3/A$ (A = activator, L = phenoxy-imine ligand) used for selective ethylene trimerization were studied by NMR and EPR spectroscopy. It was found that Ti(IV) complexes $[LTi^{IV}Me_2]^+[A]^-$ and Ti(II) complexes of the type $[LTi^{II}][A]^-$ ($[A]^- = [B(C_6F_5)_4]^-$, $[MeMAO]^-$, and $[MeMMAO]^-$) participate in the selective ethylene trimerization process, whereas Ti(III) species of the type $[LTi^{III}(\mu\text{-}H)(\mu\text{-}Cl)Al^iBu_2]^+[MeMMAO]^-$ and $[LTi^{III}(\mu\text{-}Me)(\mu\text{-}Cl)Al^iBu_2]^+[MeMMAO]^-$ can promote undesirable PE formation.

NO_x emissions from power plants and mobile combustion engines are a global concern due to the detrimental effects of NO_x on the environment and public health. The current best technology for removal of NO_x from the exhaust of both types of emission sources is based upon the selective catalytic reduction of NO_x by ammonia. The commercial catalytic systems are based on the redox active metals vanadium, copper or iron, but to this point the reaction mechanism for all of the catalytic systems are still under discussion.

We present a new reaction scheme for the SCR reaction exemplified by copper exchanged zeolites and adaptable to iron exchanged zeolites and vanadia (V_2O_5) on TiO_2.

The new reaction scheme is compatible with previous suggestions [1,2,3] but is the first to fully comply with the constraints usually put upon chemically consistent reaction schemes at moderate temperatures.

1 Experimental/methodology

Transient intermediates in catalytic reactions are often impossible to trap and to investigate spectroscopically. At the same time a large number of different metal containing species are present in the activated catalysts giving a multitude of spectator sites and sites that participate in side-reactions. Recent investigations [4,5,6] have elucidated and quantified the copper species present in dehydrated Cu-SSZ-13. The method used includes Fourier Transform Infrared (FTIR), Electron Paramagnetic Resonance (EPR) spectroscopy and X-ray Absorption Spectroscopy (XAS). Using the same spectroscopic investigation techniques and the same Cu-SSZ-13 material under *in-situ* and *operando* conditions the resting states of the Cu-SSZ-13 catalyst under reducing SCR relevant conditions (NH_3 + NO) and oxidizing conditions (NO + O_2) have been identified.

2 Results and discussion

The experimental investigation identify Cu^+ bound to the zeolite framework in the reduced resting state and $Cu^{2+}NO_3^-$ in the oxidized resting state.

When connecting these resting states to a chemically consistent cycle the following constraints were applied:

1. Only stable neutral molecules are adsorbed or desorbed during the reaction.
2. The total reaction is equal to the SCR reaction:

$$4\ NH_3 + 4\ NO + O_2 \rightarrow 4\ N_2 + 6\ H_2O$$

The approach was successful resulting in a consistent reaction cycle for the SCR reaction on a mononuclear metal site. This includes two separate cycles each with an oxidation and a reduction step with the fast SCR reaction being identified as being an integral part of the SCR reaction.

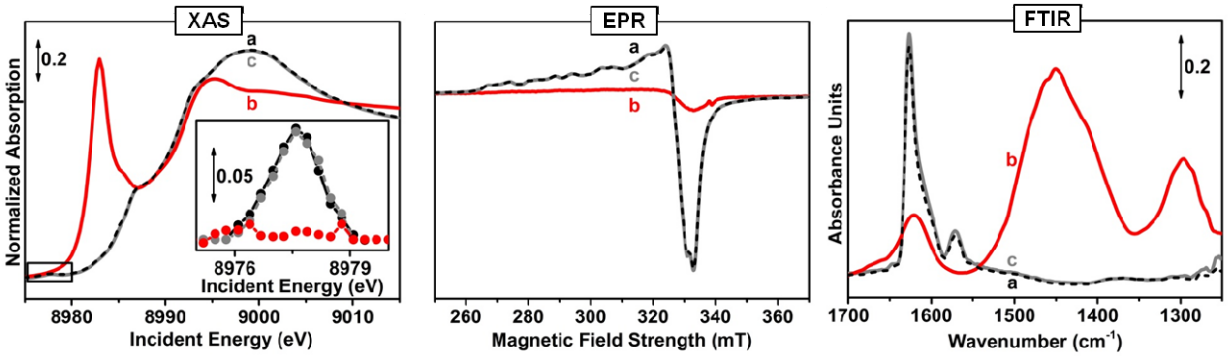

Figure 1. Spectra of Cu-SSZ-13 (Cu/Al = 0.44, Si/Al = 14) at flow conditions at 250 ºC exposed first to NO + O_2 (a) then to NH_3 + NO (b) and finally to NO + O_2 (c).

3 Conclusions

A consistent cycle for the SCR reaction of NO with NH_3 is suggested. The implications on the chemical requirements of the metal of the active site can be summarized as follows:

1. Able to perform one-electron redox reactions.
2. Able to coordinate a NO molecule in both the reduced and the oxidized state.
3. Able to support an OH^- ligand in the oxidized state under reaction conditions.

These requirements are all fulfilled by V^{5+}/V^{4+}, Cu^{2+}/Cu^{+} and Fe^{3+}/Fe^{2+}, which are active in the SCR reaction.

1 Introduction

The nature of the support-catalyst interaction and the influence of the boundary between a metal-catalyst and a support could be crucial for understanding the working mechanism of a catalyst. These questions can be addressed through design of a reverse catalyst, which is basically oxide particles or thin film deposited on the surface of a bulk metal catalytic support. The reverse catalysts approach allows researchers to overcome technical problems such as sample conductivity and sensitivity, which are typical for regular catalysts where small amount of interface between metal-catalyst and oxide support could be hardly detected.

The controlled preparation of a model reverse catalyst is not always straightforward. To understand the relative importance of oxide and metal-catalyst during a catalytic event, the oxide layer must be synthesized in a well-controlled manner. Oxide films are typically prepared by e-beam evaporation of desired metal in O_2. The evaporation/oxidation protocol cannot be easily transferred between experimental set-ups. Here we report a new approach to the synthesis of thin oxide films on Pt(111), Pd(111) and Cu(111) by atomic layer deposition (ALD). The advantages of this approach are that: (i) the amount of deposited material can be well controlled by adjusting the number of deposition cycles; (ii) the method can be easily used on the other system without laborious adjustments of the deposition parameters; (iii) the method can be transferred to porous materials; and (iv) the deposition can be achieved at relatively low temperatures compared to conventional evaporation deposition techniques.

Commensurate with the foregoing objectives, we study the adsorption and oxidation of trimethylaluminum (TMA) and bis(η_5-cyclopentadienyl)iron (ferrocene), which is a well-known ALD precursors for Fe and Al oxide deposition. The reactivity of reverse model catalysts FeO and Al_2O_3 Pt(111), Pd(111) and Cu(111) were tested for CO oxidation and H_2O dissociation.

2 Experimental/methodology

Samples used were Pt(111), Pd(111) and Cu(111) single crystals with orientation accuracy < 0.1°. Two experimental apparatuses were used. The first was a Surface Analysis Cluster at Birck Nanotechnology Center in West Lafayette, IN, USA, equipped with the following tools: X-ray Photoelectron Spectroscopy (XPS), Low Energy Electron Diffraction (LEED), High Resolution Electron Energy Loss Spectroscopy (HREELS), and Scanning Tunneling Microscopy (STM). The second apparatus was a synchrotron-based XPS at the ISISS (Innovative Station for In Situ Spectroscopy) beamline at the BESSY II synchrotron in Berlin, Germany, which is capable of operating at pressures up to 1 mbar.

The single crystals were prepared via multiple cycles of Ar^+ sputtering, annealing in O_2 and in

UHV. Sample cleanliness was checked with XPS, HREELS, STM, LEED. The following ALD precursors were used trimethylaluminum (97%, Sigma Aldrich), bis(η_5-cyclopentadienyl)iron (ferrocene or $Fe(Cp)_2$) (97%, Sigma Aldrich). The precursors was contained in stainless steel Swagelok mini cylinders and dosed to the preparation chamber via a system of leak valves. Prior to dosing, several cycles of freeze-pump-thaw were performed for purification.

3 Results and discussion

First, the adsorption of ferrocene and TMA was studied on Pt(111), Pd(111) and Cu(111). Ferrocene was found to adsorb dissociatively on Pt(111) at low exposures. At high exposure, molecularly adsorbed $Fe(Cp)_2$ dominated. The chemistry of TMA on Pt(111), Pd(111) and Cu(111) is governed by activity of a surface and in particularly in the carbon chemistry. TMA adsorb dissociatively to monomethyl aluminium on Pt(111), whereas dissociation to aluminium was observed on Pd(111). This difference was explained by efficient removing of hydrocarbon fragments on Pd(111), whereas, on Pt(111), the active sides were blocked by carbon. Alloying of Al and Pd was observed even t RT. No adsorption of TMA was found on Cu(111). on the other hand, TMA could adsorb on Cu(111) covered with O_{ads}. Al was immediately oxidized to form alumina on the O_{ads}/Cu(111) surface and the reaction is limited by amount of O_{ads}.

In order to prepare FeO and Al_2O_3 islands, ferrocene and TMA fragments were oxidized in O_2 and water. An example of FeO island observed by STM is shown in Fig. 1. The presence of FeO and Al_2O_3 islands was crucial for CO and H_2O adsorption. For instance, in the case of FeO/Pt(111), water was found to dissociate on the FeO islands, whereas CO adsorbed only on the Pt(111) surface. The saturated CO_{ads} could be titrated by O_2 at 300 K on FeO/Pt(111) surface, which was not possible to achieve on Pt(111) (no iron) under the same conditions. The CO_{ads} species in a bridge adsorption configuration was affected in the vicinity of the FeO and Al_2O_3 islands. Likely, this was active species in the reaction. This observation demonstrates demonstrate the importance of the boundary between oxide and metal-catalyst.

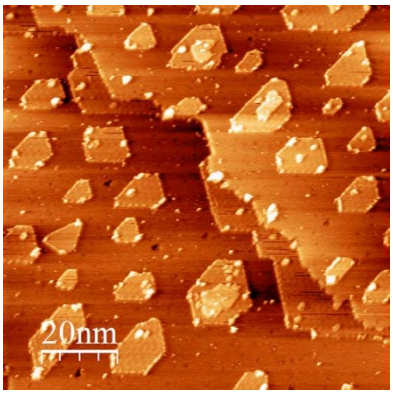

Fig. 1 FeO islands on Pt (111) observed after 3 ALD cycles.

4 Conclusions

The developed procedures of novel reverse catalysts preparation are providing the precise control of chemical composition and morphology of reverse catalysts. Application of such models in fundamental research is allowing study of the ample scope of aspects of catalysts behaviour. CO adsorbed in the vicinity of the oxide islands was identified as an active species of the $CO+O_2$ reaction lowering temperature threshold. The oxides demonstrated the critical role in water dissociation.

Keywords: carbon gasification, Ag nanoparticles, dynamic high resolution, environmental TEM

1 Introduction

Gasification of carbon can be achieved, in the presence of metal catalysts supported on solid carbon materials, at high temperature in oxidative environments. Indeed, oxygen adsorbs and dissociates on the metal surface then interacts with the carbon at the interface with the metal leading to the formation of carbon dioxide; concurrently carbon is consumed and the metallic nanoparticle maintains the interface with the carbon and thus advances, forming in this way a trench on the surface of the carbon. On structured materials such as graphite or graphene these trenches tend to be rather 2D [1,2] at the surface of the material (hereafter named "pacman effect"). In this work we have studied the gasification of a non-structured material (amorphous carbon) by silver-based nanoparticles (NPs) in presence of oxygen and at variable temperatures. We were particularly interested on the dynamic structural evolution of the silver NPs observed in real-time within an environmental TEM and at atomic resolution as permitted by the imaging Cs corrector.

2 Experimental/methodology

This work was performed in the Ly-EtTEM (Lyon Environmental and tomographic Transmission Electron Microscope), a 80-300 kV TITAN objective lens C_s-corrected Environmental TEM from FEI equipped with a GATAN high resolution Imaging Filter (GIF) recently installed in Lyon.

Samples were prepared according to a synthesis described in [3]; the silver based NPs stand on the supporting carbon film and gasification of this film is observed between 400 and 500°C under variable oxygen partial pressures (between 10^{-1} and 5 mbar).

3 Results and discussion

We were able to follow in real-time the dynamics of carbon gasification and catalyst evolution by high resolution imaging (Fig.1) unlike previous studies. *In situ* EELS yields complementary information necessary to fully interpret the observed phenomena (structural changes, shrinking and coating of the catalyst, …). The mechanism deduced from our *in situ* study is schematically summarized in Fig.2 : (i) at the beginning of the gasification experiment the NP have surprisingly an hexagonal structure consistent with previously identified hexagonal forms of silver, either metallic or containing diluted oxygen (Fig.2 a-c); (ii) at a given moment during gasification the NP transforms to fcc-Ag, gasification slows down, the particle begins to shrink (surface oxide formation that decomposes) while a coating forms around it (Fig.2 d); (iii) once the particle is completely coated gasification stops and the NP shrinking stops (Fig.2 e).

The hexagonal to fcc transition (which occurs over a period of 4-5 seconds) and the

phenomenon that induces this transition remain however unexplained but most certainly related to the influence of oxygen.

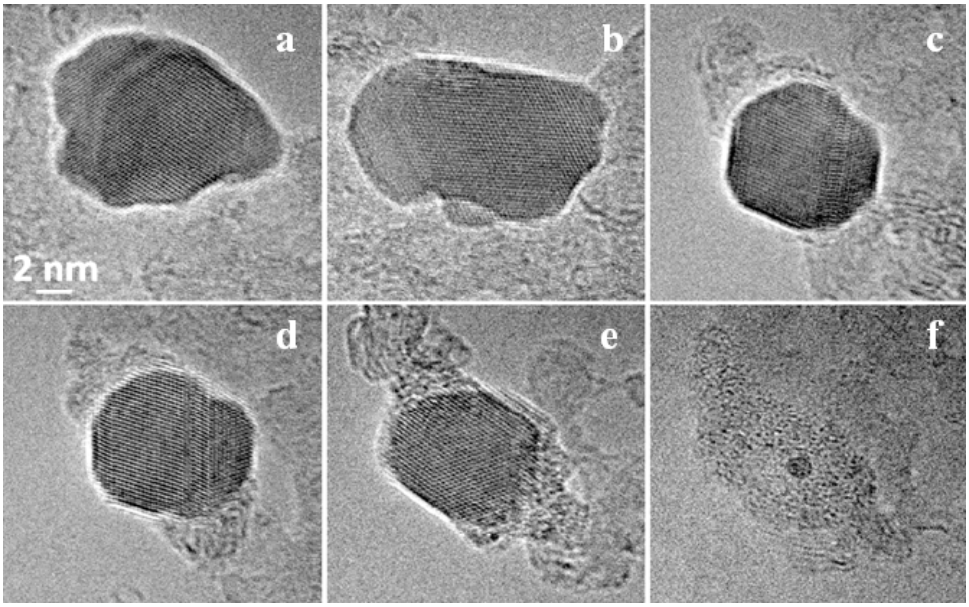

Fig. 1. Selected video frames from an HRTEM sequence recorded *in situ* at 495°C under 0.6 mbar of oxygen (see text for details).

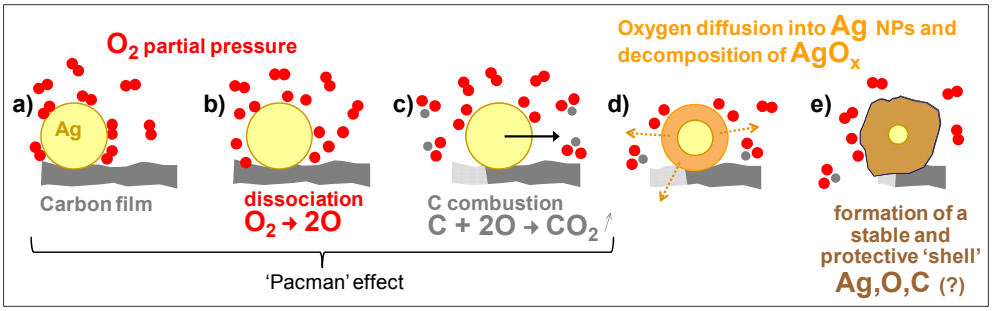

Fig. 2. Schematic interpretation of the sequence shown in Fig.1 (see text for details).

4 Conclusions

Gasification of amorphous carbon by Ag NPs was studied *in situ* (P_{oxygen}, T variables) in an ETEM. Gasification rate slows when the Ag NPs transform from initial hexagonal structure to fcc; concurrently the Ag NPs shrink rapidly. The dynamic real-time high resolution images associated with local EELS measurements allowed to propose a mechanism for the observed phenomena; however the motor behind the hexagonal to fcc transition still remains to be clarified.

Keywords: transmission, electron microscopy, single-atom, sensitivity, *in-situ*, studies, HDS, SCR

1 Introduction

In recent years, electron microscopy has made considerable progress that is beneficial to heterogeneous catalysis. With advances in electron optics and in gas cells, atomic-resolution electron microscopy can now provide images of catalysts at the level of single atoms or in catalytic reaction environments. Such imaging capabilities offer unprecedented new atomic-scale information about surface structures and dynamics in catalysts and, in turn, open up new ways to improve the understanding of structure-sensitivity in catalytic processes.
Here, we demonstrate such electron microscopy advances on two catalysts for environmental purposes: Co-promoted MoS_2 on graphite for hydrodesulfurization (HDS) processes in oil refining, and V_2O_5/TiO_2 for selective catalytic reduction (SCR) of nitrogen oxides in automotive exhaust abatement. Imaging of these catalysts has long remained particularly challenging as the active phases are atomically dispersed on the support.

2 Experimental section

Observation of the catalysts in their pristine states was made possible by careful optimization of the imaging conditions and sample environment. Single-atom sensitivity imaging of the HDS catalyst was therefore done by means of low-voltage and low dose-rate scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) conducted at the SuperSTEM facility [1,2]. Likewise, for the SCR catalyst, *in-situ* observations during exposure to reactive gas environments was done by means of low dose-rate high-resolution transmission electron microscopy (TEM) and EELS at Haldor Topsoe A/S [3].

3 Results and discussion

Figure 1 shows a STEM image of a graphite-supported MoS_2 nanocrystal in a [001] orientation at single-atom sensitivity. Quantitative analysis of the image contrast was used to assign the atomic columns in the basal plane to 1Mo or 2S atoms, allowing the edge terminations of the nanocrystal to be determined. Moreover, STEM-EELS image contrast analysis of the MoS_2 edges unambiguously demonstrate that the single Co promoter atoms attach preferentially to the S-edge and are each coordinated by four S atoms. These observations are significant because the HDS catalytic activity is associated with the edges. Comparison with model studies suggests that the observed edge structures under high vacuum conditions resemble the catalytic active sites under working conditions [1,2].

Figure 2A shows EELS data of the V_2O_5/TiO_2 catalyst acquired at room temperature and high vacuum, as used in conventional electron microscopy, and at oxidizing conditions. The spectra show that the catalytically relevant V_2O_5 oxidation state is, however, only preserved during exposure to oxidizing conditions in the microscope. Under such *in-situ* conditions, atomic-resolution TEM images as in figure 2B were produced by summation of high-resolution

TEM image series in order to enhance the sensitivity toward the single atom level [3]. Hereby it was observed that the vanadia surface layer was isostructural with the anatase TiO_2 support, and that no amorphous phases were present on the particle surfaces.

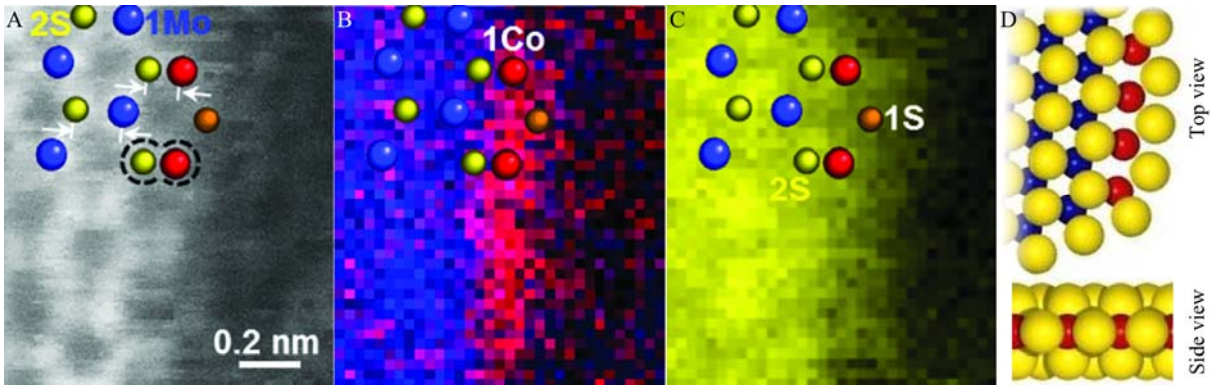

Fig. 1. (A) Atomic-resolution STEM image of the S-edge of a Co-promoted MoS_2 nanocrystal and corresponding EELS maps of the distribution of Co and Mo (B) and S (C). Each image is overlaid with an atomic model, which is also shown in its entirety in the last panel (D). Adapted from [2].

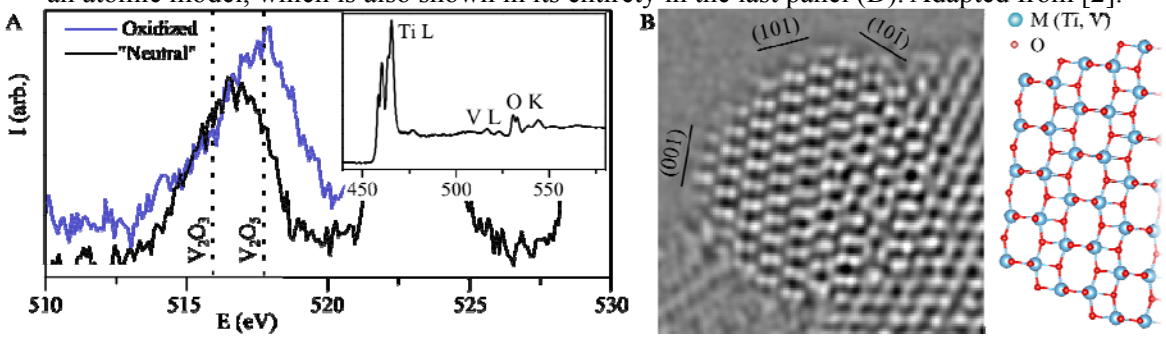

Fig. 2. (A) EELS of the V_xO_y/TiO_2 catalyst at the V $L_{2,3}$ ionization edge acquired under oxidizing (300°C, 1 mbar O_2) and conventional TEM (room temperature, vacuum) conditions. Vertical lines indicating the energy loss for two bulk vanadium oxides are included for comparison. (B) Atomic-resolution TEM image of a V_2O_5/TiO_2 particle acquired at oxidizing conditions.

4 Conclusions

The ability to observe the HDS and SCR catalysts at atomic resolution and sensitivity and in their pristine states was made possible by careful control of the imaging and sample environment. The structural information about industrial-style catalysts open up new important opportunities; the interplay with information, measured or calculated, from simple model systems, allowing the description of the catalysis to be extended with information specific to the exposed surface sites, will be discussed.

Keywords: zeolite, NOx, reduction, X-ray, absorption, emission, spectroscopy, NEDC

1 Introduction

In the last decade, Fe- and Cu-exchanged zeolites have received significant attention due to their superior performance and thermal stability as compared to the widely used V_2O_5-WO_3/TiO_2 for selective catalytic reduction (SCR) of NOx with NH_3 [1]. Many efforts are under way for gaining a detailed understanding of the structural parameters essential for a high performance and also for enhanced hydrothermal durability. This will allow further tuning of the preparation methods and rational design of improved catalysts. Furthermore, knowledge about the reaction mechanism is essential for modelling of the exhaust aftertreatment control algorithms.

Among the different characterization methods, X-ray absorption spectroscopy (XAS) is one of the few techniques which can be applied under realistic reaction conditions without altering the process dynamics. Important information such as oxidation state, coordination geometry, type and number of nearest neighbours of a metal site including the structural changes due to interaction with reactants, can be derived by monitoring the changes occurring in the pre-edge, near edge (XANES) and extended X-ray absorption fine structure (EXAFS) of a XAS spectrum [2]. The "quick scanning" technique QEXAFS [3] allows gaining this information during transient runs with 1-10 Hz frequency. Complementary information about species reacting with the metal site can be gained using valence-to-core X-ray emission spectroscopy (V2C-XES), which allows e.g. to distinguish between atoms with close atomic numbers like O and N [2]. Importantly, due to penetration nature of X-rays we can apply XAS and XES techniques *in-situ* or *operando* employing reaction cells with a fixed bed as plug-flow reactors and realistic gas mixtures, flows, and temperatures [4].

Here we report results of a spatially- and time-resolved operando XAS study on various Fe- and Cu-zeolite catalysts and XES studies of Fe-ZSM-5 and Cu-SSZ-13 catalysts during SCR of NOx with NH_3 [5,6]. The obtained data significantly extend the understanding of the SCR reaction mechanism over zeolite-based catalysts and allowed obtaining additional input data for modeling the catalyst behavior.

2 Experimental/methodology

Fe- and Cu-zeolites were obtained either by preparation in our laboratories or as commercial samples. XRD, BET surface area, AAS, EXAFS and UV-Vis were employed for the material characterization. A quartz capillary microreactor (plug-flow reactor geometry) which allows on-line monitoring of the catalytic performance was used for the XAS/XES measurements. The catalyst bed was heated by a hot gas blower between 185 – 550 °C while dosing a gas stream containing 0 – 1000 ppm NO, 0-1000 NO_2, 0 – 1200 ppm NH_3, 5% O_2,

~1.5% H_2O in He. The simulation of the NEDC driving cycle was conducted using a Silicon etched microreactor with an integrated heater and low thermal mass. The spatially-and time-resolved XAS measurements were carried out at the X10DA SuperXAS beamline (Swiss Light Source) and the XES data were acquired at the ID26 beamline (European Synchrotron Radiation Facility). Simulated XES-spectra were calculated by DFT for comparison with the obtained experimental data.

3 Results and discussion

Strong gradients of Fe and Cu oxidation state and a decrease of coordination number have been observed along the catalyst bed for all processes involving NH_3. Inlet of the catalyst bed typically had more reduced Fe (Cu) sites with lower average coordination number. Furthermore, the gradient was stronger when both NO and NH_3 were in the reaction mixture. This indicates a reaction of NOx and NH_3 adsorbed on Fe^{3+} (Cu^{2+}) leaving Fe^{2+} (Cu^{+}) with a lower coordination number [5]. Reoxidation of metal sites by oxygen is suggested to be the rate-limiting step of the NH_3-SCR which is strongly inhibited by NH_3 at lower temperatures for Fe-zeolites. Concurrently it was observed that water inhibits the SCR reaction by coordination to the Fe-active center.

This is further supported by application of V2C-XES which provided evidence of the adsorption of NH_3 and NO (Fig. 1) in the presence of water and in combination with DFT-calculations allowed the identification of potential reaction intermediates for the SCR process on Fe- [6] and Cu-zeolites [7]. Interestingly, V2C-XES spectra of Cu-SSZ-13 uncovered different NH_3 and NO adsorption structures as compared to the case of Fe-ZSM-5 zeolite.

To supplement the steady-state data and to describe Fe and Cu oxidation state dynamics XAS measurements were done in a quick scanning mode during NH_3 concentration transients [5] as well as during temperature transients. As a result, the behavior of the metal sites was monitored during a simulated driving cycle (New European Driving cycle, NEDC) and correlated with the catalyst performance.

4 Conclusions

By application of novel *operando* spectroscopic techniques we could unravel mechanistic steps of the NH_3-SCR. Spatially-resolved XAS allowed to describe gradients of the oxidation state and coordination number of Fe and Cu active sites supporting previously proposed mechanistic schemes [5], while results of XES and QEXAFS during NEDC simulations underlined differences in adsorbed intermediates and redox dynamics of Fe- and Cu-sites in zeolite catalysts.

Keywords: selective oxidation, VPP, synchrotron, NAP-XPS, XAS, *in situ*

1 Introduction

The surface of functional materials like catalysts responds to the ambient conditions. X-ray photoelectron spectroscopy (XPS) and soft X-ray absorption spectroscopy (XAS) are one of the most versatile methods for the investigation of surfaces on the atomic scale providing quantitative information about the elemental composition and chemical specificity. Surface sensitive *in situ* spectroscopy, i.e. in the presence of a reactive environment allows studying the formation of the interface (gas/solid or liquid/solid) of a catalyst with time and thus adds a dynamic dimension to the spectroscopic characterization. The ISISS facility (Innovative Station for *In Situ* Spectroscopy) operated by the Fritz-Haber-Institut (FHI) at the synchrotron radiation source BESSY II of the Helmholtz-Zentrum Berlin (HZB) is dedicated to this kind of *in situ* studies by near ambient pressure XPS (NAP-XPS) and variable pressure soft-XAS (vP-XAS). Examples for the dynamic formation of the electronic surface structure by interaction with the ambient gas under equilibrium will be presented. Furthermore, vP-XAS studies will be discussed to investigate the pressure dependence of complex alkane oxidation reactions.

Finally, an outlook on future activities at HZB/BESSY to develop further synchrotron based ambient pressure characterisation methodologies will be given. Recently, the advent of reaction cells based on electron transparent membranes at low kinetic energy (i.e. high surface sensitivity) has found much interest [1]. First results of the application of this type of cells allowing performing XPS studies at 1000mbar gas pressure and in liquids will be presented. Currently, HZB and FHI are establishing EMIL, The Energy Materials In-Situ Laboratory Berlin at BESSY II. This novel facility includes a new laboratory building hosting beamlines providing an unusual broad photon energy range from 80eV – 8000eV in one spot and (among others) a NAP-high kinetic energy XPS endstation capable to operate at kinetic energy of photoelectrons up to 7000eV that allows studying buried layers and liquid/solid interfaces [2]. Prospects of this new facility for catalyst research will be discussed.

2 Experimental/methodology

We characterized the surface of the alkane oxidation catalyst vanadyl pyrophosphate $(VO)_2P_2O_7$ (VPP) with NAP-XPS in the mbar pressure range and with vP-soft XAS in the electron yield mode at pressures up to 1000mbar at various gas compositions at temperature up to 400°C. Simultaneously, the catalytic performance was determined by mass spectrometry.

3 Results and discussion

Analysis of NAP-XPS spectra provide evidence that details of the electronic structure like work function, core level binding energies, valence and electron affinity of the technical catalyst VPP do respond systematically on the gas phase (Fig. 1a). This indicates the formation of a dynamic surface/subsurface space charge region that has an impact on the charge transport properties of the active catalyst [3]. Additionally, the vanadium oxidation state has been extracted from the V L_3-edge XAS under O_2, C_4H_{10}, and C_4H_{10}+O_2 feed in a variable pressure XAS experiment (vP-XAS). It was found that the vanadium oxidation state changes both with the gas composition and the total pressure (Fig. 1b). The observed pressure gap is understood in terms of Gibbs free energy of the surface and its dependence on the oxygen partial pressure of the surrounding gas phase [4].

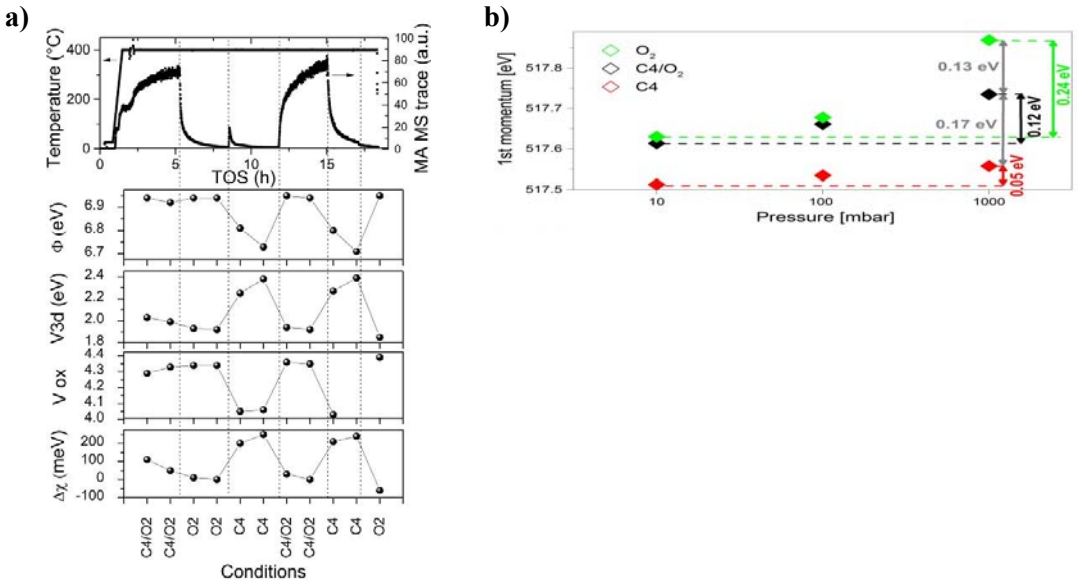

Fig. 1. a) Maleic anhydride (MA) product trace compared with work function Φ, V3d binding energy, vanadium oxidation state V_{ox} and electron affinity change Δχ of VPP at 400°C in different gas mixtures. **Fig. 1b)** 1st momentum of the VL_3-edge as a measure for the vanadium oxidation state of VPP at 400°C in different gas mixtures as a function of the total pressure.

4 Conclusions

This study demonstrates the power and versatility of NAP-electron spectroscopy methodologies to determine details of the electronic surface structure on a molecular level in various gas mixtures at relevant temperature and at total pressures up to 1000mbar. The feasibility of NAP-XPS and vP-XAS has been exemplified in the selective n-butane oxidation to MSA on the technical catalyst VPP. Vanadium oxidation state, work function, and surface dipole moment are related to the catalytic performance. Details of the pressure dependence of the vanadium oxidation state have been elucidated. Thus, both the pressure gap and the materials gap between model and technical catalysts have been tackled.

Keywords: ethanol oxidation, acetaldehyde, acetic acid, vanadium oxide

1 Introduction

Over the past several years, an idea to use renewable resources in chemical industry has been becoming popular in the whole world. Especially many efforts have been focused on the development of technologies for production of alternative fuels based on bio-oil, biodiesel, or bioethanol. At the same time, bioethanol or simply "ethanol", which is produced from biomass by the hydrolysis and sugar fermentation processes, can be used as a raw material for catalytic production of various useful chemical compounds. Depending on the catalyst and reaction conditions, ethanol can be transformed to acetaldehyde, acetic acid, diethyl ether, butadiene, or ethyl acetate with a high selectivity. A special attention is paid to the development of novel catalytic technologies for the industrial production of acetaldehyde and acetic acid via one-step gas-phase conversion of ethanol. Here, we report the first results of our mechanistic study of the gas-phase selective oxidation of ethanol to acetaldehyde and acetic acid over titania-supported vanadium oxide catalysts. We used Fourier transform infrared spectroscopy (FTIR) and near ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) that allowed us to study the catalyst state and adsorbed species during the oxidation of ethanol. The data are complemented by results of temperature-programmed reaction spectroscopy (TPRS) and kinetic measurements.

2 Experimental

All experiments were performed using a monolayer V_2O_5/TiO_2 catalyst, which was prepared by the impregnation as described in details elsewhere [1]. The steady-state activity of the catalyst was tested at atmospheric pressure in a differential reactor with a flow-circulating configuration. The reactor was constructed from Pyrex glass tubing with a 12-mm inner diameter and a 50-mm length. The feed consisted of ethanol, oxygen, and nitrogen in a molar ratio of 1:4:15. The concentrations of products and reactants were determined with an on-line gas chromatograph equipped with thermal conductivity and flame ionization detectors [1].

The *in situ* XPS and TPRS experiments were performed at the synchrotron facility BESSY II, Berlin, using the ISISS beamline equipped with an on-line quadrupole mass spectrometer Prizma QMS-200. The experiments were performed in a flow regime at 0.5 mbar. The *in situ* FTIR measurements were performed at atmospheric pressure on a BOMEM MB-102 spectrometer using a feed of 1.5 vol% C_2H_5OH in air flowing at 50 mL/s.

3 Results and discussion

The oxidation of ethanol was examined over the catalyst in a temperature range of 110-230 °C. Acetaldehyde (CH_3CHO), acetic acid (CH_3COOH), diethyl ether ($(C_2H_5)_2O$), ethyl acetate (CH_3-COO-CH_2-CH_3), crotonaldehyde (CH_3CH=$CHCHO$), ethylene (C_2H_4), carbon oxides (CO and CO_2), and water were detected as products. It was found that the conversion of

ethanol increases monotonically with the reaction temperature and achieves 100% at 230 °C. At low temperatures, acetaldehyde is the major product. Its selectivity is 100% at 110 °C. The selectivity toward acetaldehyde decreases with temperature, and the reaction shifts toward acetic acid. The formation of small amounts of ethyl acetate, ethylene, crotonaldehyde, CO, and CO_2 was also observed. Between 180 and 230 °C, acetic acid becomes the main reaction product. At 200 °C, its selectivity achieves approximately 60% at the conversion of ethanol near 95%. At temperatures above 250 °C, the oxidation of ethanol to CO and CO_2 predominates. Such dependence of selectivity on the reaction temperature and conversion suggests that acetic acid is formed consecutively from acetaldehyde, while carbon oxides are formed during the further oxidation of acetic acid.

The formation of adsorbed species during the oxidation of ethanol was examined by infrared spectroscopy *in situ* at 100, 150, and 230 °C. At 100 °C, the main reaction intermediate adsorbed on the catalyst surface was ethoxide, which results from the dissociative adsorption of ethanol on acid-basic surface sites (V-O). In addition, the spectrum exhibits an extra peak at 1267 cm^{-1}, which corresponds to the δ(OH) mode of adsorbed molecular ethanol, and a broad band at 3600-2800 cm^{-1} due to H-bonded hydroxyl groups. At 230 °C, the surface is mainly covered by acetate species. According to NAP-XPS data, titanium cations remain in the Ti^{4+} state, while V^{5+} cations undergo a reversible reduction under reaction conditions. It means that the selective oxidation of ethanol over vanadium oxide catalysts occurs at the redox V^{n+} sites via the Mars-van Krevelen mechanism involving the surface lattice oxygen species. We suggest that the catalytic cycle starts with the catalyst in the oxidized state. Ethanol adsorbs intact on the acid-base sites of the catalyst and further can dissociate to form the adsorbed ethoxide species and OH group. The formation of ethoxide species is accompanied with a decrease in the ν(V=O) bands appearance of a strong band due to H-bonded hydroxyl groups. We believe that the chemisorption of ethanol is a heterolytic process, during which the proton from the alcohol hydroxyl group is transferred to the vanadyl oxygen atom and the oxidation state of vanadium changes from V^{5+} to V^{4+}. Acetaldehyde is formed in a subsequent step via a transfer of a proton from a CH_2 group to the adjacent vanadyl oxygen atom, which is accompanied with the partial reduction of the next vanadium atom. The OH species ultimately recombines with another OH to form H_2O and a vanadyl oxygen species; adsorbed acetaldehyde can desorb as a product. Hence, two terminal V=O bonds are involved in the oxidative dehydrogenation of ethanol through the transfer of two electrons.

Because the selectivity toward acetic acid increases with ethanol conversion, we can speculate that the formation of acetic acid should occur as a consecutive reaction by oxidation of initially formed acetaldehyde. Thus, adsorbed acetaldehyde reacts with lattice oxygen atoms to form an adsorbed acetate species, which then desorbs as acetic acid at temperatures in the range of 170-230 °C or decomposes to CO and CO_2 at higher temperatures. The formation of acetate is accompanied with the further reduction of vanadium to V^{3+} and formation of an oxygen vacancy. It is confirmed by NAP-XPS, which indicates the high concentration of the adsorbed acetate species and V^{3+} cations observed in pure ethanol at 110°C. The catalytic cycle is finally closed by oxidizing the V^{3+} and V^{4+} cations via irreversible chemisorption of oxygen with the formation of the active sites. Therefore, the catalytic cycle for the oxidation of ethanol to acetic acid involves the transfer of four electrons.

Keywords: Au nanoparticles, X-ray, photoemission, spectra, strong, metal-support, interaction

1 Introduction.

The discovery that gold nanoparticles (Au NPs) supported on metal oxides are active in low-temperature CO oxidation [1] has inspired a considerable amount of research focused on understanding the basis of activity of Au catalysts [2]. Various factors—such as quantum size effects, low coordinated atoms, surface ions and the support interaction [3]—have been proposed as factors that influence Au activity. Here we report the findings from our recent study on the catalytic properties of oxidized Au and Au NPs on various supports in CO oxidation reaction.

2 Experimental/methodology.

All measurements were performed in the near ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) endstation at the ISISS beamline at HZB/BESSY II (Berlin, Germany) [4]. Gold containing samples (Au foil, Au NPs supported on carbon and transition metal oxides) were characterized using *in-situ* XPS and *ex-situ* techniques, such as electron energy loss spectroscopy (EELS), scanning and transmission electron microscopy (SEM and TEM). CO and O_2/O_3 were introduced to the chamber at different ratios, keeping the pressure and temperature constant, at 0.3 mbar and 100°C, respectively.

The procedure, used to prepare the Au/HOPG (highly oriented pyrolytic graphite) model catalysts, is described in detail elsewhere [5]. The procedure involves forming defects on the HOPG surface via soft Ar^+ sputtering, followed by Au deposition and surface annealing at 300°C in UHV (for Au NPs stabilization). Au NPs supported on functionalized carbon nanotubes (CNTs) were prepared using immobilization and incipient impregnation methods. Nanoscopic Au was electrochemically deposited on Au foil. Au NPs on transition metal oxides were synthesized by deposition-precipitation (Au/Fe_2O_3, Au/TiO_2) [6,7] and photochemical decomposition of intermediate gold-azido complexes (Au/Fe_2O_3, Au/Cr_2O_3) [8].

3 Results and discussion.

Our *in-situ* measurements show that the oxidation of extended Au surfaces by O_3 treatment is accompanied by the formation of meta-stable surface oxide(s) [9]. It was found that Au oxide does not directly participate in CO oxidation on Au-based catalysts. Our experiments on Au foil allow us to conclude that low-coordinated Au atoms, present on the surface after oxidation, do not possess sufficient CO conversion at room temperature. Similar to oxidized Au foil, Au NPs on oxygen-free supports (HOPG, functionalized CNTs, Au foil) do not show any catalytic activity, regardless of the NPs' size, the type of the support and the method of synthesis. Therefore, NP size reduction and/or oxidation are not sufficient to activate Au.

In contrast, the Au NPs on oxygen containing supports show high catalytic activity, which depends on the method of preparation, and can be associated with the formation of positively charged Au species (Figure 1). Indeed, only the samples prepared by deposition-precipitation methods showed significant CO conversion at low temperature. XPS revealed the presence of two Au species (Au^0 and $Au^{\delta+}$) on the surface of active Au/TiO_2 and Au/Fe_2O_3 samples. The energy shift of the $Au^{\delta+}$ peak, relatively to bulk gold (Au^0), depends on the support, and is 0.7 eV and 0.85 eV to higher binding energy for Au/TiO_2 and Au/Fe_2O_3, respectively. TEM images indicate the formation of overlayers on Au particles. EELS spectra confirm the formation of transition metal oxide overlayers on top of the Au NPs.

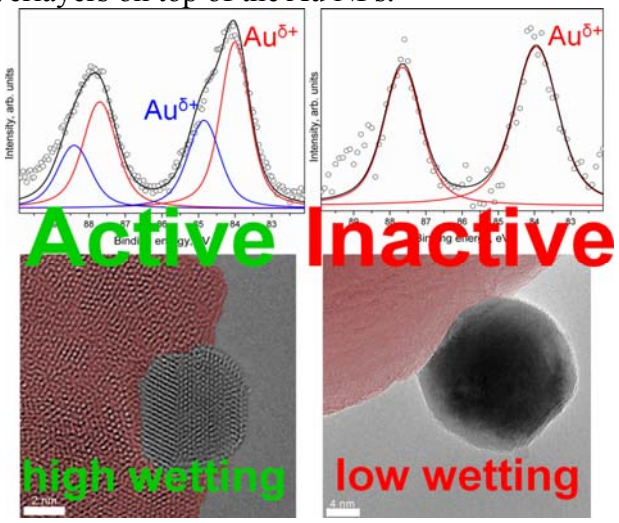

Figure 1. Au 4f XP spectrum and TEM image of Au/Fe_2O_3 synthesized by deposition-precipitation (left) and photochemical decomposition of intermediate gold-azido complex (right) method.

4 Conclusions.

Our results suggest a mechanism of Au activation via Strong Metal Support Interaction (SMSI), assuming a strong influence of the support on the electronic structure of the gold through charge transfer and stabilization of low-coordinated Au atoms. Therefore SMSI plays key role in Au activation and is more important than size reduction.

Ceria Supported Gold Catalysts: Mechanistic Studies of CO Oxidation Using a Combined Operando Approach

Schilling C. M.[1,2,3], Lohrenscheit M.[1,2,3], Hess C.[1,2,3*]

1 - Technische Universität Darmstadt, Darmstadt, Germany
2 - Eduard Zintl-Institut für Anorganische und Physikalische Chemie, Darmstadt, Germany

* schilling@chemie.tu-darmstadt.de

Keywords: operando, gold, ceria, Raman, IR

1 Introduction

Gold catalysis is a research area of growing interest. Ceria supported gold catalysts show a high activity and stability in low-temperature CO oxidation. However, the influence of active support materials such as ceria on the catalytic properties of gold nanoparticles is not well understood. In this context, we prepare gold loaded ceria catalysts and employ *operando* spectroscopy to study the room temperature oxidation of CO. In particular, combined operando Raman and UV/Vis spectroscopy, *quasi in situ* X-ray photoelectron spectroscopy (XPS) as well as *operando* diffuse reflectance infrared spectroscopy (DRIFTS) are used. It will be shown that the use of complementary Raman and IR spectroscopic methods provides new insight into the mode of operation of ceria supported gold catalysts.

2 Experimental

Ceria is prepared by calcination of cerium(III) nitrate and loaded with gold via deposition precipitation. Gold loadings of 0,1, 0,5 and 1,0 wt% were deposited on the calcined (ca) and a commercial (co) ceria support (Fluka). The Au/CeO_2 catalysts are investigated in the *multi in situ*-setup.[1,2] Which allows for simultaneous Raman and UV/Vis spectroscopy under *operando* conditions plus *quasi in situ* X-ray photoelectron spectroscopy without air exposure. The activity is monitored by gas phase infrared spectroscopy. Additionally, *operando* DRIFTS measurements were performed at comparable conditions and at equal CO conversion as in the *multi in situ*-setup. The total flow rate was 100 ml/min. 25 V% O_2 in Ar for oxidative conditions, 5 V% CO and 25 V% O_2 in Ar for reaction conditions and 5 V% CO in Ar for reductive conditions. The experiments were performed at room temperature. Samples are studied as pellets and powders.

3 Results and discussion

UV-Vis data of synthesized Au/CeO_2 catalysts show a broad band in the visible region around 600 nm irrespective of the used ceria support material. This band is attributed to a reduction of ceria indicating the presence oxygen defects in ceria support. While ceria is reduced upon gold loading gold is partially oxidized. XP spectra reveal that the majority of gold particles is in a metallic state (Au^0) and only about 6% in an oxidized state (Au^+).
Fig. 1 shows the CO stretching region of the Raman spectra of 0,5 wt% Au/CeO_2 (ca) under oxidative, reaction and reductive conditions. If CO is provided in the gas phase Raman spectra indicate a band of gas phase CO at 2142 cm^{-1} as well as bands of adsorbed CO (2113 cm^{-1} and 2130 cm^{-1}), whereas the intensities of the latter bands decrease under reaction conditions. The redshift of the two bands compared to gas phase CO indicates a softening of the C-O bond upon adsorption. So far these CO-related bands have only been observed in IR experiments and have been assigned to CO adsorbed on gold; the band at 2113 cm^{-1} is also confirmed by our own IR data. Therefore, we conclude that CO is adsorbed at net electron donor gold particles. This is

consistent with partially oxidised gold particles indicated by XPS. Interestingly, when switching from oxidative to reaction conditions *operando* Raman spectra also reveal distinct changes regarding ceria phonons and peroxide species indicating the influence of the ceria support on catalysis.

Operando DRIFT spectra are depicted in Fig. 2. As indicated by the solid and dashed lines adsorbed carbonate and formate are observed, respectively. The carbonate region of a sample with 0,5 wt% gold loading on commercial ceria (co) exhibits a rapid build-up of bidendate carbonate species (solid lines, 1300 cm^{-1} and 1575 cm^{-1}) under reaction conditions, which transform into bidendate formate species (dashed lines, 1370 cm^{-1} and 1595 cm^{-1}) under reductive conditions.[3] Monodendate carbonate species (solid lines, 1395 cm^{-1} and 1465 cm^{-1}) remained unchanged upon treatment for 1h under oxidative conditions and switching to reaction conditions.

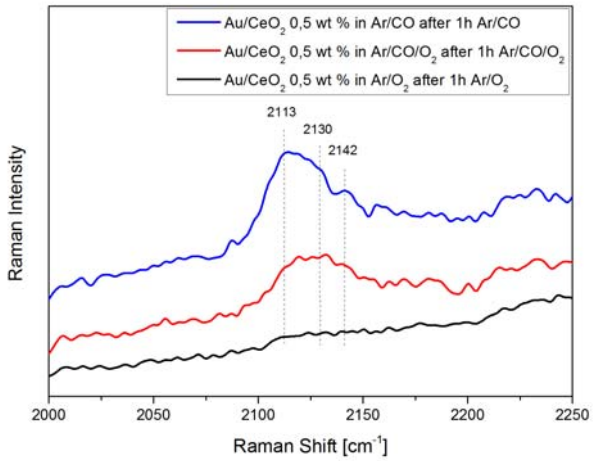

Fig. 1. *Operando* Raman spectra of 0,5 wt% Au/CeO_2 (ca) under oxidative, reaction and reductive conditions showing adsorbed CO at 2113 and 2130 cm^{-1}.

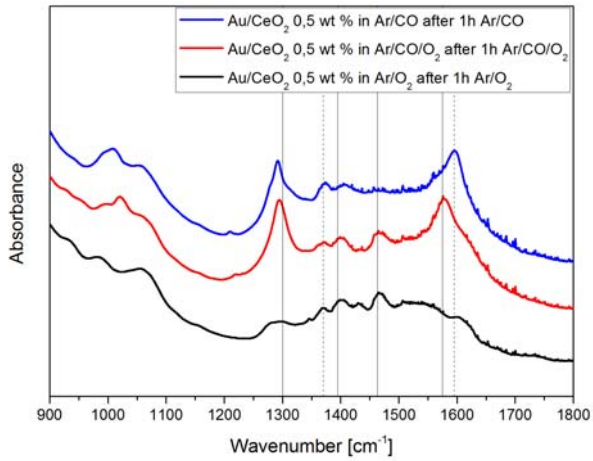

Fig. 2. *Operando* DRIFT spectra of 0,5 wt% Au/CeO_2 (co) showing a build-up of bidendate carbonate (solid) during reaction and formate (dashed) in

4 Conclusions and outlook

Operando Raman and IR data demonstrate the potential of a complementary vibrational spectroscopic approach to elucidate the mode of operation of Au/CeO_2 catalysts in CO oxidation. Depending on the gas environment (oxidative, reaction, reductive) a distinct spectral signature of adsorbed CO, carbonate, formate, hydroxyl and peroxide species as well as ceria phonons is observed allowing for new insight regarding the presence of reaction intermediates and the role of the support.

The presented combined *operando* spectroscopic approach will also be a promising strategy to elucidate the catalytic mechanism of other oxidation reaction over supported gold loaded ceria catalysts such as preferential oxidation of CO or selective oxidation reaction of organic compounds.

Keywords: oxygen, gold, gold, oxide, subsurface, oxygen, methanol partial oxidation

1 Introduction

Gold is very active and selective in various partial oxidation processes and oxidative coupling reactions [1,2]. One of the crucial requirements for the selective oxidation reactions on gold is the adsorbed atomic oxygen. Atomic oxygen on gold surfaces can be prepared by various methods including ozone decomposition. Activity of the oxygen on the gold surface strongly depends on the temperature. In this contribution, we investigate the atomic oxygen overlayers on the Au(111) model catalyst surface and their reaction with methanol in an attempt to elucidate the nature of the different oxygen species and their dissimilar activities.

2 Experimental

All experiments were performed in a multifunctional ultra-high vacuum chamber equipped with Temperature Programmed Desorption (TPD) /Temperature Programmed Reaction Spectroscopy (TPRS), X-ray Photoelectron Spectroscopy (XPS), Low Energy Electron Diffraction (LEED) and Infrared Reflection Absorption Spectroscopy (IRAS) techniques. Atomic oxygen layers on the Au(111) surface were prepared by ozone exposure onto the clean gold surface.

3 Results and discussion

We have found that adsorbed oxygen layers prepared at various temperatures reveal drastically different reactivities towards methanol. Figure 1 presents the TPRS profiles recorded after ozone exposure onto the clean Au(111) surface at 460 K (Fig. 1a) or 140 K (Fig. 1b) followed by subsequent methanol adsorption at 140 K. The peaks corresponding to the m/z = 31 and 32 channels at ~ 200 K are associated with molecular desorption of unreacted methanol, which is known to desorb from the clean gold surface non-dissociatively (i.e. molecularly). The unreacted oxygen desorbs recombinatively (m/z = 32) at ~ 500 K. The oxygen prepared at 460 K and methanol desorb separately, where almost no (or extremely limited) interaction is detected, as indicated by the insignificant CO_2 (m/z = 44) production (Fig. 1a). The oxygen layer prepared at 140 K interacts with methanol with complete oxygen utilization, and unreacted oxygen is not detected (Fig. 1b). In this latter case, methanol is partially oxidized producing CO_2 (m/z = 44) desorbing at 300 K as well as methyl formate (m/z = 60) due to the oxidative coupling reaction. At higher oxygen coverages, formaldehyde can be also detected as an additional partial oxidation product.

In order to understand the nature of the oxygen species, we have performed TPD experiments of adsorbed oxygen prepared at various temperatures. The oxygen overlayers prepared at 460 K demonstrate zero-order desorption kinetics without an apparent saturation. Zero-order desorption behavior is interpreted by the formation of subsurface oxygen via diffusion/solvation. The presence of the bulk gold oxide (which can also explain zero-order kinetics) was not confirmed in XPS measurements. The formation of subsurface oxygen

explains deactivation of oxygen on the gold surface with increasing temperature (Fig. 2).

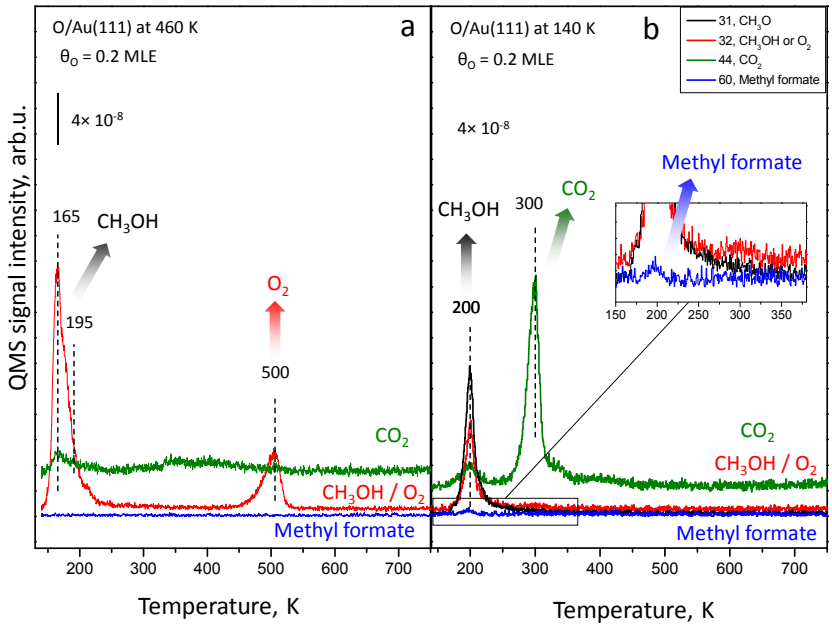

Fig. 1. TPRS profiles obtained after exposure of Au(111) to ozone at 460 K (a) or 140 K (b), followed by methanol exposure at 140 K.

4 Conclusions

In the current contribution, we have investigated the oxygen overlayers prepared at different temperatures on Au(111) model catalyst surface and their different reactivities in methanol partial oxidation. Our findings suggest that the reactivity of oxygen is closely linked to the presence/absence of oxygen diffusion into the subsurface of the gold catalyst as summarized in Fig. 2.

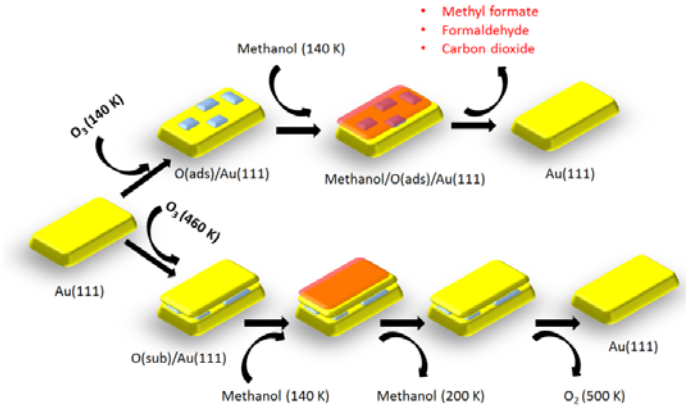

Fig. 2. Methanol interaction with oxygen layers prepared at 140 K vs. 460 K.

Keywords: SCR, Cu-SAPO-34, DeNOx

1 Introduction

Selective catalytic reduction (SCR) is one of the most used technologies for the NO_x abatement in stationary sources and heavy-duty vehicles. Recently, it is proposed as an advanced technology to reduce NO_x from lean-burn engines vehicles. For this purpose, copper exchanged zeolites have been reported as an excellent choice, showing suitable acidity, for ammonia adsorption, and a metal, which promotes the activation of NO_x and, subsequent H_2O and N_2 formation [1]. Due to the low hydrothermal stability of large pore zeolites, such as ZSM5 or BETA, small pores materials with a chabazite structure are being studied [2]. It is important to know the species that are involved in the process as well as its relation with the synthesis process. The aim of this contribution is to study the influence of the preparation of the Cu-SAPO-34 in its properties and its performance and possible species involved in the SCR mechanism.

2 Experimental

A series of silicoaluminophosphates was synthesized by ultrasonic assisted hydrothermal method. The molar gel composition was 2 DEA: 0.6 SiO_2:1 Al_2O_3: (0.2-0.8) P_2O_5:50 H_2O. The Cu-loading was modified from 0 to 4 wt% and was incorporated during the synthesis [3]. Materials were characterized by DRX, XPS, N_2 adsorption-desorption, TEM, SEM and Raman. NH_3 adsorption was analyzed by in situ FTIR to evaluate the acid-strength and acid-sites distribution; as well as isothermal experiments of NH_3 adsorption were carried out in a TG-MSruns. NO adsorption was studied by FTIR observing the species involved in the process. The behavior in the SCR process was analyzed in stationary experiments at different temperatures.

3 Results and discussion

From all the synthesized materials, in Table 1 the characteristics obtained by low temperature N_2 adsorption-desorption and XPS of two phosphorus content (45 and 17wt%) in the acidic form, identified as SAPO-34+1 and SAPO-34+2, respectively, and with 2wt% of copper are shown. The structural properties are modified with the gel composition. In the same synthesis conditions of temperature and time, increasing the amount of phosphorus, the zeolitic materials show higher cristallinity, an increment in the relation between metaphosphate (PO_3^-) and P_2O_5 and a stabilization of copper in oxidation state +1, as well as the formation of copper oxides. The copper incorporation increases the total pore volume since a strong cristallinity loss takes place. The samples with higher cristallinity and more metaphosphate amount show greater ammonia retention net capacity, adsorbing more NH_3 in Brönsted acid centers.

Table 1. Textural properties and copper oxidation states relation

	S_{BET} ($m^2 \cdot g^{-1}$)	V_p ($cm^3 \cdot g^{-1}$)	Cu(I)/ Cu(II)
SAPO-34+1	559	0.29	-
SAPO-34+2	439	0.59	-
2Cu-SAPO+1	556	0.43	5
2Cu-SAPO+2	456	0.63	1.5

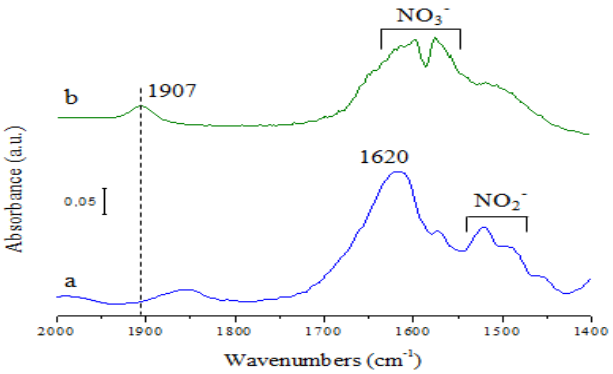

Fig. 1. FT-IR spectra of NO adsorbed (16torr) onto the samples after outgassing at 100ºC for a) 2Cu-SAPO+1 and b) 2Cu-SAPO+2

In Figure 1, the species of NO adsorbed onto the Cu-containing catalysts after outgassing at 100ºC are shown. At low Cu(I)/Cu(II) ratio, mononitrosyl-Cu^{+2} species are detected at 1907cm^{-1}, which are the active sites to the selective catalytic reduction of NO_x with NH_3, being selective to nitrogen. The predominance of copper in oxidation state +1, favours the oxidation of ammonia, decreasing drastically the NO_x conversion at temperatures above 300ºC. Nevertheless, in these conditions, the selectivity to N_2 is almost 100%. In the case of 2Cu-SAPO+2 bridged bidentate and bridged monodentate nitrate are observed; whereas 2Cu-SAPO+1 adsorb a higher amount of NO as nitrates (c.a.1620 cm^{-1}) as well as nitrite and monodentate nitrite in the framework. For that reason, the N_2O production between 250 and 350ºC is increased due to the ammonia nitrates decomposition.

4 Conclusions

The synthesis and the gel composition influence the textural properties as well as the copper oxidation states ratio in zeolitic materials. The variation of the synthesis parameters yields a material with high cristallinity, constant ammonia retention capacity in the operation window of SCR technology and a suitable Cu(I)/Cu(II) ratio to ensure the efficient selective catalytic reduction of NO_x with NH_3 and avoid co-side products.

Keywords: $V_2O_5/Ce_xZr_{1-x}O_2$ catalysts, low-temperature, NH3-SCR, *in situ*, UV/Vis, *in situ*, EPR

1 Introduction

The selective catalytic reduction (SCR) of nitrogen oxides by ammonia is one of the most important processes for NO_x abatement from exhaust gases [1]. While V_2O_5-WO_3/TiO_2 catalysts are industrially used in power plants, noble metals such as Pt supported on CeO_2 are part of 3-way catalysts for mobile engines. The operation of both types of catalysts is limited to high and narrow temperature windows of 400-500°C. A promising way to develop inexpensive and stable catalysts for NO_x abatement at low temperature (needed, e. g., for diesel and lean-burn engines) may be to support V_2O_5 on CeO_2, due to the high oxygen mobility and interesting redox properties of the CeO_2 support. However only a few studies exist so far which show almost total NO conversion on 5 % V_2O_5/CeO_2 at about 240 °C and low gas-hourly space velocities (GHSV) of only 12000 h^{-1} [2].

It is the aim of this study to explore the potential of catalysts containing V_2O_5 dispersed on mixed CeO_2/ZrO_2 supports for the SCR of NO by NH_3 at low temperature (100-300°C). We expect that partial replacement of Ce^{4+} by smaller Zr^{4+} ions could promote defect formation and oxygen transport within the catalyst lattice [3], which could enhance the catalytic performance. Various techniques such as XRD, XPS, EPR and UV-Vis-DRS were used, partly *in situ* under catalytic reaction conditions, to elucidate relations between structural properties and catalytic performance.

2 Experimental

Different $Ce_xZr_{1-x}O_2$ supports (x = 1, 0.9, 0.8, 0.7, 0.5, 0.3 and 0) were prepared by a citrate method, impregnated with NH_4VO_3 and calcined at 400°C to reach V_2O_5 loadings of 5 %. The SCR activity measurements of the $V_2O_5/Ce_xZr_{1-x}O_2$ catalysts were performed in a fixed-bed quartz continuous flow reactor operating at atmospheric pressure, in the temperature range from 100°C to 300°C, using reactant gas composition of 1000 ppm NO, 1000ppm NH_3, 5 vol% O_2, balance He, and a total flow rate of 100 mL/min. *In situ* UV-Vis DRS were recorded at 200 °C using the same gas composition with a flow rate of 25 mL/min after 1h pretreatment at 275 °C in air. Kinetic studies of reduction and reoxidation were performed by *in situ*-UV-vis-DRS monitoring the absorbance at 700 nm in the range of d-d-transitions of reduced V-species.

3 Results and discussion

XRD powder patterns of all catalysts indicate that ZrO_2 was incorporated into the CeO_2 lattice to form a homogeneous solid solution while maintaining the fluorite structure. No reflections of crystalline V_2O_5 were observed, pointing to high dispersion. XPS results suggest a higher surface V concentration on the mixed oxide supports compared to pure CeO_2 and ZrO_2. This may be due to the higher BET surface areas of the mixed oxides. EPR and XPS results revealed that the 5% V_2O_5/ZrO_2 catalyst contains the highest amount of V^{4+}, yet enriched in the

bulk, while the surface contains exclusively few highly dispersed V^{5+} species. In contrast, the catalyst 5 % V_2O_5/CeO_2 contains exclusively V^{4+}, while on the mixed $Ce_xZr_{1-x}O_2$ support, both V^{5+} and V^{4+} are present. *In situ* UV-Vis-DRS spectra indicate that 5% V_2O_5/ZrO_2 contains a significant amount of tetrahedral VO_4 sites while octahedrally coordinated V is dominating on CeO_2 and the mixed supports.

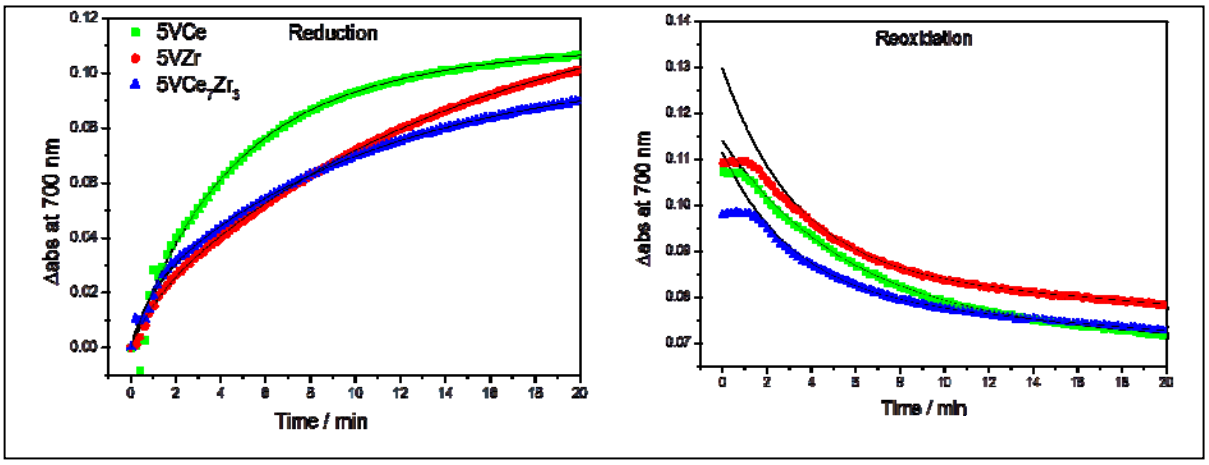

Fig. 1. Difference in absorbance at 700 nm during reduction of oxidized VO_x species by 0,1% NH_3/He and during reoxidation of reduced VO_x species by 5% O_2/He at 200 °C. Experimental data – colored filled symbols, black solid line – simulated curve according 2-sites model.

Fitting of the time-dependent redox behavior of the V sites by a first-order rate law revealed the presence of two types of oxidized and reduced VO_x species (probably on the surface and in the bulk) in all these catalysts (Fig. 1). Maximum rate constants for both reduction and reoxidation were obtained for the highly active 5 % $V_2O_5/Ce_{0.7}Zr_{0.3}O_2$ (compared to the less active catalysts supported on pure CeO_2 and ZrO_2). This suggests that the mixed oxide support might promote oxygen mobility and improve the redox behavior of the supported VO_x species which in turn raises the catalytic performance. In situ-EPR studies of $VO_x/Ce_xZr_{1-x}O_2$ under NH_3-SCR feed indicate the presence of V^{4+} in states of low activity (150°C) while exclusively V^{5+} is present in states of high activity (250°C).

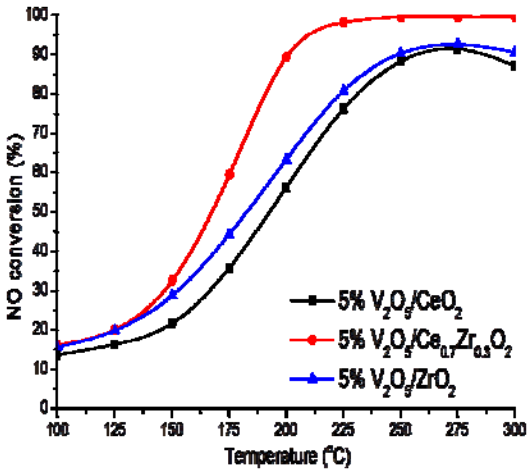

Fig. 2. Catalytic behaviour of 5% $V_2O_5/Ce_xZr_{1-x}O_2$

Highest catalytic performance was measured with catalyst 5 % $V_2O_5/ Ce_{0.7}Zr_{0.3}O_2$ which, compared to literature values [2] reached full conversion of NO at a significantly lower temperature (200 °C compared to 240 °C) and at a 5-fold GHSV of 60000 h^{-1} (compared to 12000 h^{-1}) (Fig. 2). These are the best results ever achieved with this catalytic system.

Keywords: $CuCl_2/\gamma\text{-}Al_2O_3$ catalyst, UV/Vis, spectroscopy, *in situ* spectroscopy, oxychlorination, process

1 Introduction

Oxychlorination of ethylene is the most important route to produce 1, 2-dichloroethane (EDC), which is a key step for poly-vinyl chloride (PVC) [1]. In commercial ethylene oxychlorination reactors, gaseous ethylene, HCl and air react with $CuCl_2/\gamma\text{-}Al_2O_3$ catalyst at a temperature range of 217 ^{0}C-257 ^{0}C and a pressure 5-6 atm.

The $CuCl_2/\gamma\text{-}Al_2O_3$ catalyst is effective in the oxychlorination of ethylene because $CuCl_2$ can catalyze the conversion of HCl to chlorine. In the literature [2], it has been shown that by feeding the three reactants separately, the oxychlorination reaction is catalyzed by a highly dispersed $CuCl_2$ phase and thereby follows a three step redox mechanism:

Step 1. Reduction of $CuCl_2$ to CuCl. (1)
Step 2. Oxidation of CuCl to form an oxy-chloride. (2)
Step 3. Hydrochlorination of the oxy-chloride using HCl to form $CuCl_2$ and H_2O. (3)

Despite more than 30 years of great research and commercial application of oxychlorination reaction, the reaction mechanism is not fully understood [1]. However, most of the work has been performed in the past to study qualitatively the oxidation state of the $CuCl_2$ catalyst during the reaction, which is of great importance for catalyst activity and stability. It is generally agreed that the oxychlorination involves a redox process in which copper cycles between Cu^I- and Cu^{II} states [1]. One of the main challenges of this process is that the Cu^I deposits on the surface of the catalyst during the reaction thereby caused the aggregation, and loss of Cu active materials due to its low melting temperature and volatility. Hence, a spatial-time prediction of oxidation state of Cu in industrial reactors is of great importance, which requires detailed kinetics of the both reaction including catalyst active component involved in elementary reaction steps in the redox cycle.

In-situ spectroscopy is an approach to monitor online the physicochemical phenomena of the catalyst material in a reactor [3]. The results from such in-situ study at industrial relevant conditions provide detailed insight into the working principles of the catalytic material. So that it would then be possible to improve the existing catalyst formulations or design completely new catalysts, which are more active and/or selective. In this respect, it is advantageous to look on catalytic systems from different perspectives by making use of multiple characterization techniques. However, to the best of our knowledge, a spatially-time resolved systematic in-situ quantitative kinetic study on the Cu^{II}/ Cu^I of the $CuCl_2/\gamma\text{-}Al_2O_3$ catalyst in a fixed-bed reactor is still missing.

2 Experimental/methodology

A strategy of combined transient and steady-state kinetic study was employed. The transient kinetic study was performed for individual reaction steps such as the reduction- (Eq. 1), oxidation- (Eq. 2) and hydrochlorination (Eq. 3) in the catalytic cycle of oxychlorination

process. The UV-Vis spectroscopic technique in the reactor focuses on the same spot of a catalyst in a reactor under true reaction conditions and is capable of delivering sub second time resolution. However, in the overall reaction study, the UV-Vis focuses on the same spot of catalysts in the reactor first until the process reached steady-state to get the time resolved kinetic data. After that the whole catalyst bed of the reactor is scanned by UV-Vis spectroscopy to measure the active Cu^{II} along the reactor axis.

3 Results and discussion

The Cl in the catalysts gradually is reacted with ethylene to form EDC, and the amount of Cl in the catalysts decreases with time, resulted in a decrease in the reaction rate for the chlorination of ethylene cycle (Eq. 1). The selectivity to EDC is close to 100%. Based on the mass balance according to the equation (1), the uptake of removable Cl with time can be. From it, the amount of the Cu^{II} active sites of the catalyst reduced to Cu^{I} upon exposure to ethylene could be estimated. The change of Cu state from Cu^{II} to Cu^{I} has been studied by the use of UV-Vis spectroscopy, which changes in the relative conversion of ethylene or relative changes in amount of Cu^{II}. The oxidation step with oxygen transforms Cu^{I} to Cu^{II} in the form of Cu_2OCl_2. The time required for a complete reaction is much longer in the oxidation step than in the reduction step, at the identical reactant pressure. It suggests that the rate of the oxidation step (step 2, Eq. 2) is lower than the one of the reduction step (step 1, Eq. 1). It was found that the kinetics of hydro-chlorination (3) is much fast than other two steps, which is not relevant step for the kinetics of the total catalytic cycle. The steady-state experiments were performed with co-feeding of ethylene, oxygen and HCl for two different reaction conditions (condition I; one with excess of oxygen and condition II; with stoichiometric amounts). It has been found that near to the inlet of the reactor, Cu^{II} has been reduced to Cu^{I} and Cu^{I} dominates in the catalyst bed. However, near to the outlet of the reactor the reduction of Cu^{II} to Cu^{I} was not complete. At the reaction condition II, where the stoichiometric amounts of reactants were fed, the reactor was scanned after reaching steady-state (at 46 mins). It is found that Cu^{I} dominates in the whole reactor bed in the steady-state condition and they are much lower than the values at reaction condition, i.e., excess oxygen, due to the lower oxygen concentration and thus the lower oxidation rate. As a result, the conversion is higher at the higher oxygen concentration (condition I) compared to the one at the stoichiometric composition (condition II). The combined results of conversions in gas phase and Cu^{II} concentration at the catalyst surfaces at the steady-state conditions further confirmed the dynamic nature of the active sites.

4 Conclusion

We expect that the developed methodology will be generally useful for developing catalyst diagnostics strategies, in cases where the catalyst undergoes oxidation state changes, in particular in redox reactions. Therefore, the combined transient and steady-state kinetic study by the use of UV/Vis- and mass spectroscopy is a powerful tool for kinetic study of the reactions involving redox cycles. It will provide not only the kinetics of the main reactions, but also oxidation state changes of the catalyst active component.

Keywords: ethylbenzene, zeolite catalyst, alkylation, bio-ethanol, FCC, off-gas

1 Introduction

As an important bulk chemical, ethylbenzene is mainly manufactured through catalytic benzene alkylation processes, which in turn is used for the production of styrene, and then to produce polystyrene, ABS resin, SAN resin and some other products [1]. For the manufacture of ethylbenzene, liquid phase $AlCl_3$-based alkylation process was first introduced in 1950s, and then zeolite-based alkylation processes, both vapor phase and liquid phase, were developed to solve the corrosion problem of $AlCl_3$ process [2]. However, due to the oil shortage and requirements for sustainable developments, it is of great desire to develop new catalytic processes with raw materials diversity. For ethylbenzene manufacture, the challenge is how to design and prepare different catalysts suitable for different ethylation agents and the processes thereof. Herein, pure ethylene, bio-ethanol and FCC (Fluid Catalytic Cracking) off-gas were used in vapor phase benzene alkylation processes. According to the processes characteristics, three different catalysts using ZSM-5 zeolite as the major active component were designed, prepared and applied.

2 Experimental/methodology

ZSM-5 zeolites were synthesized using silica sol (40 wt %) and $Al_2(SO_4)_3$•$18H_2O$ as silicon and aluminum sources, respectively. After hydrothermal crystallization, the products were filtered, washed with deionized water and dried overnight. The obtained ZSM-5 zeolites were extruded into small pellets with 2 mm in diameter and 10mm in length. Then, calcination and ion-exchange with 1 M NH_4NO_3 solution were carried out with combinations of modification treatments with steam and/or phosphoric acid solution. Vapor phase benzene alkylation experiments were carried out in a fixed bed reactor.

3 Results and discussion

Figure 1 illustrates different vapour phase benzene alkylation processes using different ZSM-5 zeolite catalysts of nano-ZSM-5, Phosphorous modified ZSM-5 and oriented ZSM-5.

For benzene alkylation process using pure ethylene, the key point is to inhibit coke formation and reduce the main byproduct of xylene, so that catalyst with high diffusion property was needed. Nano-sized ZSM-5 zeolite was chosen as the active component, and a steam treatment procedure was needed to make a good alkylation catalyst [3].

Ethylene is usually produced from the catalytic thermo cracking of naphtha originating from crude oil. The rise of price of crude oil thus drives up the price of ethylene. Meanwhile, due to the rapid development of biochemical engineering technology, the cost for obtaining ethanol has greatly decreased. For instance, ethanol can be produced through fermentation of crops, such as maize and cassava, and crop straw. Thus, catalytic process that uses ethanol instead of ethylene for ethylbenzene manufacture has certain competitive advantages. However, either water in bio-ethanol raw material, or that produced in the alkylation reaction would cause the loss of active Al sites, result in bad performance of the catalyst. So that combination

treatments with steam and phosphoric acid solution were introduced to insure the catalyst possess a long lifetime, high selectivity and capability of converting a substantial amount of ethanol to minimize the generation of impurities such as xylene [4].

FCC off-gas contains 10-30% ethylene, which can be used as ethylene source to produce ethylbenzene. However, separation process of ethylene from FCC off-gas would increase the overall investment and running cost, and the impurities, like propylene, would cause side reactions and catalyst deactivation when FCC off-gas is directly fed. In order to meet commercial requirements, ZSM-5 zeolite with b-orientation was synthesized. Moreover, the shaped catalyst possessed abundant macro and mesopores, and combinations of hydrothermal treatment and acid leaching modification were carried out to remove the Lewis acid site to inhibit side reactions. Over the as prepared catalyst, reactants could easily diffuse through the macropores and mesopores to reach the active sites located in micropores. The catalyst showed a stable reaction level in both ethylene conversion and selectivity, while the industrial runtime went beyond 12 months [5,6]. These enhanced catalytic performances can be attributed to the decreased mass transfer limitation in the straight channels along the b-axis in zeolite and further combined modification. Since the first commercialization of this catalyst in 2009, the overall ethylbenzene capacity in 2013 was about 700 kt, and it will reach 1.3 Mt in 2015.

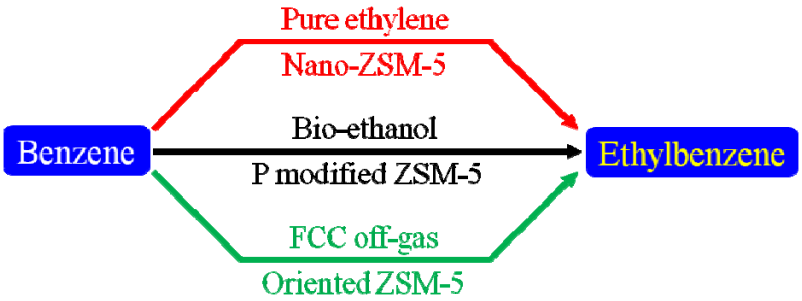

Fig. 1. SRIPT's ethylbenzene manufacture processes using different raw materials and catalysts.

4 Conclusions

Three different ZSM-5 zeolite based catalysts were designed, prepared and commercialized in vapour phase benzene alkylation processes for ethylbenzene manufacture using ethylene, bio-ethanol and FCC off-gas as raw materials by Sinopec Shanghai Research Institute of Petrochemical Technology. The key point to obtain ideal catalysts is the combination of ZSM-5 zeolites and the post-treatment procedures. New catalysts and processes for industrial and fine chemicals production are under investigation and will be commercialized in the coming future.

Hydrotreating Catalyst Activation under Industrial Conditions

Van Haandel L., Hensen E.J.M., Weber Th.*

Inorganic Materials Chemistry, Eindhoven University of Technology, Department of Chemical Engineering and Chemistry, Eindhoven, The Netherlands

* th.weber@tue.nl

Keywords: hydrotreating, Mo S_2, activation, promoter, EXAFS

1 Introduction

Two-dimensional transition metal sulfides are chemically versatile and have a wide range of applications in catalysis, opto-electronics and batteries [1]. MoS_2 can provide a low cost alternative to Pt as hydrogen evolution catalyst and has been applied successfully for many years in oil-refining to catalytically remove sulfur from oil. In hydrodesulfurization (HDS) catalysts, the electronic properties of MoS_2 are tuned by the addition of Co/Ni, improving the intrinsic activity by about one order of magnitude. Studies on model systems, often performed under reaction conditions deviating substantially from those in industrial practice, have led to the Co-Mo-S model with Co/Ni atoms located at the edges of MoS_2 nanosheets [2]. A drawback of these model studies is that trends in model HDS reactions using thiophene or dibenzothiophene (DBT) usually do not match with those observed in industrial gas-oil HDS tests. Consequently, structure-performance relations at the lab scale are not well suited to predict performance under real HDS conditions (20-60 bar, 350-400°C, gas-oil feed).

In the present work, we follow the activation of Co-Mo HDS catalysts by *in situ* X-ray absorption spectroscopy (XAS) under conditions close to industrial practice (20 bar, 350°C, model diesel feed). We demonstrate that the temperature of the oxide-to-sulfide phase transition strongly depends on activation parameters (pressure, sulfiding agent) and the composition of the catalyst precursor. The influence of a range of organic additives with varying chelating propensity for the precursor metals on the catalytic performance in model and gas-oil HDS reactions is determined. By correlating these activity trends to the structure of the active phase, we obtain deeper insight into structure-performance relations in real gas-oil HDS.

2 Experimental/methodology

High metal loading catalyst precursors (~20 wt%), representative of commercial ones, were prepared via impregnation of γ-alumina with an aqueous solution of Co and Mo salts and various additives such as phosphoric acid (P), polyethylene glycol (PEG), citric acid (Cit) and nitrilotriacetic acid (NTA). The dried or calcined precursors were activated in a sulfur-rich feed (H_2/H_2S (10%) or H_2 and an organosulfide dissolved in n-hexadecane) at 1 or 20 bar pressure. The sulfided catalysts were characterized by XAS, X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM); their performance was evaluated in thiophene, DBT and gas-oil HDS reactions. XAS experiments were performed at the Co K and Mo K edge with a homemade *in situ* cell at BM26A of the European Synchrotron Radiation Facility (ESRF, France).

3 Results and discussion

Figure 1 shows that the Co sulfide phase forms in a very short timespan (< 5 min) when Co-Mo HDS catalysts are activated under conditions similar to industry (20 bar H_2, model diesel feed). This 'ignition' is very different from the gradual sulfide phase formation, which is usually

observed under model laboratory conditions (1 bar H_2/H_2S); it emphasizes that active phase genesis should be monitored under conditions as close as possible to commercial practice [3]. The rapid phase transition can be ascribed to *in situ* generation of H_2S by the decomposition of organosulfides in the feed at elevated temperatures, where Co would already be sulfided in a conventional H_2/H_2S sulfidation procedure..

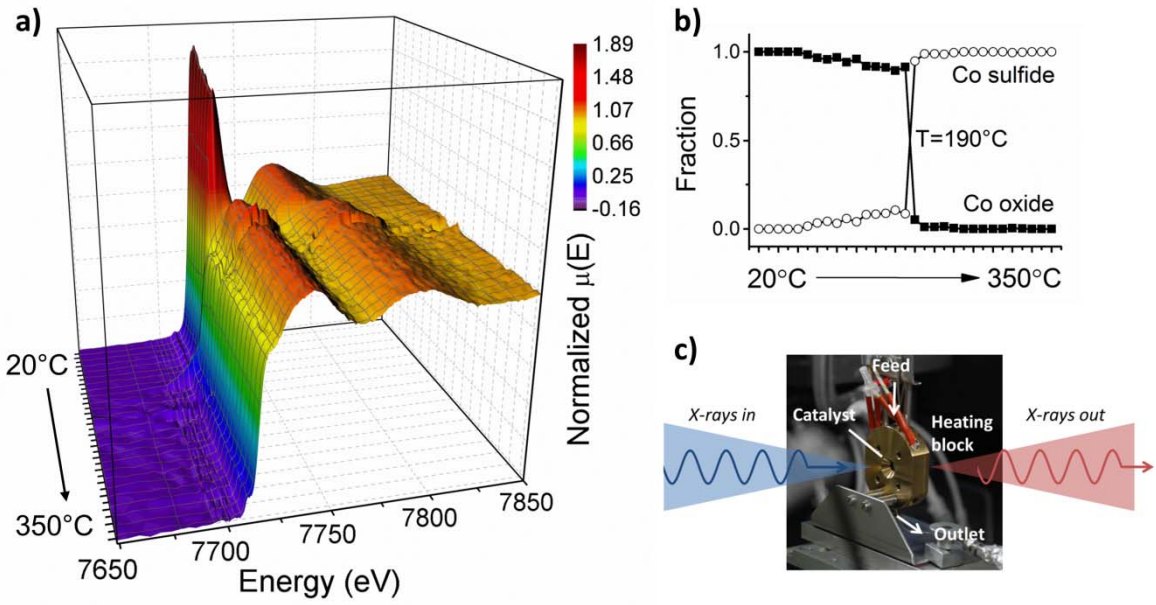

Fig. 1. a) *in situ* Co K XANES of a Co-Mo catalyst heated in a mixture of n-hexadecane/tert-nonylpolysulfide(5%) and H_2 gas (20 ml/min) at 20 bar. The time per spectrum was 5 minutes. b) composition of the catalyst as determined by linear combination fitting (LCF). c) picture of the experimental setup.

In dried and calcined catalyst precursors prepared without additives, a significant portion of the Mo remains oxidic (20-25%) and Co preferentially forms Co_9S_8, which is undesired because of its low HDS activity. Catalytic performance was strongly improved by incorporating additives in the impregnation step, which facilitated the formation of MoS_2. The use of weakly chelating additives led to the highest HDS activity in model compound reactions (DBT, thiophene), which can be ascribed to optimal Co-Mo interaction. These catalysts were found to form sulfides at temperatures as low as 50°C; this finding contradicts the general notion that delayed sulfidation of the promoter leads to catalysts with optimal Co-Mo interaction [3]. We propose that the reducibility of Mo in the precursor is the key parameter that determines the efficient incorporation of the promoter ions into the active 'Co-Mo-S' phase.

4 Conclusions

We have for the first time characterized the structure of the active phase for a suite of Co-Mo catalysts under real HDS conditions. Activation in a model diesel feed led to rapid active phase genesis , initiated by thermal decomposition of organosulfides in the feed. An optimum interaction of the promoter and the active phase was achieved for catalyst precursors prepared with weakly chelating ligands. It is proposed that the reducibility of Mo in the precursor is the key parameter that determines the efficient formation of the active 'Co-Mo-S' phase.

1 Introduction

Being a low carbon technology, hydrogen production from water electrolysis is especially appealing nowadays. The hydrogen generated can either be deployed for further synthesis of fuels or stored and later fed into fuel cells. For the design of suitable electrode materials for water splitting, it is crucial to understand the structural transformations of electrocatalyst surfaces upon the sluggish oxygen evolution reaction (OER). To monitor changes in the electronic structure of electrocatalysts while the OER proceeds, we have designed an electrochemical cell based on the proton exchange membrane (PEM) Nafion® that is compatible with a Near-Ambient-Pressure X-ray Photoelectron Spectroscopy (NAP-XPS) setup. The cell makes a step towards bridging the pressure gap between classical XPS measurements in UHV and electrochemical measurements in aqueous electrolytes.

2 Experimental

The electrochemical Nafion®- cell, as depicted in Fig. 1, can be integrated into the NAP-XPS setup of the ISISS beam line at BESSY II. The samples tested are sputter-coated Nafion® membranes. Nafion® serves as electrolyte and additionally as separation between liquid water and the reduced pressure measurement chamber. The OER electrocatalyst is the working electrode and faces the X-rays. The mud crack type structure of the sputtered electrodes is both water permeable and conductive. A continuous flow of water is provided through the channels on the counter electrode side. Due to the pressure difference, the water diffuses through the mud cracked electrodes as well as the Nafion® into the measurement chamber; a pressure of 10^{-2} mbar results. The water serves two purposes: First, it enables proton conductivity by hydrating Nafion®. Second, it supplies the electrodes with the molecules for the electrocatalytic reaction. The anode and the cathode are externally connected to a potentiostat that allows the application of potentials for electrochemical testing. Gas evolution is monitored by online mass spectrometry (MS). Overall, the Nafion®-cell is suitable to investigate low-temperature gas-phase water electrolysis *in situ*: while the OER proceeds, changes in the electronic structure of the working electrode catalyst can be identified via XPS measurements.

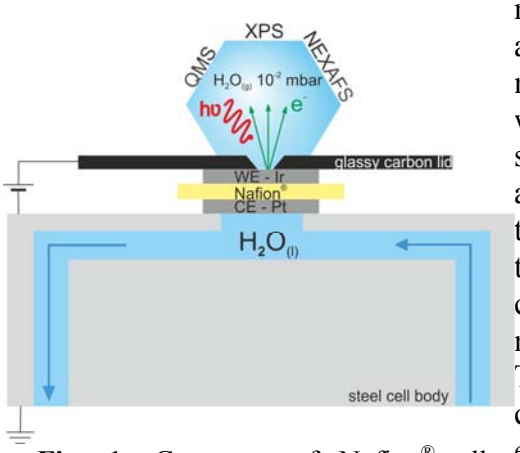

Fig. 1: Geometry of Nafion®-cell. Water penetrates the porous Pt and Ir films, diffuses through the membrane and generates a water pressure in the range of mbars in the XPS chamber.

3 Results

For Pt as model OER electrocatalysts, the Nafion®-cell enabled us to find that the active Pt surface is an electronically modified, metallic Pt surface with oxygen in the surface and surface-near region. The surface oxide layer formed is needed for water dissociation. Furthermore, we learned that a stable oxidic phase with stronger Pt-O bonds induces an overpotential and is detrimental for the OER activity.[1]

Currently, we are investigating the more active OER catalyst Ir. Figure 2a) shows the chronoamperograms at two applied potentials. The resulting gas evolution is evident in the O_2 trace of the MS. As expected, the OER rate increases when applying higher potentials. In the Ir 4f XP spectra in Fig. 2b), it is apparent that Ir is oxidized during the OER. According to the binding energy and the line shape of the formed oxidized species, it seems to be neither crystalline nor stoichiometric IrO_2 but rather hydrous Ir oxohydroxide that catalyzes the OER.

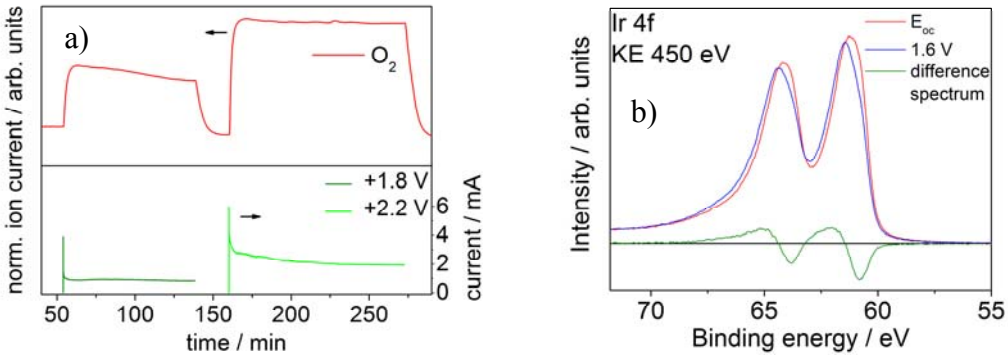

Fig. 2: a) CAs and MS O_2 trace that evidence the current flow in the Nafion®-cell and gas evolution upon voltage application. b) Ir 4f XP spectra recorded at OCP and at 1.6 V. The oxidation of Ir is clearly visible in the difference spectrum by the growing contribution at higher binding energy.

4 Conclusions and outlook

The potential of the Nafion®-cell for investigating gas-phase water electrolysis *in situ* has been demonstrated. It is a candidate for contributing to a better understanding of surface transformations of electrode materials occurring under reaction conditions. The next upgrade of the cell will be the integration of a reference electrode to work at well-defined potentials. Furthermore, another electrochemical cell based on a graphene membrane separating the liquid from the UHV is under development. This cell should finally allow us to also tackle liquid-phase water electrolysis and close the pressure gap.

Keywords: ZrO_2, CO_2, H_2O, co-adsorption, *in situ* XPS, *in situ* IRAS

1 Introduction

Being a carbon source, the utilization of carbon dioxide (CO_2) became attractive from both an environmental and economical perspective. However, CO_2 is a very stable molecule, thus to induce a reaction the activation of CO_2 by catalysts is required [1]. One way of activating CO_2 is dry reforming of methane (DRM), when CH_4 is reformed by CO_2 on Ni or Pt particles supported by zirconia (ZrO_2). During DRM, CO_2 is reduced to carbon monoxide (CO) via reaction precursors or intermediates, which can further oxidize the carbon formed via CH_4 dissociation. Such activation can occur on the ZrO_2 or on the interfacial sites [2]. As a support, technical ZrO_2 powder material can activate CO_2 by forming carbonate with basic anionic sites, or by forming formate with hydroxyl groups [2]. However, due to the possible different reaction pathways, microscopic mechanisms of the functions of ZrO_2 need to be further understood via a surface science approach. We therefore conducted a systematic study of the interaction between CO_2 and a pristine ZrO_2 ultra-thin film (CO_2 adsorption on ZrO_2), as well as the interaction between CO_2 and a hydroxylated ZrO_2 ultra-thin film (CO_2 and H_2O co-adsorption).

2 Experimental/methodology

In this study the pristine ultrathin ZrO_2 film was prepared following a route described before [3,4]. The structure and the chemical composition of the films were characterized by Low Energy Electron Diffraction (LEED) and high resolution X-ray Photoelectron Spectroscopy (XPS), respectively [4]. CO_2 Temperature Programmed Desorption (TPD) was used to investigate desorption of CO_2 upon dosing at 90 K and subsequent heating. In situ XPS was employed to study the change of the electronic structure of the ZrO_2 film and the oxidation state of the accumulated carbon related species upon CO_2 or CO_2+H_2O adsorption. Infrared Reflection Absorption Spectroscopy (IRAS) was used to examine the functional groups of the formed species. In addition, formic acid (HCOOH) and formaldehyde (HCHO) were dosed on ZrO_2 and measured by IRAS in order to obtain reference data of vibrational frequencies for the measured absorption bands.

3 Results and discussion

LEED and XPS indicated the formation of a well-structured ZrO_2 film, corresponding to the (111) facet of cubic ZrO_2. After dosing at 90 K, CO_2 only weakly bonded to the ZrO_2 film and desorbed at 117 K, as shown by CO_2 TPD. Also, in situ XPS and IRAS did not detect any electronic changes of the ZrO_2 film or accumulated carbon related species upon exposure to CO_2 (from 1×10^{-6} mbar to 3×10^{-2} mbar) at 343 K. However, when ZrO_2 was subjected to a reactive mixture of CO_2 and H_2O various carbon related species were formed on the surface, as shown in Fig. 1. Specifically, species at a binding energy of 284.4 eV (elementary carbon), 285.5 eV and 286.4 eV (CH_xO) and 288.3 eV (formate) were observed in presence of CO_2 and H_2O. Except the elementary carbon, the formed features disappeared upon heating to 523 K in the reaction

mixture, but reversibly reappeared after cooling in the same gas atmosphere to 343 K. IRAS measurements confirmed the formation of CH_xO and formate species on ZrO_2 when it was exposed to CO_2 and H_2O at the same conditions. Characteristic adsorption bands for ν(C=O), ν(C-O) and CH_2 bending were observed at similar wavenumbers as obtained by measuring HCOOH and HCHO, respectively, on the ZrO_2 film as a reference. Therefore, we assume that CO_2 and H_2O codosing induces the formation of formaldehyde, dioxymethylene and formate on the surface of ZrO_2.

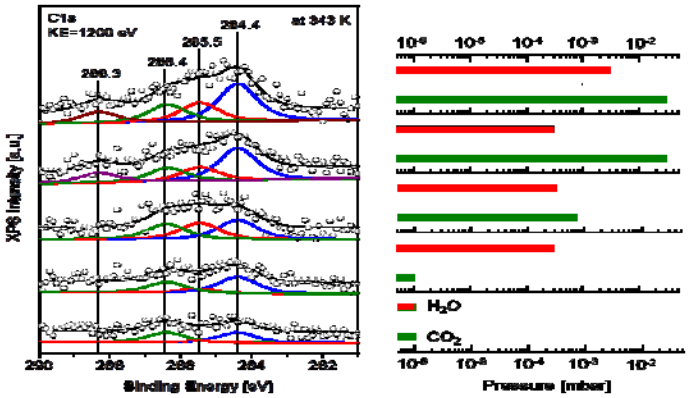

Fig. 1. C 1s spectra of the ZrO_2 ultrathin film in the presence of CO_2 and H_2O mixture (spectra taken at 343 K, KE=1200 eV)

4 Conclusions

CO_2 adsorbs only weakly on ZrO_2 ultrathin film and desorbs at low temperature. H_2O can activate CO_2 via hydrogenation and leads to the formation of formaldehyde, dioxymethylene and formate on the ZrO_2 surface.

Operando Raman and UV-Visible Spectroscopy of $H_3PW_{12}O_{40}$ in the Gas Phase Dehydration of Methanol to Dimethylether

Schnee J.*, Gaigneaux E.M.

Université catholique de Louvain, Institute of Condensed Matter and Nanosciences (IMCN/MOST), Louvain la Neuve, Belgium

Keywords: heteropolyacids, dimethylether, operando, spectroscopy, coke, methanol, dehydration

1 Introduction

Heteropolyacids (HPAs) are molecular clusters possessing a very high Brönsted acidity. They are widely used as acid catalysts. For gas phase reactions, the main issue in HPA-based catalysis is their deactivation due to the formation of carbonaceous deposits called "coke" [1]. We currently investigate the catalytic activity of $H_3PW_{12}O_{40}$ (HPW12), the most acidic Keggin-type HPA, in the gas phase dehydration of methanol to dimethylether (DME). DME is nowadays seen as one of the most important and promising renewable fuels for the future [2]. Herein, we demonstrate via *operando* Raman and UV-Visible characterization that changes in the selectivity to DME over HPW12 as catalyst are related to the amount of coke produced and to the latter's degree of disorganization.

2 Experimental/methodology

The catalytic performance of HPW12 (800 mg, 100-200 µm) in the dehydration of methanol was investigated *operando* in a quartz reactor provided with optical windows. The latter allowed characterizing the catalyst *at work* throughout the reaction by Raman and UV-Visible spectroscopies. Spectra of both techniques were recorded simultaneously every 2 minutes. For Raman spectroscopy, an Nd-YAG laser with 532 nm wavelength was used. For UV-Visible spectroscopy, a deuterium-halogen light source and a temperature-resistant reflection probe were used. The catalytic tests were performed following a temperature program from room temperature to 350°C (7 steps of 2 hours at 100, 150, 200, 250, 300 and 350°C, ramps of 1°C/min in-between). The inlet gas flow was composed of 27 mL/min of nitrogen saturated with 10 vol% of methanol. The outlet gas flow was analyzed by fast GC (5.5 min/run). The catalytic activity is herein reported in terms of conversion of methanol and selectivity to dimethylether.

3 Results and discussion

As shown on Fig.1, in the here applied test conditions, the conversion of methanol on HPW12 was of 3%, 65% and 90% at respectively 100°C, 150°C and 200°C. Then it remained constant up to 350°C (with small variations). The selectivity to DME was around 90% up to 200°C. From 200°C on, it dropped (85%, 70% and 40% at respectively 250°C, 300°C and 350°C), with methane, ethylene and propylene detected as byproducts. The peak of selectivity observed after having cooled the reactor back to room temperature is considered as an artefact.

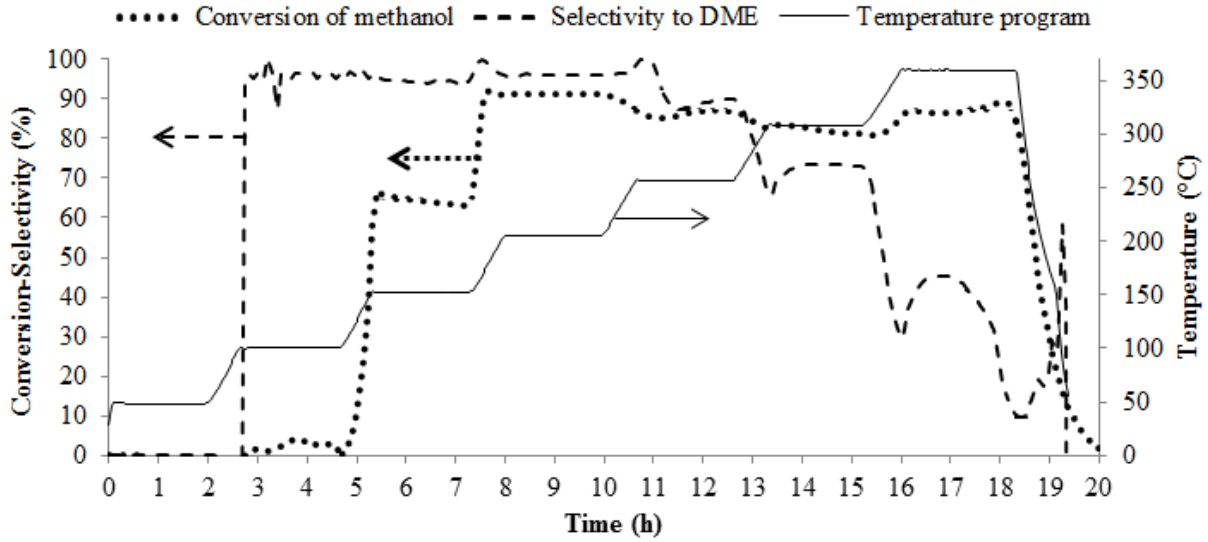

Fig. 1. Conversion of methanol and selectivity to DME during the temperature programmed reaction with HPW12 as catalyst.

Operando UV-Visible spectra reveal an increase of absorption in the visible region as soon as the reaction was started, reflecting the rapid formation of dark-colored coke. Up to 200°C, the UV absorption edge of HPW12 remained visible (O^{2-} to W^{6+} charge transfer absorption bands at 250 nm and 350 nm). At 250-300-350°C however, when the selectivity to DME was dropping, the coke's absorption in the visible region reached its maximum and completely masked HPW12's UV absorption edge. On *operando* Raman spectra, the bands of polyaromatic coke became visible at 100°C: a D1 band at 1300-1450 cm^{-1} reflecting disorganized non-graphitic coke and a D2 band at 1600-1650 cm^{-1} reflecting less disorganized coke [3]. Up to 250°C, the D2 band was more intense than the D1 one. At 300°C, the relative intensity of the D1 one started to increase with time on stream. At 350°C, both bands had nearly equal intensities. The increase of relative intensity of the D1 band, reflecting an increase of the structural disorganization of coke, here occurs together with the production of methane which is the byproduct of reactions that increase the aromaticity of coke.

4 Conclusions

The *operando* Raman and UV-Visible spectra reflect the changes in the selectivity to DME obtained with HPW12. More precisely, a drop of selectivity to DME is associated to an increased production of coke (revealed via UV-Vis) possessing an increasing degree of disorganization (revealed via Raman) and an increasing aromaticity (indicated by the production of methane).

Keywords: UV-Raman, Methanol-to-Olefines, coke, aromatic-hydrocarbons, ceolites

1 Introduction

Allowing the production of valuable chemicals from a source different from oil, the Methanol to Olefines (MTO) reaction is an industrial process which relevance is continuously increasing in the last years. One of the main limitations affecting MTO is the relatively fast catalysts deactivation, due to coking [1]. Moving to a deeper insight, coke is composed by molecules belonging to the arenes and particularly to methylated benzenes (MBs) and polycyclic aromatic hydrocarbons (PAHs). Raman spectroscopy finds large application in the study of carbonaceous materials [2, 3], of which aromatic hydrocarbons are a particular subset. Each MB/PAH shows a peculiar vibrational spectrum, allowing to determine the nature of the coke species [4]. The main drawback related to the application of Raman is the fluorescence of the sample: MBs and PAHs are highly emissive in the visible region and their fluorescence can overlap the Raman signal. Generally such interference can be avoided by using an excitation wavelength falling outside of the visible [4, 5]. As most of the interesting molecules show their electronic transitions in the 200-400 nm spectral region [6, 7], a further advantage can be achieved by exciting by means of a UV radiation, that is the exploitation of the resonant Raman effect. This allows to increase of orders of magnitude the sensitivity toward the resonant species, i.e. significantly reducing their limit of detection and allowing their analysis even when diluted. Being in a real catalytic system the coke species dispersed on a porous material with high surface area, the possibility to exploit the resonance makes feasible their characterization, even *in situ*. A picture of the deactivation products has been obtained combining the experimental data with molecular simulation: the Raman spectra of MBs and PAHs have been computed and compared with experimental data. Advanced computational tools have been adopted in order to properly simulate the Raman intensities when the resonance conditions are achieved [8].

2 Experimental/methodology

To get a better knowledge in the deactivation of MTO catalysts, the characterization performed by UV Raman spectroscopy has been coupled to the simulation of the Raman spectra of the investigated species. The study can be articulated in three key steps:

1. Some selected aromatic molecules have been studied by Raman in different matter states (pure solids/liquids, in diluted solution and adsorbed from gas phase on high surface area materials) in order to build a reference database for the following step.
2. Different zeolites have been deactivated under different reaction conditions (varying e.g. the temperature, the feed,…) and their Raman spectra have been compared with ones of the reference molecules. This allowed to unambiguously recognize the main deactivation products and the effect of the zeolite topology on their formation. Wanting to avoid spurious contribution to the spectra, all the materials have been carefully activated in controlled conditions and then characterized *in situ* in order to remove the already adsorbed contaminants and avoid their re-adsorption.
3. The vibrational spectra of MBs and PAHs have been simulated by ab initio calculation: different computational approaches have been tested in order to get the better agreement

with the experimental data. Furthermore the simulation of the Resonant Raman intensities has been performed, allowing an easier understanding of the experimental data.

3 Results and discussion

An example of application is given in Figure 1: a H-ZSM-5 catalyst (Si/Al=45) has been deactivated in 100 mbar of MeOH at 350°C.

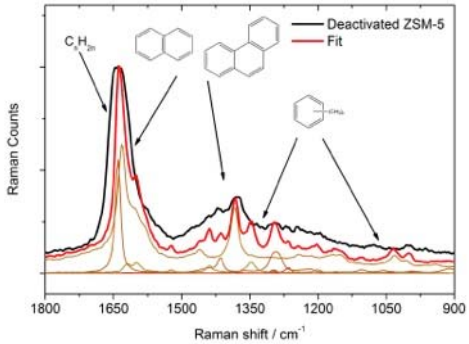

Figure 1. UV Raman spectrum of a H-ZSM-5 deactivated in 100 mbar of MeOH at 350°C (black line) and a tentative fitting based on the experimental Raman spectra of MBs and PAHs (red line).

The very complex spectrum due to deactivation products can be rationalized by comparing it with the spectra of the reference MBs and PAHs [9]. Furthermore a tentative fitting of the signal can be tried with a linear combination of their spectra: the main contributions to the Raman spectrum of deactivated zeolites can be attributed to the formation of naphthalene, phenantrene and highly methylated benzenes (mainly tetra- and hexa-MB). The further combination with computational results should help to better discriminate the observed moieties, i.e. allowing to recognize species which are difficult to obtain in a sufficiently pure form (e.g. methylated PAHs) or which can not be easily obtained outside of the reaction conditions (e.g. carbocations).

4 Conclusions

The combination of *in situ* UV Raman spectroscopy and their parallel simulation can represent an interesting tool in the characterization of the deactivation species in the MTO reaction. Starting from the fundamental insights presented in this study it is possible to extend the basic knowledge on the deactivation pathways according to the different catalysts topologies, eventually applying the same methodology to more complex experimental conditions (e.g. *operando*).

Where are the Active Sites in Zeolite Nano-Crystals? Influence on Post-Synthesis Treatment from Hard X-Ray Depth Profiling with XPS

Proff C., Fodor D., Orlando F., Van Bokhoven J.A.*

Institute for Chemical and Bioengineering, ETH Zurich and Paul Scherrer Institute, Villigen, Switzerland

* j.a.vanbokhoven@chem.ethz.ch

Keywords: hollow zeolites, quantitative aluminium distribution, base leaching, nano-reactors

1 Introduction

Framework aluminum determines the catalytic properties of zeolite crystals. Also, very often post-synthesis modification is applied to enhance the zeolite performance and the local concentration of aluminum strongly affects the outcome of such treatment. Thus, to achieve understanding of the relation between structure and performance, the aluminum distribution within a single crystal must be determined. Although aluminum enrichment at the surface is a well-known phenomenon, there is no quantitative insight into industrially relevant crystals in the size range of tens of nanometers. Non-destructive depth profiling using hard X-ray photoelectron spectroscopy (XPS) can be done at the synchrotron, based on the different penetration depth of electrons of varying kinetic energy. We quantified the aluminum distribution in ZSM-5 crystals of 50 to 100 nm in size. Slight differences in synthesis procedure lead to significant differences in the aluminum distribution within a single crystal. Moreover, the data unambiguously point to a significant redistribution of aluminum and silicon atoms within a crystal during base leaching. Thus, besides mesopore formation, base leaching additionally modifies the structure of the remaining zeolite. These data are of fundamental importance for the interpretation of the difference in catalytic performance between various zeolite batches and of the changes in performance after post-synthesis modification.

2 Experimental/methodology

ZSM-5 nano-crystals with a Si/Al ratio of 50 were synthesized as described in detail elsewhere [1]. XPS depth profiling measurements were performed at the near ambient pressure photoemission (NAPP) endstation at the PHOENIX beamline of the Swiss Light Source (SLS). Si 1s and Al 1s core level spectra were measured at photon energies between 2175 and 6860 eV, corresponding to photoelectron kinetic energies between 600 and 5000 eV. Cross-section dependency was corrected using the data from Trzhaskovskaya et al. [2]. The Al 1s and Si 1s spectra were best fitted with Gaussians and a linear background. The measurements were performed with the photon beam impinging at 60° off the surface normal, while photoelectrons were collected at 30° emission angle. The inelastic mean free path corresponding to each kinetic energy was calculated assuming a 9 eV band gap and ZSM-5 structure [3] and the composition. Concentration profiles were extrapolated from the Si/Al ratio vs. kinetic energy profiles using the maximum entropy regularization procedures presented by Weiland et al. [4].

3 Results and discussion

Figure 1 shows the aluminum distribution obtained using the XPS depth profiling of two differently synthesized batches of ZSM-5, both with tetrapropyl amine (TPA) as structure-directing agent and a Si/Al ratio of 50. ZSM-5A, of which the TPA was made in our lab, has a high surface concentration of aluminum, which rapidly decreases to zero within about 10 nm.

ZSM-5B, synthesized using commercially available TPA, has a similar decline in aluminum concentration, however, there is a remaining aluminum content in the bulk of the crystal.

Upon base leaching the material with no aluminum in its core yields hollow zeolite crystals, the other one the more typical cheese-like mesoporous structure. Also, the aluminum showed a different depth profile (not shown in the figure) in the outermost layer after this treatment, pointing to dissolution and re-insertion of silicon and aluminum in the framework during the base treatment.

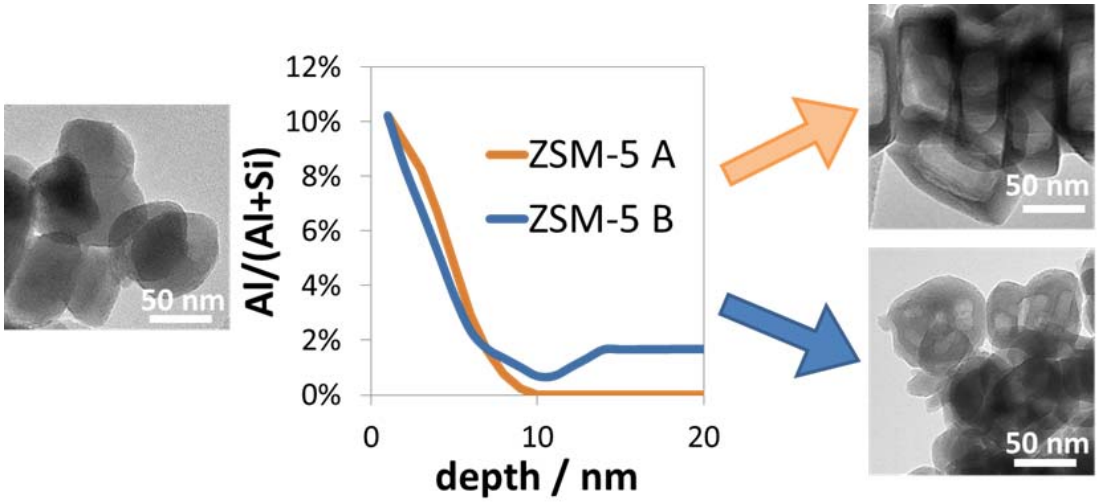

Fig. 1. Quantitative aluminum distribution in ZSM-5 crystals with Si/Al ratio of 50. Base leaching of these crystals yield very different material: the one with no aluminum in its core yields hollow zeolite crystals.

4 Conclusions

The Si/Al ratio vs depth inside ZSM-5 nanocrystals before and after NaOH leaching was quantified with synchrotron-based (XPS) depth profiling. This revealed a distinct variation of the Si/Al ratio with depth between two different materials with very similar composition, but slightly differing synthesis conditions. Leaching created hollow nano-crystals in case of one material and cheese-like nano-crystals with many pores in case of the other. An aluminum-rich surface zone is followed by an aluminum devoid zone in case of the parent material forming after leaching hollow crystals, while the other parent material exhibits after the aluminum-rich zone a low non-zero aluminum level in the bulk. The structure of the nano-crystals is well preserved after leaching as well as the crystal size. This can be attributed to the high aluminum concentration in the outer shell, protecting the outer shell of the nano-crystals from dissolution. However, even within this shell, dissolution and recrystallization occurs during base leaching changing the aluminum depth profile.

Keywords: zeolites, nanoparticles, gold, encapsulation, eTEM

1 Introduction

Supported gold nanoparticles, since the first report on their high catalytic activity in low-temperature CO reduction, have been used extensively in organic chemistry reactions [1]. However, supported nanoparticles are prone to sintering which is causing a thermal deactivation of the catalyst [2]. The stability might be improved by encapsulation of individual nanoparticles inside the porous inorganic material. Such materials were proven to be size-selective and stable under extreme temperature conditions [3].

The preparation of gold nanoparticle encapsulated zeolite silicalite-1 is reported. The zeolites are modified by a recrystallization process (desilication), which creates voids and mesopores inside the crystal structure of individual particles. This additional porosity facilitates the formation of gold nanoparticles inside the zeolite channels upon wet impregnation. Environmental Transmission Electron Microscopy (eTEM) is applied for the characterization of the material with the emphasis on the process of *in-situ* nanoparticle formation inside the zeolite channels, sintering stability at elevated temperatures, and the reactivity of the material in the simple oxidation reaction. Furthermore, the influence of degree of desilication and temperature of desilication on the recrystallized material is investigated. Variation in choice of gold precursor and water content for impregnation of the recrystallized silicalite-1 are examined in terms of size of nanoparticles and their distribution inside the zeolite framework.

2 Experimental

All the reported materials were synthesized form commercially available chemicals. Zeolite silicalite-1 was prepared using traditional synthesis method. Preparation of gold recrystallized silicalite-1 was based on impregnation of recrystallized silicalite-1 prepared by an alkaline dissolution-reassembly process in the presence of the surfactant [4]. Obtained materials were investigated using HRTEM in terms of *ex-situ* nanoparticle formation and eTEM for the *in-situ* formation under the atmosphere of hydrogen at elevated temperature. Other analytical techniques like BET, ICP-MS, and XRD were applied for the standard characterization.

3 Results and discussion

eTEM imaging of the gold recrystallized silicalite-1 was performed under elevated temperature and hydrogen atmosphere in order to investigate the *in-situ* formation of gold nanoparticles. Figure 1 depicts recrystallized zeolite crystals with encapsulated gold nanoparticles. Immediate *in-situ* formation of Au-NP was observed under the irradiation with electron beam in vacuum (right side Figure 1). In this case, nanoparticles were located at the surface of the inner voids in the crystals. Gradual reduction of metal nanoparticles was performed using blanked-beam, where specimen was exposed to the electron beam only for the time to sample an image (left side Figure 1). In this case, distribution of nanoparticles is more uniform between the voids surface and channels of the zeolite.

Stability against sintering was monitored *in-situ* in oxygen atmosphere at elevated temperatures in eTEM and showed promising results. Catalytic activity was confirmed based on simple oxidation reaction.

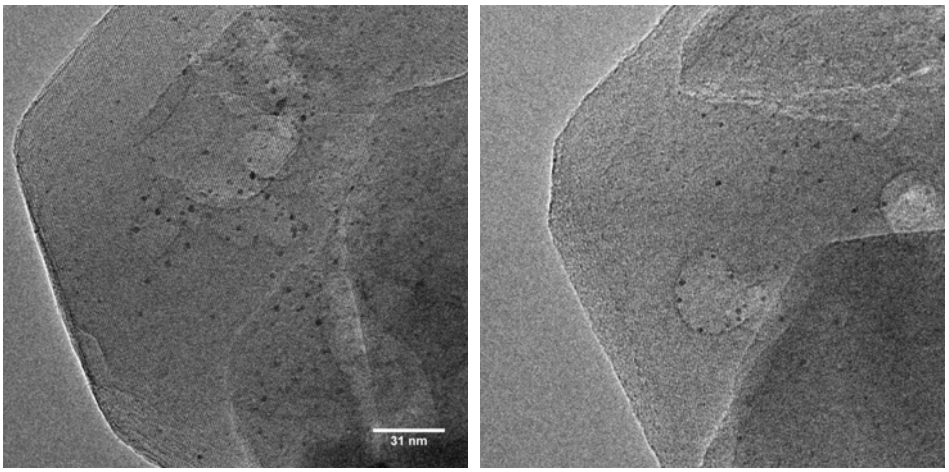

Fig. 1. eTEM image of recrystallized silicate-1 with encapsulated Au nanoparticles. Left: beam-blanked specimen; right: constant-illumination specimen. Cavities inside the zeolite crystal are visible as large voids localized in the centre of the crystal. Nanoparticles are visible in the matrix of zeolite – in the channels and at the edges of cavities. Gold nanoparticles are 3nm in size. The channels structure of silicate-1 is visible.

4 Conclusions

Environmental Electron Transmission Microscopy was used as a main tool for *in-situ* investigation of nanoparticle formation in the recrystallized zeolite silicalite-1. Various parameters influencing the characteristics of material were examined using above technique. Stability for sintering and catalytic activity were proven and observed.

1 Introduction

Shape and size of nanoparticles considerably affect catalytic activity. [1] Their synthesis in a controlled manner resulting in well-defined shape and size as well as their characterization at the single particle level will help gaining deeper insight into chemical mechanisms and elucidating size and shape effects. The mechanism of oxidation of iron has extensively been investigated in the past and studies have concluded that the behavior of bulk iron is different from nanoparticles but knowledge about the behavior in nanoscale is limited. [2] To determine size-dependent redox behaviour in iron, we have fabricated model systems with well-defined particle sizes using top-down nanolithography. Single particle spectro-microscopy was performed on all different sizes and effect of particle size in oxidation and reduction of iron nanoparticles has been determined.

2 Experimental/methodology

In this work, well-defined model systems consisting of ordered single iron nanodots of different sizes from 6 nm to 80 nm were realized in a 5 × 5 cm^2 field-of-view using top-down nanofabrication. This involves accurate proximity effect correction during exposure of PMMA resist using electron beam lithography (EBL), followed by optimization of resist development, thermal evaporation of iron and lift-off. X-ray photoemission electron microscopy (PEEM) enables measuring the structure of individual iron particles (schematic shown in Fig. 1a). Simultaneous microscopy and in-situ x-ray absorption spectroscopy (XAS) was performed on all different sizes under the same conditions with high elemental sensitivity through annealing and leading to the observation of a clear size effect of the controlled oxidation of the iron nanoparticle.

3 Results and discussion

The SEM image of the fabricated model system consisting of iron oxide nanoparticles of different sizes in a 5 × 5 cm^2 field-of-view is shown in Fig. 1b. Elemental contrast image at Fe L_3 edge observed during PEEM measurement is shown in Fig. 1c. XAS spectra from single particle were extracted at different stages of oxygen dosage and all different sizes were studied simultaneously under identical condition. Having the same spectra for all sizes at the initial state of metallic iron, clear size dependence was seen already in the XAS spectra after five minutes of controlled oxygen dosing at 10^{-8} mbar. The smaller nanodots oxidized much faster than the larger ones. The percentage concentration of iron(0) and evolution of different oxides over duration of oxygen dosage could be simulated for all sizes using reference spectra of each of the possible species (FeO, Fe_2O_3, and Fe_3O_4), as shown for 80 nm dot in Fig. 2a. Comparison of oxidation rates and composition for different sizes clearly indicate a size-effect. Fig. 2b shows

the plot comparing the initial rate of oxidation per unit area for all different sizes. The rate of oxidation per surface area increases exponentially for nanoparticles below 20 nm. Based on the kinetics and thermodynamic stability of different oxides, activity of different sizes is compared and a reaction mechanism for the inter-conversion of oxides in iron nanoparticles was proposed.

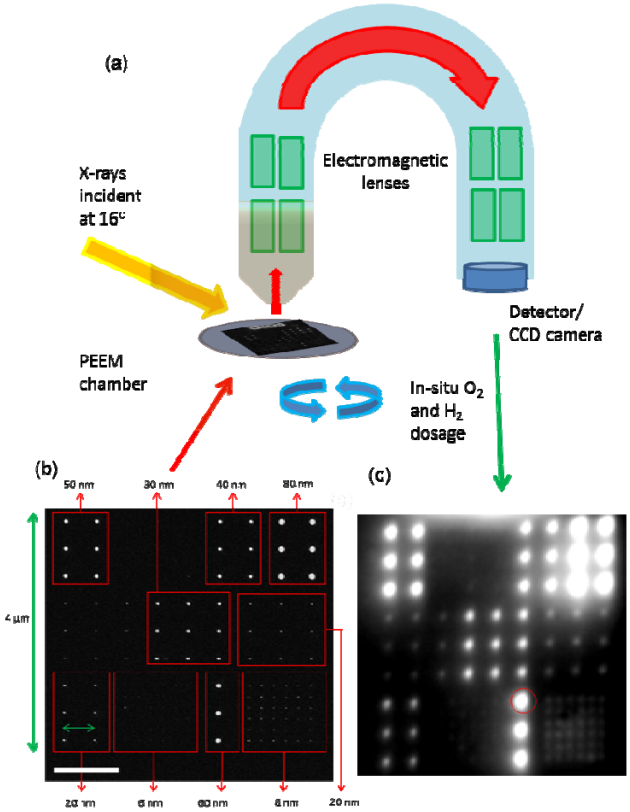

Fig. 1 (a) Schematic of PEEM setup for single particle spectroscopy. (b) SEM image of the model system consisting of particles from 6 nm to 80 nm prepared using top-down nanofabrication. (c) Elemental contrast image of the model system measured in the PEEM at the Fe L_3 edge. Nanoparticles of all different sizes were probed simultaneously.

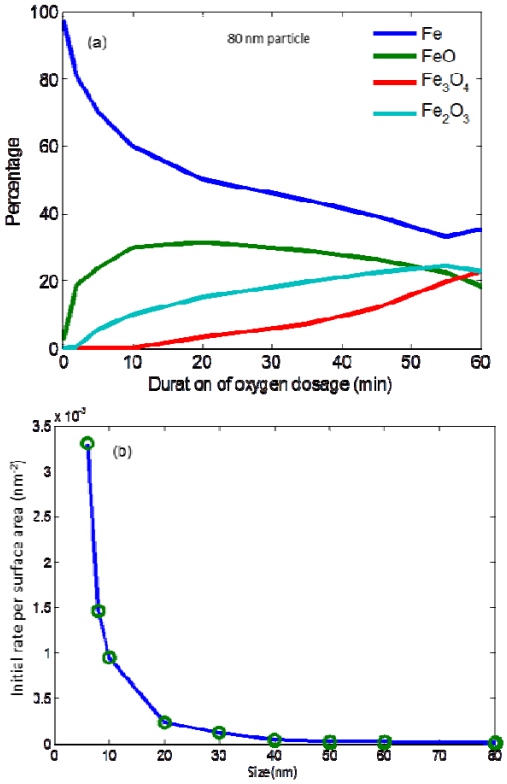

Fig. 2 (a) Change in concentration of Fe, FeO, Fe_2O and Fe_3O_4 during oxygen dosage for 1 hour observed for 80 nm sized particles. Similar analysis was performed for nanoparticle of different sizes. (b) Initial rate of oxidation per surface area compared for all sizes. The rate increases exponentially for particle size below 20 nm.

4 Conclusions

In summary, we have achieved state-of-the-art top-down nanofabrication methods enabling well-defined to fabricate novel model systems. In conjunction with in-situ spectroscopy technique to study single particles using PEEM, we have determined size effect in redox reactions of iron nanoparticles.

Investigating Fundamental Properties of Syngas Conversion Catalysts - a Model Approach

Fredriksson H.O.A.*, Bu Y., Dad E., Sui H., Niemantsverdriet J.W.

Eindhoven University of Technology, Eindhoven, The Netherlands

* h.o.a.fredriksson@tue.nl

Keywords: syngas, model-catalyst, UV-vis, XPS, sintering, oxidation

1 Introduction

Although both methanol synthesis and Fischer-Tropsch synthesis are well-established, commercially used processes, our understanding of the catalysts, and in particular their de-activation mechanisms is incomplete. A reason for this is of course the complexity of the reaction, including many possible side reactions. Another reason is the complexity of commercially used catalysts, containing promoter and support materials as well as three-dimensional, random distributions of the catalyst materials in pores[1, 2]. On such catalysts, it is hard to determine the relative importance of reactant and product diffusion, contact and spill-over effects between catalyst and support/promoter or changes in particle distributions. Furthermore, in larger catalytic beds it is difficult to avoid local variations in gas composition and temperature. A catalyst can therefore exhibit different properties at different locations in the catalytic bed. Post reaction analysis of catalyst can thus yield different results depending on from where in the reactor the sample is collected, making it difficult to determine well-defined catalyst properties and to correlate these with overall reactivity. This problem is elegantly circumvented by the use of flat model catalysts in micro-reactors[3]. For such systems, the gas composition and temperature of the catalyst can be precisely controlled and measured. Therefore, fundamental properties of the catalysts, such as oxidation state, stability towards sintering and contact between the various catalyst components can be conveniently studied.

2 Experimental/methodology

We have prepared well defined, flat model catalysts, supported on quartz and TEM-windows by wet-chemical methods or physical vapor deposition. The catalysts consist either of Fe or Cu nanoparticles, with various amounts of promoters. Pre- and post-reaction XPS characterization of the model catalysts were performed using a Kratos, Axis Ultra and a Thermo Scientific, K-alpha spectrometer with monochromatic Al Kα sources and TEM characterization was performed using a FEI, Tecnai G2 Sphera microscope. In addition, we have used a modified Insplorion X1 instrument (Insplorion AB, Gothenburg, Sweden) to perform in-situ UV-vis spectroscopy, nanoplasmonic sensing and mass-spectroscopy. The latter equipment allowed us to follow sintering behavior and changes in oxidation state, while simultaneously measuring the catalyst activity.

3 Results and discussion

Using the complementary techniques, XPS, TEM, UV-vis and mass spectroscopy allowed us to correlate changes in fundamental catalyst properties to changes in activity. In particular, the newly developed combination of in-situ, UV-vis spectroscopy and mass spectroscopy on model catalysts facilitates characterization of changes in the catalyst properties in real time. We have successfully demonstrated the oxidation, reduction and carburization behaviour of Cu- and Mn-promoted Fe catalysts in different gas compositions. Cu acts as a reduction promoter while Mn retards reduction but stabilizes the catalyst towards sintering. In our investigations of Cu-catalysts, we have shown how the oxidation state of the catalyst influences its reactivity in CO-

oxidation experiments. Inclusion of small amounts of oxygen in the feed gas (~1 %) leads to oxidation of the metallic copper, which is accompanied by an immediate decrease in catalyst activity. Furthermore, we show how the catalyst sintering is influenced by the gas environment. In reducing gas, sintering sets in at significantly lower temperatures than in an oxidizing environment.

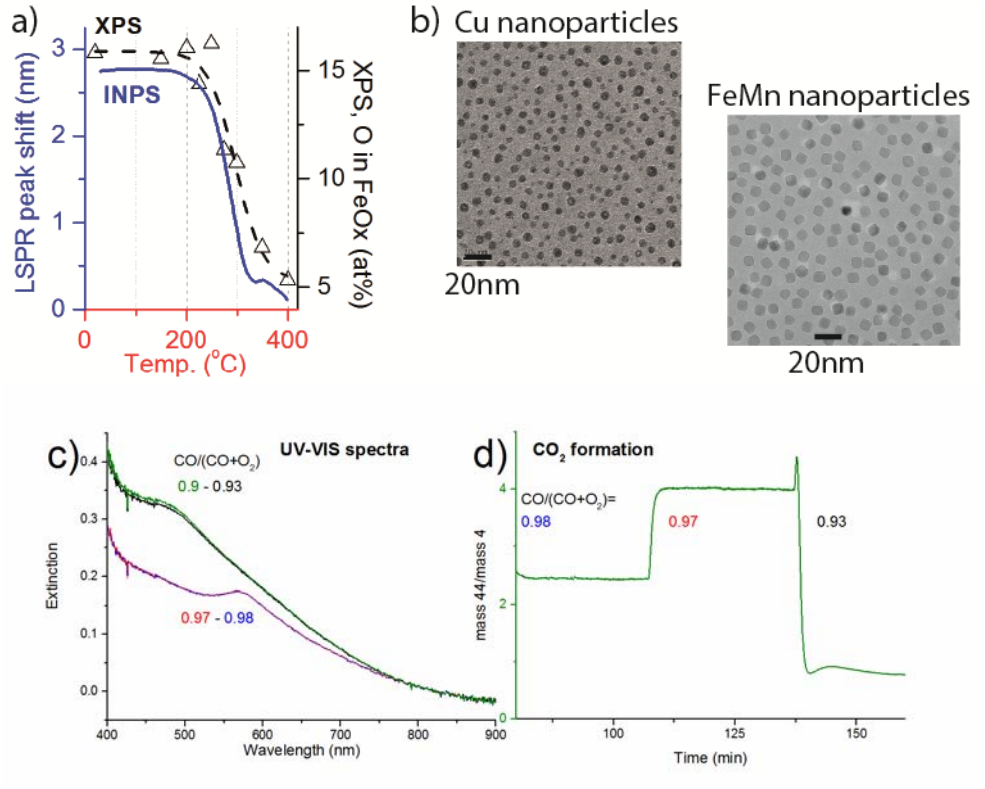

Fig. 1. a) Reduction of an Fe model-catalyst measured by in-situ nano-plasmonic sensing and XPS. The big drops in both signals indicate catalyst reduction. b) TEM images of Cu and Fe, flat model catalysts. c) Optical extinction measured from a Cu-model catalyst during CO-oxidation experiments with increasing oxygen content and d) the corresponding CO_2 formation during the experiment. The big drop in CO_2 formation when the oxygen content is increased to 7% correlates with a sharp shift in the optical spectra caused by catalyst oxidation.

4 Conclusions

Fabrication and characterization of model catalysts using XPS, TEM and in-situ UV-vis and mass spectroscopy has been demonstrated. The strength of the approach was demonstrated in several experiments including catalyst oxidation/reduction and sintering of catalysts used for syngas conversion.

CeO_2 Carrier Shape Effects on CuO_x/CeO_2 CO-PROX Catalysis: Operando X-Ray Spectroscopy and DFT Modelling Studies

Monte M.[1], Bolívar C.L.[1], Munuera G.[2], Martínez-Arias A.[1], Conesa J.C.[1*]

Keywords: ceria, nanocubes, ambient, pressure, XPS, XAFS, DFT modelling, hydrogen, technology, copper, oxide

1 Introduction

CuO_x/CeO_2 is a nonexpensive catalyst with good activity and selectivity in the CO-PROX reaction. Its active centres for the CO oxidation are assumed to be located at the CuO_x-CeO_2 interface borderline [1], so that modifying that interface is expected to provide ways to tailor the catalytic properties. In recent work [2] we have shown that with a nanocube-shaped ceria support, which exposes mainly the more reactive (001) surface, the selectivity is improved. Further XANES/XPS and XAFS results coupled to DFT modelling are reported here which confirm previous data indicating that on the mentioned (001) surface a stronger oxide-oxide interaction exists together with a stabilization of a less reduced state of copper. This explains the retardation of H_2 oxidation, as the latter requires a deeper reduction of the Cu oxide phase.

2 Experimental/methodology

Copper oxide was deposited via impregnation on ceria nanospheres (NS), nanorods (NR) or nanocubes (NC) of different specific surfaces as already reported; details of the preparation, multitechnique characterization (using XRD, Raman, HRTEM, S_{BET}, H_2-TPR and EPR) and CO-PROX performance (catalytic tests and *operando*-DRIFTS measurements) of the catalysts can be found elsewhere [2,3]. We have now carried out *operando* XPS/XANES experiments ($P \leq 100$ Pa) at the ISISS station of BESSY II synchrotron in Berlin, and Cu K edge XAFS measurements at CLAESS station in synchrotron ALBA near Barcelona. DFT+U calculations on models consisting of $(CuO)_{12}$ rodlike clusters lying of CeO_2 (111) and (001) slabs were made using periodic program VASP and PAW representation of the electronic cores.

3 Results and discussion

Surface-sensitive XANES at the Cu L_3 edge of the Cu-NC and Cu-NS catalysts measured under small CO pressure at increasing temperatures show (see e.g. Fig. 1a) that copper in the nanocube-supported sample resists reduction better than in the nanosphere-supported one. Also, Cu atoms at the interface can be distinguished by an XPS feature with unusually low energy values of the Cu(2p) peak and of Auger LMM features. Furthermore, preliminary analysis of recently acquired EXAFS data at Cu K edge on the calcined catalysts (Fig. 1b) indicates that a 0.16% Cu-NC sample, which has similar surface concentration of Cu than a 1% Cu-NS sample, has a much more distorted coordination environment, i.e. the CuO particles are significantly altered by the interaction with the CeO_2 (001) surface. This agrees with the previous observation by XRD that CuO nanocrystals do not form easily on ceria nanocubes [2]. XANES data also confirm that the 0.16% Cu-NS sample is more resistant to reduction under CO-PROX reaction than the NC-supported sample having similar Cu surface concentration.

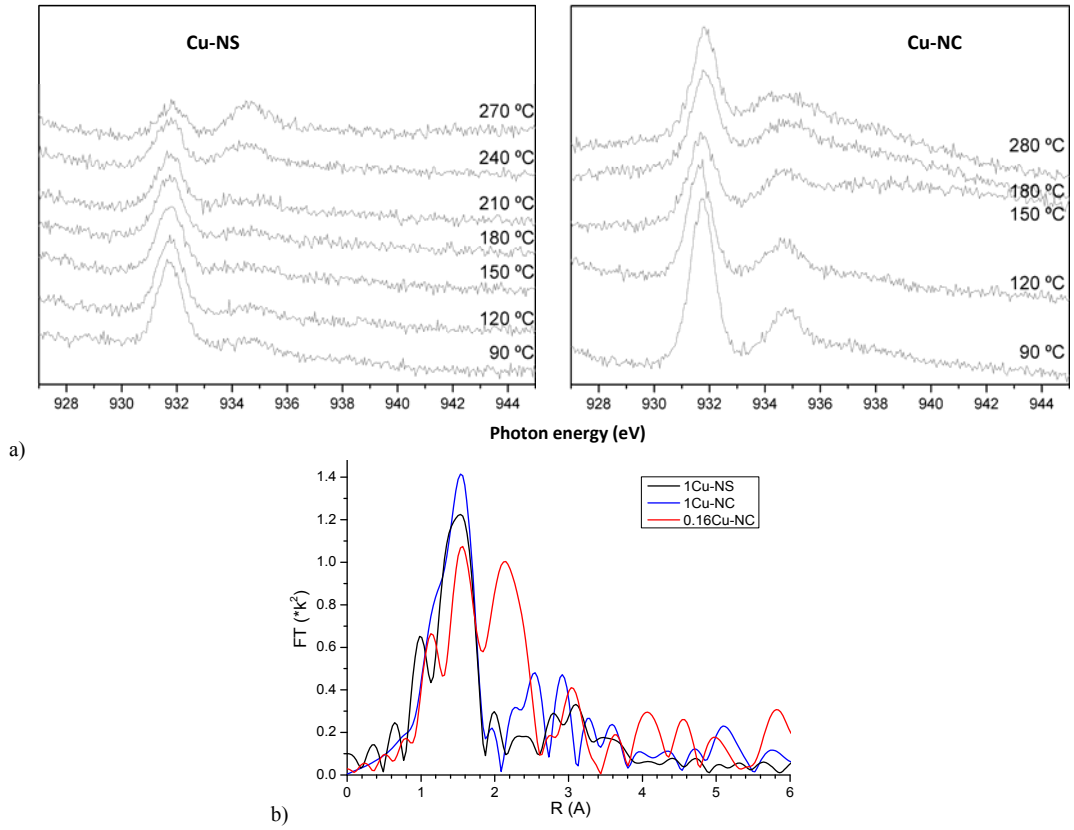

Fig. 1 a) Cu L_3 XANES spectra (recorded through the Cu LMM Auger electrons) of samples Cu-NC and Cu-NS under 0.5 mbar CO at increasing temperatures. b) k^2-weighted Fourier transforms of Cu K edge EXAFS oscillations recorded for calcined catalysts

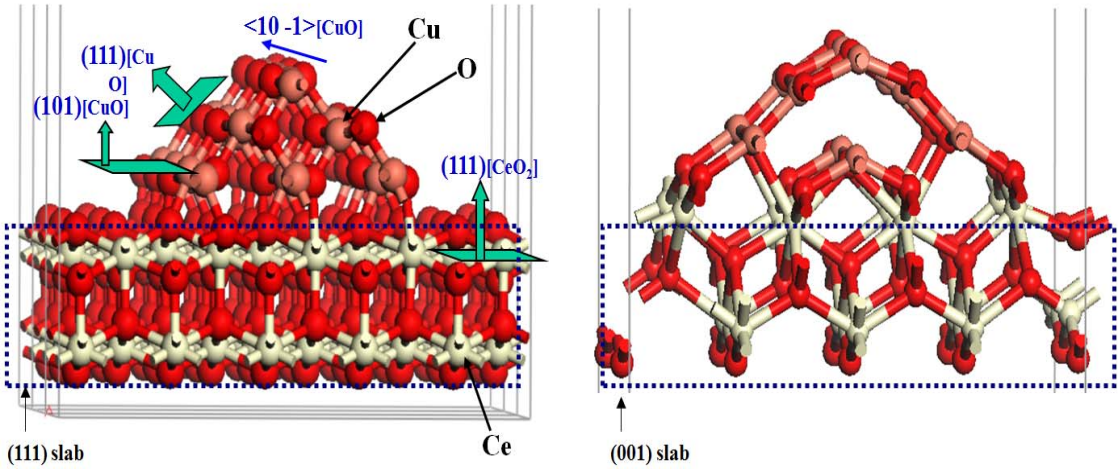

Fig. 2 Models of CuO clusters on CeO_2 surfaces. Left: (111), right: (001)

Both observations are justified by DFT+U calculations. CuO particles (represented by a CuO nanorod) become much more distorted on CeO_2 (001) (Fig. 2), due to a stronger interaction with the more reactive (001) surface (which contains less coordinated Ce ions). Adhesion energy difference between both systems in this case amounts to 0.67 eV/interface Cu atom. Furthermore, creating oxygen vacancies in both CuO and Cu_2O clusters is found to require more energy in the $CuO_x/CeO_2(001)$ case.

4 Conclusions

Synchrotron-based X-ray spectroscopies and DFT modelling confirm that CuO interacts more strongly with the (001) surface of ceria, leading to important particle distortion and to a more favoured transfer of electrons from CuO_x to CeO_2 upon reduction, which keeps copper in a more oxidized state. This explains the differences in CO-PROX selectivity between Cu-NC and Cu-NS catalysts.

A Density Functional Theory Study on the Mechanism of the Cycloaddition of CO_2 and Epoxides

Offermans W.K.[1*], Gürtler C.[1], North M.[2], Leitner W.[3], Müller T. E.[1]

1 - CAT Catalytic Center, ITMC, RWTH Aachen University, Aachen, Germany

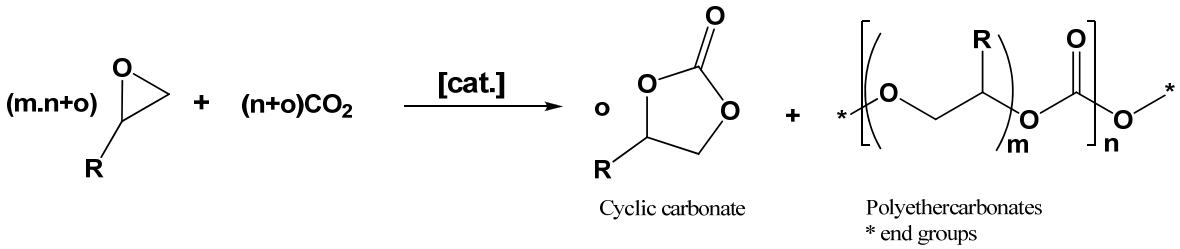
* Willy.Offermans@CatalyticCenter.RWTH-Aachen.de

Keywords: carbon dioxide utilisation, carbonates, epoxides, modelling reaction mechanism, homogeneous catalysis, DFT

1 Introduction

Depending on applied conditions and the choice of catalyst, the cycloaddition of carbon dioxide and epoxides leads to cyclic carbonates or polyethercarbonates (Scheme 1). Both possible products represent valuable, industrial compounds [1]. For example, cyclic carbonates can be used as aprotic solvents, precursors for polymers and pharmaceutical intermediates. Most current catalysts for the cycloaddition, which are used in industrial processes, require the use of high reaction temperatures and/or high pressures of carbon dioxide.



Scheme 1: Catalyzed (poly)cycloaddition of CO_2 and epoxides to polyethercarbonates and/or cyclic carbonates

Systems based on tetrabutylammonium bromide and μ-oxo bridged bimetallic aluminum complexes, such as [{Al(acen)}$_2$•(μ-O)] or [{Al(salen)}$_2$•(μ-O)], have been identified as catalysts for the cycloaddition of CO_2 and epoxides to cyclic carbonates at atmospheric pressure and close to room temperature [2]. It has been anticipated that these μ-oxo bridged bimetallic aluminum complexes act as Lewis acid [2]. A likely mechanism is proposed as follows: The epoxide coordinates to one of the aluminum centers and is ring-opened by bromide to a halogenated alkoxide. CO_2 is presumably activated by tributylamine to a zwitter-ionic carbonate, that can add to the other free aluminum atom of the adduct of [{Al(acen)}$_2$•(μ-O)] and epoxide. The carbonate and alkoxide are envisaged to react at the scaffold of the bimetallic aluminum complex to the cyclic carbonate. Inspired by this, we started density functional theory calculations to model the proposed mechanism *in silico*.

2 Experimental/methodology

Electronic structure calculations within the framework of density functional theory (DFT) were performed by using the DMol^3 program [2,3]. The Perdew-Burke-Ernzerhof functional to account for the exchange-correlation of the electrons was applied [4]. A correction for dispersion interactions, as proposed by Grimme and implemented by McNellis et al., was applied [5,6]. A double numerical basis set plus a polarization d-function on all non-hydrogen atoms and a polarization p-function on all hydrogen atoms was used to expand the one-electron Kohn-Sham eigenfunctions. Full electron, spin restricted calculations were performed. No constraints were

applied during geometry optimization. All reactant and product states were shown to be minima by a normal mode frequency analysis. The synchronous-transit method was applied to localize possible transition states [2]. These states were further optimized by following eigenvectors to gain the best predicted configuration of the transition state. Transition states were analyzed by a normal mode frequency analysis and confirmed by only one imaginary frequency for the normal mode pointing into the direction of the reaction coordinate. It was confirmed by the calculation of the minimum energy path that the transition state connected the reactant and product state on the potential energy surface.

3 Results and discussion

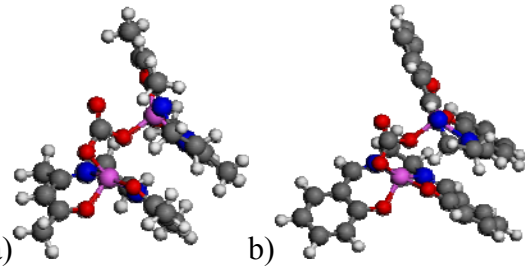


Fig. 1: Ball and stick models of predicted incorporation products of CO_2 and μ-oxo bridged bimetallic aluminum complexes: a) [{Al(acen)}$_2$(μ-CO_3)] and b) [{Al(salen)}$_2$(μ-CO_3)]. The colour coding of these carbonate complexes is intuitively: hydrogen, carbon, oxygen, nitrogen, and aluminum are white, grey, red, blue, and pink, respectively.

Already in an early stage, the modelling predicted incorporation products of CO_2 and [{Al(acen)}$_2$(μ-O)] or of CO_2 and [{Al(salen)}$_2$(μ-O)] (Figure 1), which were not considered in the reaction mechanism before. The isolation of [{Al(acen)}$_2$(μ-CO_3)] was not yet successful, but the existence of [{Al(salen)}$_2$(μ-CO_3)], its salen analogon, was proven experimentally by ESI-MS, NMR, and IR analytics. Moreover a chemical proof was found by showing that the latter carbonate complex can react with propylene oxide to produce propylene carbonate. Thus it is plausible that the carbonate complex plays a role in the catalysis.

4 Conclusions

Incorporation products of CO_2 and μ-oxo bridged bimetallic aluminum complexes were predicted by DFT modelling. Inspired by these findings, the existence of [{Al(salen)}$_2$(μ-CO_3)] was proven experimentally and this compound was shown to react with propylene oxide to propylene carbonate. Based on this we tentatively conclude that we have predicted and found interesting intermediates in the catalytic cycle of epoxides and CO_2. The focus of the modelling is now to elucidate their role in the cycloaddition of CO_2 and epoxides.

Effect of Structure and Composition of Gold and Gold-Palladium Clusters in H_2O_2 Formation

Pichugina D. A.*, Beletskaya A.V., Kuzmenko N.E.

Lomonosov Moscow State University, Department of Chemistry, Moscow, Russia

* daria@phys.chem.msu.ru

Keywords: DFT, gold, palladium, clusters, hydrogen, peroxide

1 Introduction

Hydrogen peroxide is one of the most important green oxidants. The synthesis of H_2O_2 involving a direct hydrogenation of oxygen has attracted interest as it is an environmentally friendly process. Palladium-based catalysts have high activity in direct synthesis of H_2O_2 but low selectivity due to H_2O formation as an unwanted biproduct. Using a bimetallic $AuPd/Al_2O_3$ and AuPd/C catalysts it is possible to increase the yield of H_2O_2 [1-3]. Precise information concerning the catalytic sites of Au, Pd, and AuPd particles governing H_2O_2 and H_2O formation has not been achieved yet. A quantum chemical simulation based on DFT was widely used for the study of the catalytic reaction mechanism and the nature of active sites of gold clusters [4,5]. Here we present the results of DFT simulation of H_2O_2 formation from H_2 and O_2 including the steps 1-10 (Fig. 1) on gold and gold-palladium clusters: Au_n, $Au_{n-1}Pd$ (n=8, 20, 32), Au_4Pd_4, $AuPd_7$.

2 Methodology

Structures optimization and energy calculation were performed using spin-polarized Perdew−Burke−Ernzerhof (PBE) functional of density functional theory (DFT). The Priroda code was used for an all-electron calculation in scalar−relativistic approximation, which is based on the full four component one-electron Dirac equation with spin−orbit effects separated out. The energy-optimized extended Gaussian basis set of triple-polarized quality of the large component, and the corresponding kinetically balanced basis for the small component was used: Au [30s29p20d14f/8s756d2f], Pd [26s23p16d5f/7s6p4d1f], O [10s7p3d/3s2p1d], and H [6s2p/2s1p]. We have considered the influence of cluster's structure and composition on the energy differences (ΔE) and activation energy (E_a) of the steps of H_2O_2 formation (Fig. 1). The exact structure of TS has been determined according to the procedure of eigenvector following with the Berny algorithm.

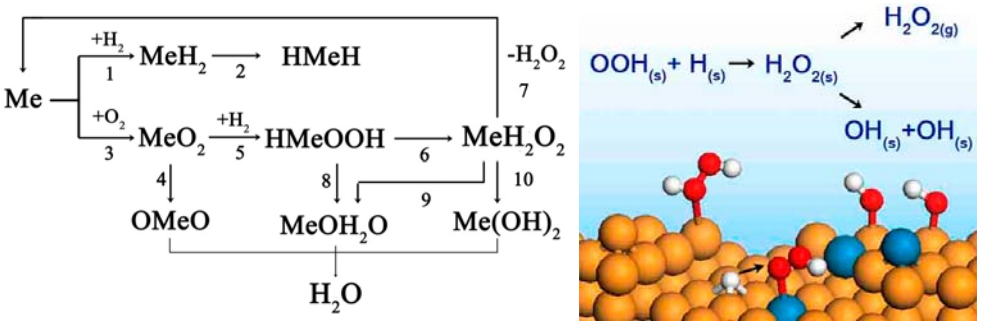

Fig. 1. The steps of the H_2O_2 formation from H_2 and O_2.

3 Results and discussion

An ambiguous mechanism is hidden behind the seemingly simplistic chemical equation ($H_2 + O_2 = H_2O_2$). According to physical chemistry formalism, the negative value of ΔE, low E_a in steps 1-3,5, and 6 favor the formation of $H_2O_{2(s)}$, and the small value of desorption energy of H_2O_2 (step 7) provides the formation of the final product, $H_2O_{2(g)}$. The formation of H_2O requires breaking of the O−O bond in at least one of the intermediates ($O_{2(s)}$, $OOH_{(s)}$, and $H_2O_{2(s)}$). Thus to increase the selectivity, steps 4, 8-10 should have high E_a, and desorption energy of H_2O_2 should be lower than the E_a of step 10. The condition of activity and selectivity is considered on Au_n, $Au_{n-1}Pd$ (n=8, 20, 32), Au_4Pd_4, $AuPd_7$ clusters which are simulated the active site of the catalyst.

Firstly, we consider H_2O_2 formation on Au_8 and Au_7Pd. The gold cluster weakly adsorb of H_2, O_2, it has high activation energies in steps (6) and (10). So, Au_8 is inert toward the H_2O_2 synthesis as well as to H_2O byproduct formation. Bimetallic $Au_{8-x}Pd_x$ (x=1, 4, 7) clusters can strong adsorb H_2 and O_2 on Pd atom and form active $H_{(s)}$ and $O_{(s)}$. The low E_a's in step (6) obtained for $Au_{8-x}Pd_x$ promote H_2O_2 formation with high activity, but low E_a in step (10) causes low selectivity due to O−O bond rupture in $H_2O_{2(s)}$. The spin conservation according to the Winger–Witmer rules from the triplet state in the intermediates to the singlet state occurs in step (5). The rate-determining step is the hydrogenation of $OOH_{(s)}$.

Influence of the cluster's structure on the H_2O_2 formation is studied on Au_n and $Au_{n-1}Pd$ (n=2, 8, 20, 32). A gold atom located on the top of Au_{20} and Au_{32} is considered as active sites. For bimetallic $Au_{19}Pd$ and $Au_{31}Pd$, we study the steps (6), (7), (10) on Pd atom located on the top of $Au_{31}Pd$ and facet of $Au_{19}Pd$. The gold clusters demonstrate low activity in hydrogen peroxide formation. Substitution of gold atoms by palladium in Au_{20} leads to an increase in the activity of a catalyst in the considered reaction of H_2O_2 formation, but low coordinated Pd atoms are also responsible lowering the selectivity because of H_2O formation. The compromise between activity and selectivity suggests that a Pd atom surrounded by gold atoms facilitates H_2O_2 synthesis.

4 Conclusions

Based on physical chemistry formalism, the conditions of the activity and selectivity of the H_2O_2 formation are supposed and tested on small Au and AuPd clusters as a model of active sites. The gold clusters demonstrate low activity in hydrogen peroxide formation. A Pd atom surrounded by gold atoms in AuPd clusters facilitates H_2O_2 synthesis.

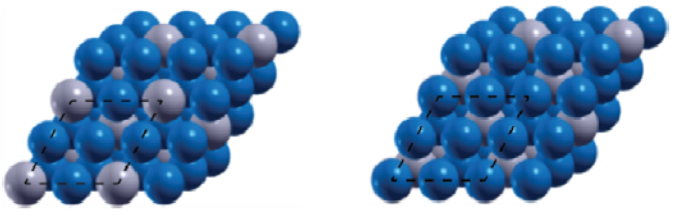
Keywords: PdAg, surface, density, functional, theory, hydrogen, carbon, monoxide, adsorption, permeation

1 Introduction

Palladium based alloys have interesting catalytic properties in selective hydrogenations, and are also important in hydrogen separation membrane technology [1]. By alloying, it is possible to enhance the catalytic activity or selectivity [2], as well as to suppress the formation of hydride phases under hydrogen exposure. Pd alloyed with Ag has been heavily investigated in this respect [3], and the structure and composition of the PdAg surface will affect the bond strength of adsorbed species. On the other hand, the reactive environment may alter the surface composition through segregation [4,5]. In order to investigate adsorption and dissociation of H_2 on PdAg alloy surfaces we have performed a combined experimental and theoretical study of surface phenomena affecting hydrogen transport through PdAg membranes.

2 Methodology



The theoretical investigations have been performed using periodic, self-consistent DFT calculations with the DACAPO code [6,7]. The exchange-correlation energy and potential are described by the generalized gradient approximation (GGA-PW91) [8]. The Pd_3Ag surface is modelled using a slab orientated in the (111) direction. Adsorption and reaction properties of $Pd_3Ag(111)$ with varying surface composition are investigated, as represented by either bulk (25% Ag) or Pd (0% Ag) termination, as displayed in Figure 1. Activation barriers for H_2 dissociation with increasing amount of CO pre-adsorbed are calculated using the climbing image nudged elastic band (CI-NEB) method [9].

Pd-23 wt% Ag thin films were prepared by a two-step magnetron sputtering technique [10,11]. Exposures and membrane permeation measurements were performed in a micro channel configuration that eliminates gas phase mass transfer limitations, before and after heat treatment in air. Competitive adsorption was investigated by addition of CO to the feed, and the PdAg thin films were further analysed through equilibrium sorption measurements and atomic force microscopy.

3 Results and discussion

Experimentally, we find that the hydrogen transport through thin Pd-Ag membranes is limited by surface phenomena below a certain thickness, which depends on how the surface has been treated (exposure and temperature) [12,13]. Exposure to air at elevated temperature is found to lift the surface limitations to the H_2 transport kinetics in the thickness range 1-5 μm, and CO poisoning effects are also reduced [14]. The hydrogen solubility remains, however, unaffected. The membrane surface generally roughens, but this cannot fully account for the observed improvements. This suggests that phenomena affecting the surface kinetics need further investigation.

The experimental data have been correlated to DFT calculations, revealing that the structure and composition of the PdAg surface is important with respect to hydrogen adsorption, dissociation, dissolution and desorption phenomena. At low coverage, H and CO favour hollow sites on bulk- and Pd-terminated $Pd_3Ag(111)$ [5]. The binding weakens upon increasing coverage, but is consistently stronger when the surface termination is Pd dominated. CO and H generally also favour the same adsorption sites, leading to inhibition of H adsorption by CO. The adsorption energetics of hydrogen is weakened in the presence of CO, and these changes depend on surface composition. A higher coverage of CO co-adsorbed with H is predicted on a Pd-terminated compared to a bulk-terminated surface. Finally, the activation barrier for hydrogen dissociation is found to increase due to adsorbed CO on the surface, but is significantly lower for the Pd-terminated surface.

4 Conclusions

Hydrogen permeation experiments and theoretical investigations can be applied to elucidate surface phenomena, i.e. adsorption, dissociation, and dissolution, on Pd alloy surfaces. The theoretical investigations explain how the surface composition may be important in this respect, demonstrating how the competitive adsorption as well as the reactivity of the Pd-Ag surface is altered by changes in the on surface composition.

Understanding Selectivity Issues in Rh-Catalyzed CO Hydrogenation

Filot I.A.W., Van Santen R.A., Hensen E.J.M.*

Schuit Institute of Catalysis and Institute of Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, The Netherlands

* i.a.w.filot@tue.nl

Keywords: Fischer-Tropsch, density functional theory, microkinetic modelling, rhodium

1 Introduction

The hydrogenation of CO to ethanol is attractive, for instance, as an alternative route of light olefins production. Several catalysts are known to catalyse syngas conversion into alcohols. We investigated Rh nanoparticle catalysts for this purpose. Detailed analysis of the CO hydrogenation chemical network on Rh provides a better understanding of the Fischer-Tropsch reaction mechanism on other metals. The most important question to be answered are: what is the rate-limiting step and what factors determine the selectivity to ethanol vs. methane.

2 Methodology

Density functional theory calculations were performed to investigate all elementary reaction steps relevant to CO hydrogenation over Rh. These reaction include those steps necessary to produce alkanes, alkenes, oxygenates, methane and water. From the obtained dataset, rate constants were constructed using the Eyring equation and microkinetics simulations were performed as published previously.[1] In these simulations, a Degree of Rate Control analysis[2] as well as a Degree of Selectivity Control analysis were performed to investigate the propensity of the individual elementary reaction steps on the overall activity and selectivity of CO hydrogenation over Rh.

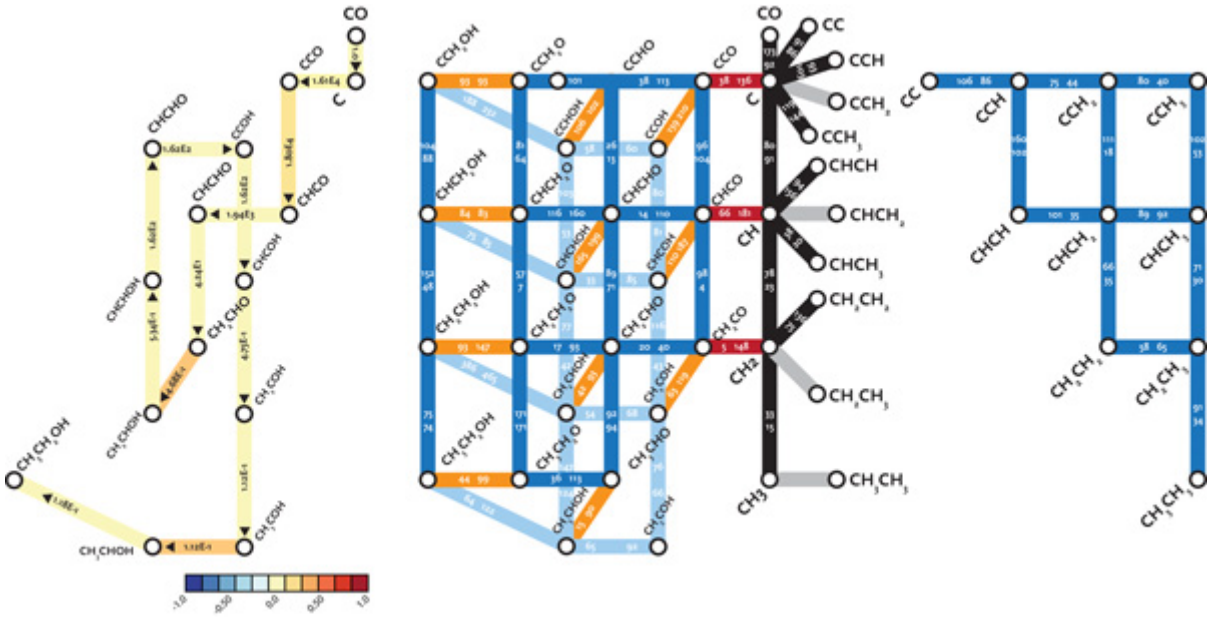

Fig. 1. (left) DRC analysis of ethanol formation.(right) CO hydrogenation reaction network diagram.

3 Results and discussion

Figure 1 shows the activation energies (both forward and backward direction) of all elementary reaction steps to form C_2 species in CO hydrogenation over Rh as well as the DRC analysis for ethanol formation. The three steps that mainly control the ethanol formation are CCO hydrogenation to CHCO, CH_3CHO hydrogenation to CH_3CHOH and CH_3COH hydrogenation to CH_3CHOH. The coupling step with the highest rate towards ethanol formation was found to be C+CO coupling (not shown here). Figure 2 shows the DSC analysis. From this analysis, we can see that ethanol production can be improved by inhibiting CH_2 and CH_3 hydrogenation.

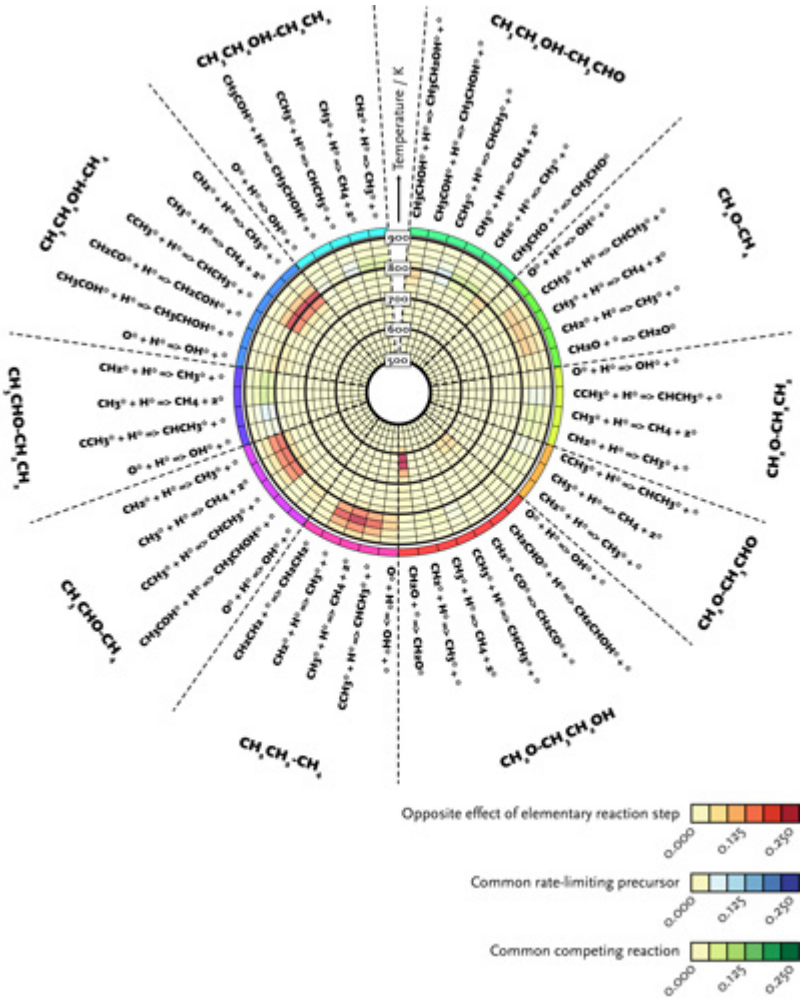

Fig. 2. Correlation between degree of selectivity control parameters showing which steps control which product selectivity as a function of temperature.

4 Conclusions

Our study reveals that (i) CO dissociation does not limit the reaction rate nor the selectivity and (ii) ethanol is formed by C+CO coupling followed by a complex series of hydrogenation and dehydrogenation reactions. Ethanol selectivity can be improved by decreasing the rate of CH_x hydrogenation that promotes methane formation. These insights will be discussed in the frame of promoter effects described in literature.

In silico Exploration of Bimetallic Sulfides Catalysts

Saab M., Raybaud P.*

Direction Catalyse et Séparation, IFP Energies nouvelles, Solaize, France

* mohamad.saab@ifp.fr

Keywords: density functional theory (DFT), transition, metal, sulfides (TMS), hydrodesulfurization, CoMoS, NiMoS

1 Introduction

Degradation of the crude oil properties and strengthening of environmental specifications on transportation fuels motivates the continuous improvement of hydrotreating catalysts efficiency. The industrial NiMoS and CoMoS active phases are constituted of MoS_2 nano-layers promoted either by nickel or cobalt (Figure 1) [1]. While the promotion effect of other 3d transition metals (Me) are known to be far much lower, MoS_2 nano-layers promoted by 3d metals remain poorly described. In this communication, we propose a systematic theoretical study of MeMoS phases in order to quantify periodic trends in structural, electronic, and energetic descriptors of MeMoS and better understand their catalytic activities.

2 Experimental/methodology

For total energy calculations, we use the Vienna ab-initio simulation package (VASP) [3], based on periodic plane wave density functional theory (DFT). We use generalized gradient approximation (GGA-PW91), including spin polarization corrections [2]. The cut-off energy of the plane wave basis set is fixed at 337.0 eV.

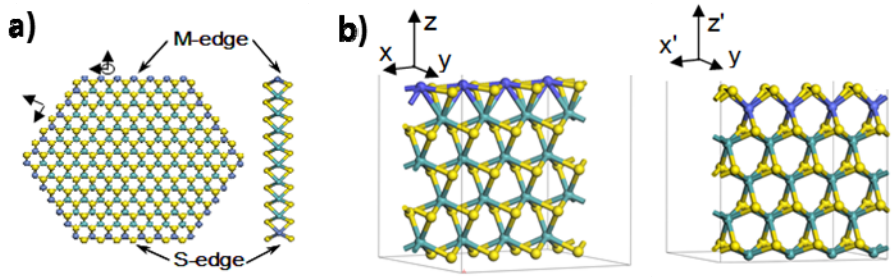

Figure 1. a) MeMoS nano-crystallite, b) $Mo_{16}Me_4S_z$ periodic slabs used to simulate the M-edge and S-edge of a promoted nano-crystallite with various promoter Me content. (Yellow balls: sulfur, green balls: molybdenum, blue balls: Me)

To determine the local structure and sulfur coverages of the two edges (M-edge and S-edge) present in HDS reaction conditions, we calculate the edge energies of the optimized slab (ionic forces smaller than 0.02 eV/Å) by using the following equations:

$$Mo_{16}Me_4S_{z_0} + (z - z_0)H_2S \rightarrow Mo_{16}Me_4S_z + (z - z_0)H_2$$

$$\Delta G = E(Mo_{16}Me_4S_z) - E(Mo_{16}Me_4S_{z0}) - (z - z_0)(\Delta\mu_s + E(S_\alpha))$$

is the stoichiometry of the slab used for simulating the promoted M- or S-edge (Figure 1) with 4 nonequivalent Me edge sites. Z represents the number of sulfur atoms which depends on the sulfidation conditions. Note: z_0=32 corresponds to the reference slab exposing M-edge with 0% S and S-edge with 100%S. $\Delta\mu_S$ represents the chemical potential of sulfur connected to (T, $p(H_2S)/p(H_2)$) conditions [4].

3 Results and discussion

Magneto-structure effects are known to play an important role in some bulk 3d TM monosulfides [5]. For MeMoS edge structures, we also found that the edge energy is influenced by the magnetic states of Me=Cr, Mn, Fe (weak effect for Co). The largest effect is revealed for the M-edge with 0%S on MnMoS exhibiting magnetism of ~3 μ_B per Mn atom (local antiferromagnetism). Moreover, this effect depends on the sulfur coverage itself. This first result shows that magnetism may be a key descriptor of these MeMoS phases.

Including spin corrections, Figure 2 shows that the S-coverage at the edge depends on HDS conditions, on the edge and on the nature of the 3d metal (Me). For the M-edge, the larger the d-band filling is, the lower the coverage of sulfur at the M-edge : Ti > Mn > Co > Ni. In HDS conditions ($-1 < \Delta\mu_S < -0.8$), the preferred S-coverage is 25% for TiMoS M-edge. By contrast, the S coverage drops to 0% S for NiMoS M-edge where Ni is stabilized in a square planar environment. Intermediate coverages and edge stabilization are found for Mn and Co. For the S-edge, Figure 2b shows that in HDS conditions, Co is strongly stabilized with 50%S leading to a tetrahedral environment as shown earlier [8]. For Ni, Ti, and Mn, the decrease of the S-coverage is also favorable as promoter, with a weaker energy stabilization.

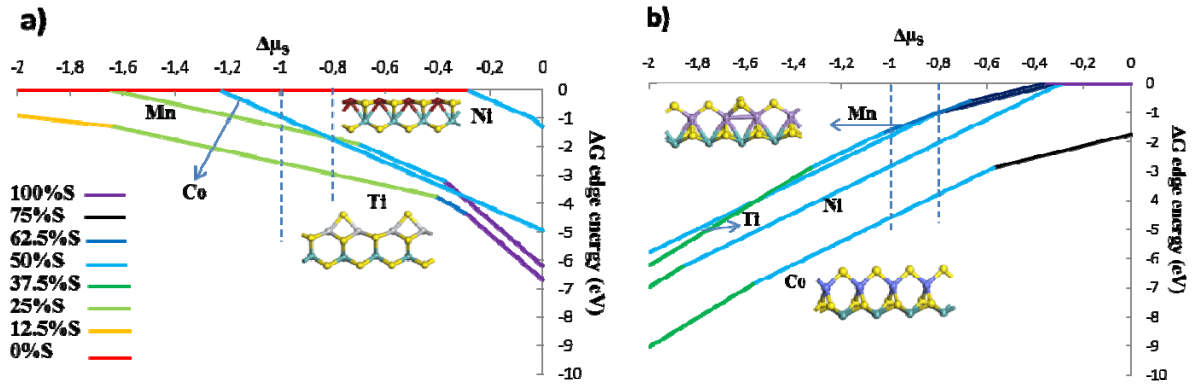

Figure 2. Edge energy diagram as a function of $\Delta\mu_S$: a) M-edge and b) S-edge. For sake of clarity we only report the results for Ti, Mn, Co and Ni.

4 Conclusions

We have determined the energy diagrams for two relevant edges of the mixed MeMoS nano-crystallites as a function of HDS reaction conditions. The nature of the 3d metal (Me) impacts differently the structure (S-coverage) and energy of the two edges. In addition, we highlight non negligible magneto-structure effects for Cr, Mn, Fe promoted systems. We will further discuss how the 3d metals influence the equilibrium shape of MeMoS nano-crystallites suspected to impact catalytic activity.

Keywords: bio-oil, hydrodeoxygenation, molybdenum, Ni-based catalysts, modification, stability

1 Introduction

Currently, the needs of the transport sector account for about one-third of global energy consumption, while 95% of them are covered by the refinery. The use of lignocellulosic biomass for biofuels production is believed to make a worthy alternative to fossil oil in future. One of the prospective approaches for the biomass conversion into biofuels is fast pyrolysis giving a liquid product − bio-oil (pyrolysis oil, PO). Among the different types of PO application [1] its co-processing with conventional oil refinery products on the FCC units should be outlined. But before such processing pyrolysis oil should be upgraded to reduce its polarity, corrosiveness, etc. to make its properties resemble those of non-polar conventional hydrocarbons. Catalytic hydrotreatment (HDO) is a potential way to improve bio-oil characteristics. The catalysts for this process should meet a number of requirements, such as high activity in hydrogenation/hydrodeoxygenation reactions, and high stability, which is obvious as PO is a quite aggressive reactive medium. The research activities in this field are still in progress as the development of perfect catalytic system presents an obstacle.

Recent works [2] have shown that Ni-based catalysts (with high Ni content, more than 50 wt.%) prepared by sol-gel technique with addition of Cu possess high activity in hydrotreatment of PO and its model mixtures. Nevertheless, these systems still needed an improvement as they did not show appropriate stability (active component leaching, coking, agglomeration). In latest investigations it was shown that modification of these catalysts by P-/Mo-containing agents results in the significant improvement of mechanical strength, resistance to corrosion, and lowering of coke deposition [3]. But the variation of modifiers content has not been studied yet. Thus the aim of the present research work was to study the effect of different Mo content on the catalysts performance in HDO process, their stability against leaching, and to make a correlation with their physicochemical properties.

2 Experimental

A series of Ni-based catalysts was prepared by sol-gel technique described elsewhere [4], using commercial $NiCO_3 \cdot 3Ni(OH)_2 \cdot 4H_2O$, $2CuCO_3 \cdot Cu(OH)_2$, and ethyl silicate-32. Mo-containing agent MoO_3 was added during the sol-gel preparation stage as well. The Ni/Cu mass ratio was kept constant, while Mo/Ni ratio was varied. Sol-gel stage was followed by drying (100 ^oC), calcination (500 ^oC), reduction in tubular quartz reactor (H_2 flow, 500 ^oC), and passivation (2 vol. % O_2 in N_2). The catalysts were designed as **NiCuMo(X)/SiO_2**, where X = 0, 0.04, 0.08, 0.125, 0.175, and 0.3 − Mo to Ni atomic ratio.

Samples thus prepared were tested in hydrotreatment of guaiacol (GUA) being a well-known model compound of pyrolysis oil. Hydrotreatment process has been carried out in a batch reactor at 320 °C, H_2 pressure 9 MPa (kept constant during the reaction), using 0.2 g of reduced

catalyst in powder form and guaiacol solution in hexadecane (V_{GUA}/V_{solv}=1/10). During the process the liquid samples were withdrawn from the reactor for further chemical analysis (GC and GC-MS). The catalysts stability to corrosion was studied by the glacial acetic acid treatment at severe conditions (boiling T = 118 ^{o}C, 2 hours). To characterize the catalysts a wide range of physicochemical methods was employed: X-Ray fluorescence, TPR, XRD, XPS, CO chemisorption, BET, HRTEM.

3 Results and discussion

The investigation of NiCuMo(X)/SiO_2 resistance to corrosion in glacial acetic acid have shown the gradual increase of stability with the amount of Mo in the catalyst. The best result was obtained for the sample with the highest Mo content − NiCuMo(0.3)/SiO_2 (only 1.8% mass loss in contrast to 30.9% for non-modified NiCu/SiO_2 system).

Very remarkable results were obtained during the catalysts testing in HDO process. It was observed that GUA conversion over NiCuMo(X)/SiO_2 series of catalysts proceeds by two main routs: (i) initial benzene ring hydrogenation (into methoxycyclohexanoles) followed by hydrodeoxygenation of O-containing groups (HYD-route, Fig. 1), (ii) first elimination of oxy-groups (with benzene formation) and further hydrogenation of aromatic ring (HDO-route, Fig. 1). In both cases cyclohexane was the final and the main product of GUA transformations. It was shown that increasing Mo content in the catalyst allowed higher contribution of HDO route with respect to HYD route, the latter was prevailing in the case of non-modified NiCu/SiO_2. Thus the use of Mo in Ni-based catalysts can shift the reaction routs and can be profitable in terms of hydrogen economy during the HDO process. Though this assumption needs to be checked further, using other model substrates and real feed. According to the catalysts characterization by physicochemical methods, the improvement of their resistance to corrosion and the changes in reaction selectivities during HDO process could be associated with the change of active component nature: electronic effects between Mo^0 and Ni^0, and the presence of coordinatively unsaturated species Mo^{x+} (x = 4, 5) in the catalysts composition, which can play a significant role in activation of O-containing compounds.

Keywords: palladium, carbon support, pyrolysis, sawdust, hydrodechlorination, chlorbenzenes

1 Introduction

Hydrodechlorination (HDC) is a prospective way of polychlorinated wastes disposal due to the intrinsic absence of polychlorinated dioxins in products, reduced energy demands and possibility to reuse the hydrocarbon moiety of chlorinated compounds being disposed. Pd, supported on activated carbon, is very effective hydrogenation catalyst. High specific surface and relative inertness of active carbon provide good Pd particle size distribution in the range optimal for catalysis. Pyrolysis of sawdust in inert atmosphere at desirable temperature is the appropriate way to produce carbon support from the timber wastes. Besides, reductive atmosphere formed during pyrolysis, could provide the reduction of metal from the salt. Therefore this is promising method of one-step production of ready-to-use Pd/C catalysts. In this work Pd/C catalysts for chlorobenzene hydrodechlorination were produced by direct pyrolysis of the birch sawdust impregnated with $Pd(NO_3)_2$ in Ar flow.

2 Experimental/methodology

The catalysts were prepared by pyrolysis of sawdust impregnated with $Pd(NO_3)_2$ at 430°C in Ar (4 h) with or without pretreatment (Table). They were characterised by SEM (JSM 6490 LV, JEOL), TEM (JEM 2100F, JEOL), low-temperature N_2 adsorption-desorption (Micometrics ASAP 2000), XPS (Kratos Axis Ultra DLD), Raman spectroscopy (Horiba Jobin Yvon LabRAM HR 800 UV), TPR and DSC-TG (449PC Jupiter Netzsch, Netzsch GmbH) before and after catalytic tests in gas-phase HDC of chlorobenzene at 100-350°C (flow-type fixed bad tubular reactor, 8 mg of catalyst, H_2:chlorobenzene = 30), and tested in multi-phase HDC of hexachlorobenzene and 1,3,5-trichlorobenzene at 50°C (batch reactor, i-octane as a solvent, aliquat 336, aq.KOH, H_2).

Table. Pd/C catalysts prepared in this work

Sample	Pretreatment	S_{BET}, m^2/g	d of 90%Pd particles, nm	Pd, mas.%	CB conversion at 150°C, %
Pd/C(S)	Soaking of sawdust in water, 72 h	135	1.5-3	2	88
Pd/C(SUS)	Soaking of sawdust in water,72 h; sonification 22 kHz 2 h during soaking	146	2-7	3	80
Pd/C(HTG)	Hydrothermal treatment in H_2O vapor, 200°C, 1 h	17	2-10, 12-22	0.5	89
Pd/C(HTL)	Hydrothermal treatment in liquid H_2O, 200°C, 1 h	225	2-10	0.5	92
Pd/C(N)	No pretreatment	7	1.5-3	7	52

Pd/C(A)	HNO_3 washing	7	1.5-3	7	100

3 Results and discussion

Raman spectroscopy and XPS data for C1s electrons demonstrated that pyrolysis in Ar at 430°C transforms sawdust impregnated with $Pd(NO_3)_2$ to the material similar to activated carbon (Raman spectra contains both D and G lines), having biomorphic structure, according to SEM data. Pretreatment of sawdust makes possible to vary and increase S_{BET} (see Table) to as high as 225 m^2/g (Pd/C(HTL)), as opposed to 7 m^2/g for Pd/C(N) and Pd/C(A). By XPS it was found that Pd on the surface is in the metal state (Pd^0) in all samples. According to TEM data, the increase of S_{BET} is accompanied with broadening of Pd particle size distribution (PSD). Narrow PSD (1.5-3) was found for Pd/C(S); for Pd/C(HTG) it is the broadest one and even bimodal (see Table); in addition, large (about 500 nm) Pd-containing particles are seen in SEM images. Small fraction of PdO (15-30 nm in size) encapsulated in carbon support was found only for Pd/C(N) by TPR and electron diffraction analysis during TEM.

All prepared Pd/C catalysts provide 90-100% conversion to benzene at 250-350°C in gas-phase HDC of chlorobenzene. At 100-200°C the most active were catalysts with increased S_{BET} (Pd/C(S), Pd/C(SUS), Pd/C(HTL))(See Table). Pd/C(HTG) containing lowest fraction of 2-5 nm Pd particles was the less active in HDC of chlorobenzene at 100°C (23% conversion). The acid washing of sawdust to remove Ca and Mg (up to 0,2% in original sawdust, EDS data) (sample Pd/C(A)) decreases the CB conversion. The H_2 treatment of Pd/C(N)(280°C, 4h) leads to decrease of low-temperature CB conversion.

XPS analysis demonstrated the relative stability of the Pd/C after prolonged catalytic tests in chlorobenzene HDC: only about 10% Pd in Pd/C(S), Pd/C(SUS), Pd/C(HTL) and Pd/C(HTG) oxidized to PdO, and about 10% Pd in Pd/C(SUS), Pd/C(HTL) and about 5% Pd in Pd/C(S), Pd/C(HTG) transformed to $PdCl_2$.

Pd/C catalysts were active also in HDC of 1,3,5-trichlorobenzene and hexachlorobenzene in multi-phase batch system. Additional improvement of catalytic performance was achieved for CoPd/C catalysts, produced by pyrolysis of sawdust co-impregnated with Co and Pd nitrates. CB conversion at 150°C increases to 91% for CoPd/C (N).

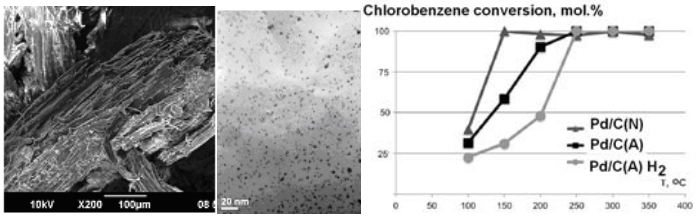

Fig. 1. TEM (a), SEM (b) images of Pd/C(N); CB conversion vs temperature

4 Conclusions

Pyrolysis of sawdust impregnated with $Pd(NO_3)_2$ in inert atmosphere is an appropriate way to produce Pd/C catalysts containing nanoparticles of Pd^0 on carbon support of biomorphic structure, active in gas-phase HDC of chlorobenzene and liquid-phase HDC of polychlorinated benzenes. Pretreatment of sawdust provides significant increase of S_{BET} (up to 225 m^2/g) at concurrent widening of Pd particle size distribution. The presence of alkali-earth metals in Pd/C and modification with Co improve catalytic properties.

Keywords: Pd/SiO_2, palladium, bis-acetylacetonate, impregnation, Sinter-resistance, preparation, mechanism

1 Introduction

Supported metal nanocatalysts with metal particles of less than 10 nm are attracting increasing attention because of their unique catalytic performance in many chemical reactions. However, maintaining the stability of metal nanoparticles on the supports in high temperature environments is usually rather difficult. Here, we report the synthesis of a well-dispersed Pd/SiO_2 catalyst with high thermal stability by using a simple impregnation method with $Pd(acac)_2$ as the Pd precursor. The interaction of $Pd(acac)_2$ with SiO_2 surface and decomposition of the $Pd(acac)_2$ on SiO_2 under air were characterized by a variety of techniques aiming at understanding the formation mechanism of the Pd nanoparticles in the above Pd/SiO_2 catalyst.

2 Experimental

The catalysts were prepared by impregnation method using $Pd(acac)_2$ (Alfa Aesar) desolved in acetylacetone as impregnation solution. The SiO_2 (Sigma-Aldrich, 430 $m^2 \cdot g^{-1}$, 35 to 60 mesh) was first treated with 20 wt% HNO_3 for 24 h followed by washed thoroughly with water, and dried overnight at 110 °C or calcined at temperature between 400 and 900 °C for 2 h before use.

TEM experiments were performed using FEI Tecnai 30 high-resolution transmission electron microscope operated at an accelerating voltage of 300 kV. Before the TEM experiments, the samples were reduced with a gas mixture of H_2/Ar = 5/95 (volume ratio) at 600 °C for 0.5 h. TG analysis was recorded on a TGA Q600-SDT apparatus. The sample (5 mg) was heated under an air flow of 100 $mL \cdot min^{-1}$ from 50 to 800 °C at a heating rate of 10 $°C \cdot min^{-1}$. The *in situ* IR experiments were carried out on a Thermo Nicolet Nexus FTIR spectrometer equipped with a liquid-nitrogen cooled MCT detector and an in-house-built high-temperature *in situ* IR cell [1]. The IR spectra were recorded at a resolution of 4 cm^{-1} and with 32 scans using the spectra of empty IR cell as references. XPS experiments were carried out by using an Omicron Sphera II hemispherical electron energy analyzer using Al Kα X-ray source as incident radiation. The binding energy of the element was reference to the Si1s peak at 103.3 eV. *In situ* XRD experiment was performed on a Panalytical X'pert PRO diffractometer equipped with a XRK-900 reactor. Cu-*Kα* radiation obtained at 40 kV and 30 mA was used as the X-ray source.

3 Results and discussion

Fig. 1 shows the TEM images of the 3wt% Pd/SiO_2 catalysts prepared by calcining a $Pd(acac)_2/SiO_2$ precursor in air at indicated temperatures followed by reducing with a H_2/Ar = 5/95 mixture at 600 °C. It can be seen that metallic Pd particles with mean size of 3.0-3.2 nm were observed over the samples calcined at temperature between 200 and 800 °C. It was also found that the size of Pd particles in the catalysts remained at approximately 3 nm even at a relatively high Pd loadings (8wt%). These results indicates that the Pd/SiO_2 catalyst prepared

using $Pd(acac)_2$ as precursor has a superior resistance against sintering at high temperatures.

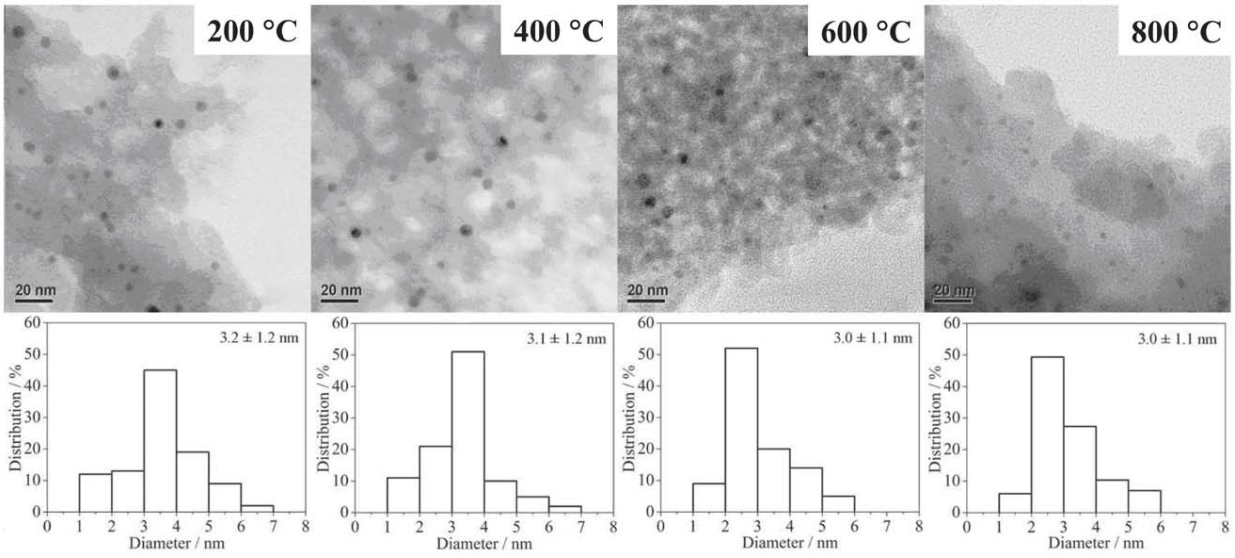

Fig. 1. TEM images and size distribution of the metallic Pd particles on the 3wt% Pd/SiO_2 calcined at different temperature.

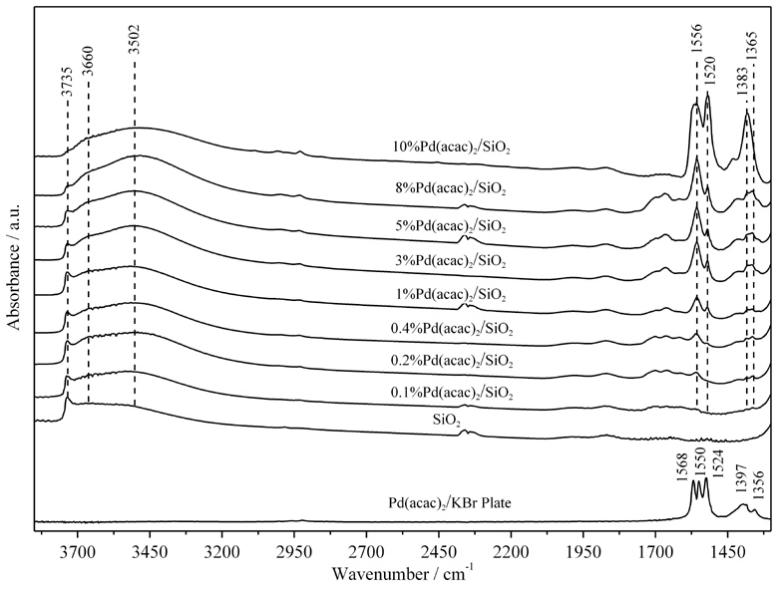

Fig. 2. IR spectra of $Pd(acac)_2$ on SiO_2 as a function of Pd loadings.

The interaction between $Pd(acac)_2$ complex and SiO_2 surface, and the thermal decomposition of the $Pd(acac)_2$ complex on SiO_2 surface under air were characterized by *in situ* IR, TG-MS, XPS and *in situ* XRD. When SiO_2 was impregnated with a solution containing $Pd(acac)_2$, the silanol groups on SiO_2 surface acted as the centers to interact with $Pd(acac)_2$ molecules, leading to the formation of hydrogen bonded $Pd(acac)_2$ single layer on SiO_2 surface (Fig. 2). Concentration of silanol groups on SiO_2 surface has a direct impact on the dispersion of $Pd(acac)_2$. On a fully hydroxylated silica surface, formation of a monolayer of $Pd(acac)_2$ on 1 g of the SiO_2 with surface area of ~400 $m^2 \cdot g^{-1}$ requires 5.7×10^{20} molecules of $Pd(acac)_2$, corresponding to ~9 wt% of Pd loadings. This is confirmed by the results of IR characterization shown in Fig. 2, in which no characteristic IR band corresponding a multiple layer of $Pd(acac)_2$ species was detected in the samples with Pd loadings below 8 wt%. When a silica supported $Pd(acac)_2$ sample was heated under air to ~200 °C, the $Pd(acac)_2$ species in the single layer on SiO_2 surface decomposed into the metallic Pd nanoparticles with average size about 2.8 nm. The

resulting Pd nanoparticles demonstrated superior stability against sintering at high temperature (Fig. 1). No significant aggregation of Pd nanoparticles was observed when the samples with Pd loadings between 0.1 and 8 wt% was heated to 800 °C in air or to 600 °C in a mixture of H_2/Ar = 5/95. In the $Pd(acac)_2/SiO_2$ samples with Pd loadings higher than 9 wt% or the samples prepared with a silica of low concentration of surface hydroxyl groups (obtained by calcining SiO_2 at temperature between 400 and 900 °C.), however, multiple layers of $Pd(acac)_2$ could also form on the SiO_2 surface, because there were no enough surface OH sites to allow all $Pd(acac)_2$ molecules to "fit" into the single layer. Decomposition of multiple layer $Pd(acac)_2$ species in air at elevated temperature result in the formation of large Pd particles on SiO_2.

4 Conclusions

A sinter-resistant Pd/SiO_2 catalyst with average Pd particle size of about 3 nm and variable metal loadings can be made using a simple impregnation method with $Pd(acac)_2$ as precursor followed by decomposition of $Pd(acac)_2/SiO_2$ in air at temperature between 200 and 800 °C. Formation of single layer of $Pd(acac)_2$ on SiO_2 surface through the hydrogen bond interaction of silanol group with $Pd(acac)_2$ is a key step towards the final formation of well-dispersed Pd nanoparticles on SiO_2. This straight forward procedure can also be used in the synthesis of other sinter-resistant metal catalysts supported on SiO_2 such as Ni/SiO_2 and $Rh\text{-}CeO_2/SiO_2$.

Keywords: nanoalloys, Au-Rh, Au-Pd, hydrogenation, thioresistance, aberration-corrected, TEM

1 Introduction

The thermodynamic properties of bulk alloys are expected to influence the structure of their nanosized counterparts. In this work, we have compared the well-known bulk-miscible Au-Pd system [1,2] to the rarely studied bulk-immiscible Au-Rh system [3] in terms of structural and catalytic hydrogenation properties. In addition, we have focused on the effect of gold on the resistance of Pd and Rh toward oxidation in air and sulfidation in catalytic conditions.

2 Experimental/methodology

TiO_2 rutile nanorods were synthesized hydrothermally from commercial TiO_2 (Degussa P25). Au-Pd and Au-Rh nanoparticles (NPs), along with their monometallic counterparts, were prepared using a colloidal chemical (co)reduction route employing chloride salts as metal precursors, polyvinyl alcohol (PVA) as surfactant, and $NaBH_4$ as reducing agent. The obtained colloids were immobilized on titania pre-acidified with HCl [4].

3 Results and discussion

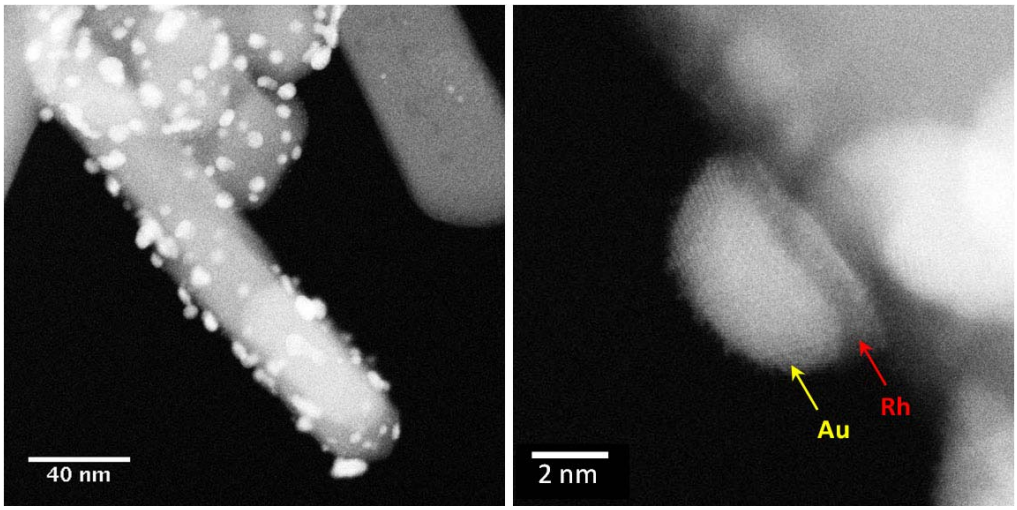

Fig. 1. STEM-HAADF images of pre-reduced $Au_{63}Rh_{37}/TiO_2$ sample.

The prepared solids were treated in H_2 flow at 350 °C, which was found efficient (as attested by FTIR) for totally removing the PVA while preserving the size (3 nm), shape and bimetallic nature of the NPs. While Au-Pd NPs are alloyed at the atomic scale, forming a solid solution, aberration-corrected scanning transmission electron microscopy (STEM) shows a well-defined segregated structure with Rh located at the interface between Au and TiO_2 (Fig. 1b).

The catalysts were evaluated in the gas-phase hydrogenation of tetralin (4 MPa of hydrogen, 24 kPa of tetralin, 350 °C) in the absence or presence of H_2S (50 ppm). Overall, gold is seen to decrease the activity of Pd- and Rh-based catalysts but it stabilizes them in the presence of sulfur, avoiding sulfidation. In the case of (Au-)Rh systems (Fig. 2), while Rh/TiO_2 is instable in S-free conditions and its activity increases upon H_2S addition to the feed, the Au-Rh/TiO_2 catalysts are much more stable and less sensitive to H_2S introduction or removal.

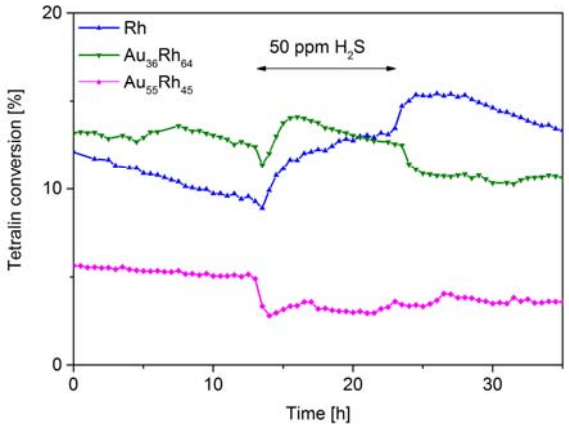

Fig. 2. Tetralin conversion to decalin on (Au-)Rh/TiO_2 catalysts without and with H_2S in the feed.

Furthermore, comparative X-ray photoelectron spectroscopy (XPS) analyses of as-prepared, pre-reduced and pre-calcined samples, supported or unsupported, show that TiO_2 and Au both stabilize Pd and Rh against oxidation in air [5].

4 Conclusions

Au-Rh/TiO_2 and Au-Pd/TiO_2 catalysts synthesized by colloidal/sol immobilization methods were characterized by (S)TEM, XPS and FTIR, and were evaluated in the hydrogenation of tetralin. While Au and Pd atoms form a solid solution, Au and Rh atoms segregate into single-phase domains within the NPs. These domains arrange in an Au/Rh/TiO_2 stacked configuration upon ligand-removal treatment at 350 °C in H_2. The presence of TiO_2 and Au is seen to inhibit surface oxidation and sulfidation of Pd and Rh, leading to improved catalyst stability.

Defectiveness of Carbon Nanomaterials as a Key Parameter of their Effectiveness as a Support for Cobalt Catalysts in Fischer-Tropsch Synthesis

Chernyak A.S., Savilov S.V., Lunin V.V., Suslova E.V.*

Lomonosov Moscow State University, Moscow, Russia

* suslova@kge.msu.ru

Keywords: Fischer-Tropsch, synthesis, carbon, nanoflakes, carbon, nanotubes, bomb, calorimetry

1 Introduction

The Fischer-Tropsch (FT) synthesis is carried out in the presence of Co or Fe catalysts supported on carbon or oxide carriers. In recent years most of the works are devoted to the study of catalysts supported on carbon nanotubes (CNT) and other carbon nanomaterials (CNM). The catalytic activity and selectivity essentially depend on the size of Co or Fe nanoparticles which on its own is determined by the method of synthesis of catalysts, the nature of surface of CNM (morphology, degree of oxidizing, content of heteroatoms in the carbon structure) and other factors. In the present investigation the attempts to systematize the influence of surface of very wide range of CNT and CNM on the stabilization of Co nanoparticles under FT synthesis were legislated in the first time. Characteristics such as the standard enthalpy of formation and the ratio of intensities of the lines I_D/I_G in the Raman spectra were criteria selected as a universal.

2 Experimental/methodology

CNT were synthesized by pyrolytic decomposition of hexane at 750 ^oC in the presence of MgO template (S = 45 m^2/g) impregnated with aqua solution of cobalt nitrate (0.1 mol. %) and ammonium molybdate (0.03 mol. %) in the quartz tube reactor with an inner diameter of 50 mm (velocity of N_2 was 500 ml/min). Nitrogen-doped CNT (N-CNT) were observed by pyrolysis of acetonitrile under the similar conditions. Nitrogen-doped carbon nanoflakes (CNF) were synthesized by pyrolysis of acetonitrile, butylamine or pyridine in the presence of MgO (S = 140 m^2/g) at 800-900 ^oC during 15-90 min. Depending on temperature and synthesis duration N-CNT and N-CNF with different nitrogen content were observed. According to XPS data the content of nitrogen in N-CNT and N-CNF was 1.6 – 2.6 and 7.2 – 10.9 at. % respectively. Purification of the CNM from the metallic impurities was carried out by boiling in 10% hydrochloric acid solution. The surface of CNT was oxidized by nitric acid during 1, 3, 6, 9 and 15 h. According to XPS data the oxygen content was 6.48 – h 8.85 at. %.

All CNT and CNM were investigated by BET, SEM, TEM, Raman spectroscopy, XPS, TG/DSK and bomb calorimetry.

Catalysts were prepared by impregnation of carbon supports with alcoholic solution of $Co(NO_3)_2 \cdot 6H_2O$, the content of Co was 15 mass. %. FT synthesis was performed in a fixed-bed reactor under atmospheric pressure, 200-220 ^oC and $CO:H_2:N_2$ mixture (2:4:1 vol. %).

3 Results and discussion

Increasing oxidation time of CNT from 1 to 9 h led to increasing the number of oxygen-containing groups on the surface of CNTs from 6.5 to 8.9 at. %, further increasing of oxidation time had no effect on the oxygen content. The increase of the ratio of intensities of I_D and I_G lines Raman spectra and of heat of combustion from 28.027 up 28.542 kJ/g may evidence the increase of degree of «defectiveness» of CNT [1].

During the study of nitrogen-doped nanomaterials (N-CNT and N-CNF) a similar pattern was observed. The increase of the synthesis's temperature does not change the shapes of Raman spectra significantly. Nevertheless the half-width at maximum of the peaks become increase while the I_D/I_G ratio decreases, which is in good agreement with supposition about the elimination of N-atoms with temperature growth.

We assume that the role of stabilization center of cobalt nanoparticles on the surface of the CNM is played defects in carbon structure: functional groups, such as carboxyl, obtained by oxidation with nitric acid, nitrogen heteroatoms, disordering of the graphene structure of CNT and CNF formed during CNM growth [2]. By increasing the number of stabilization centers of cobalt nanoparticles can be achieved after their deposition on the surface of the CNF and catalysts will differ increased stability.

Co catalysts supported on CNM demonstrated better characteristics in the cases of more degree of «defectiveness» of CNM. However, the catalysts deposited on nitrogen-doped CNM supports demonstrated low activity: CO conversion not exceed 13 vol. %.

4 Conclusions

The proposed method of assessing the effectiveness of Co-supported catalysts for FT synthesis which is based on evaluation of defects in the CNT surface or CNM Raman spectroscopy techniques and bomb calorimetry. It was found that the most promising supports can be considered oxygen-containing CNT.

Keywords: Ru nanoparticles, distribution of sizes, catalytic cooperation, low-temperature, NH_3 synthesis

1 Introduction

It has been commonly accepted that the activation of N_2 is the rate-determining step (RDS) for ammonia synthesis on metallic surfaces, and that the B_5-type sites, exposing a three-fold hollow site close together with a bridge site, are the most active sites for N_2 activation on Ru crystals. The maximum formation of these sites in Ru-supported catalysts has been found for Ru sizes of 1.8–2.5 nm [1], leading to optimal activities under high temperatures (200–500 ºC) and pressures (30–100 bar) [2]. However, under mild reaction conditions (< 200 °C, < 10 bar) the adsorption and transfer of hydrogen seem to have significant implications for the kinetics and mechanism of NH_3 synthesis. Then, additional features of the metal surface become relevant for a high catalytic activity. A broad size distribution of Ru-supported nanoparticles is required for a high activity in NH_3 synthesis under mild conditions [3], since a synergy in the catalytic activity was observed between particles of different sizes. The goal of this work is to clarify the mechanism of catalytic cooperation between Ru particles of different sizes, by separately studying the H_2 activation and transfer and the reactivity of adsorbed species on catalysts containing small and larger nanoparticles.

2 Experimental/methodology

Ruthenium catalysts (X: 1, 3 and 7 wt.% Ru) were prepared from $RuCl_3$ by a colloidal method (RuX/Al- COLL), which consists in depositing on γ-Al2O3 a colloidal suspension of RuO_2 nanoparticles prepared via hydrolysis, using H_2O_2 as oxidizing agent. A new strategy was used to prepare a Ru (10 wt.%) catalyst, by mixing the RuO_2 colloids used in the synthesis of Ru3/Al-COLL and Ru7/Al-COLL, and then depositing the resulting colloid on γ-Al_2O_3. This catalyst is denoted as Ru(7+3)/Al-COLL. Catalytic tests were carried out in a fixed-bed tubular reactor. The catalyst (400 mg) was pretreated in H_2 (80 ml/min, 200ºC/2h). The reaction was performed at 50-150ºC and 5 bar, in a N_2/H_2 mixture of 1:3 vol.% (40 ml/min, GHSV=6000 ml/h/g_{cat}). Catalysts were characterized by BET, XPS, TEM, XRD and H_2-chemisorption. Additionally, H/D isotopic exchange and 'operando' DRIFTS experiments were performed.

3 Results and discussion

The activity for NH_3 synthesis increases with the mean size of Ru particles, up to 7 nm (Fig. 1). Moreover, an enhanced catalytic performance was observed with Ru(7+3)/Al-COLL, having a broader size distribution (SD: ± 3nm) of Ru particles in the range 2–17 nm (Table 1). A reaction order of 0.05 with respect to N_2 was obtained for small Ru nanoparticles, indicating that the reaction rate depends very little on N_2 partial pressure and that the actual limiting step for the

reaction on small particles might be the release of active sites. In addition, H/D homoexchange experiments at low temperatures shown that $H_2(g)+D_2(g)=2HD(g)$ reaction is much slower on small Ru nanoparticles, and therefore, a low amount of strongly attached H atoms is expected to cover the surface. In consequence, the hydrogenation of NH_x intermediates species and the release of active sites for further N_2 adsorption may be limiting the reaction over small Ru nanoparticles, as confirmed by the study of reaction orders.

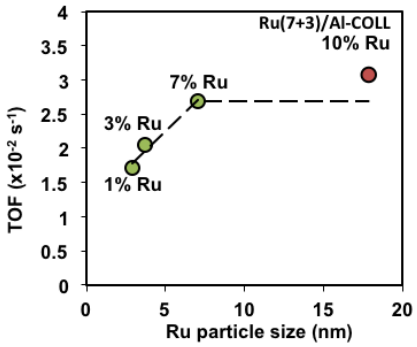

Fig. 1. TOF as a function of Ru mean size, for NH_3 synthesis at 100ºC and 5 bar

Table 1. Mean size of Ru supported particles and their activity for NH_3 synthesis at 5 bar

Catalyst	Ru loading (wt.%)	XPS Ru mean size (nm)	SD of sizes (nm)	TOF (x100 s^{-1}) 100ºC	150ºC
Ru1/Al-COLL	1	2.9	± 0.9	1.72	1.95
Ru3/Al-COLL	3	3.7	± 0.9	2.05	2.30
Ru7/Al-COLL	7	7.1	± 0.9	2.69	2.36
Ru(7+3)/Al-COLL	10	17.9	± 3	3.07	3.23

The faster H/D equilibration reaction on larger Ru nanoparticles shows that they decrease the energetic barrier for H_2 activation, ensuring an effective release of active sites. The mobility of H atoms between Ru metal particles and the alumina support was confirmed via H/D isotopic exchange experiments. Therefore, the presence of large Ru nanoparticles can influence the reaction kinetics on small particles, by activating and promoting the mobility of adsorbed H atoms. It is suggested that the catalytic cooperation mechanism between particles of different sizes involves the migration of H atoms from large to small Ru particles, promoting the hydrogenation of NH_x adsorbed on small metal particles and the release of blocked active sites.

4 Conclusions

NH_3 synthesis is better conducted on surfaces with a broad size distribution of Ru nanoparticles. Small particles contain active sites for N_2 activation, but at low temperature, they slowly activate and strongly attach H_2, affecting the hydrogenation of adsorbed NH_x and the release of active sites for N_2 adsorption. On the contrary, larger Ru nanoparticles decrease the energetic barrier for H_2 activation and allow a higher mobility of H atoms. The cooperation mechanism would involve migration of H atoms from large to small Ru particles, promoting the hydrogenation of adsorbed NH_x on small metal particles and the release of blocked active sites.

Keywords: perovskites, electron microscopy, water-gas shift reaction, mixed conducting, SOFC-anodes

1 Introduction

A current trend in catalysis sees a re-focus on the catalytic action of the individual parts of a more complex catalyst entity. As many catalyst systems represent a combination of (noble) metals and (oxidic) supporting materials, the latter are increasingly studied with respect to their intrinsic surface reactivity. However, due to the inherent structural and electronic complexity of oxides, the identification of e.g. a catalytically active site is not straightforward. These challenges are far higher if more complex oxide systems are studied. Such complex systems may also come as a single phase binary oxide adopting a distinct crystallographic structure. A well-known example are perovskitic materials. Uses as ferroelectrica or solid oxide fuel cell (SOFC) cathodes are well-known. Catalytic applications are reported for environmentally relevant deNOx processes, diesel exhaust catalysis, total oxidation of hydrocarbons or dry reforming of methane. Specifically, also the water-gas shift reactivity on perovskite systems has been in the focus of research[1]. However, direct correlations of catalytic properties and associated structural changes still remain scarce. This is a particular pity, since e.g. hydrocarbon conversion is usually carried out at high temperatures (T > 600°C), eventually giving rise to an array of structural changes, including surface reconstruction or chemical segregation of individual atom species. Especially the surface structure and chemistry (e.g. the cation or oxygen vacancy concentration) are in a dynamical state depending on the experimental conditions (e.g. hydroxylation degree of the surface or oxygen partial pressure). Thus, surface and bulk structure and composition might significantly deviate from one another and need to be separately assessed.

To clarify this issue, a comparative study of activity for hydrogen oxidation, water-gas shift and methane reforming was performed on the two perovskite-type materials $La_{0.6}Sr_{0.4}FeO_{3-\delta}$ (LSF) and $SrTi_{0.7}Fe_{0.3}O_{3-\delta}$ (STF) with the aim of directly linking surface and bulk reactivity to catalytic properties.

2 Experimental/methodology

Structure-activity correlations in doped perovskite systeme were established using a combined approach of Electrochemical Impedance and Raman spectroscopy, structural characterization by X-ray diffraction (XRD) and aberration-corrected Scanning Transmission Electron Microscopy (STEM) as well as catalytic measurements in the (inverse) water-gas shift reaction and methane reforming.

3 Results and discussion

Impedance measurements on model-type LSF thin film electrodes revealed a comparatively

high surface activity of the material in oxidizing as well as reducing atmospheres. On powder samples the water-gas shift reactivity as well as conversion of CO_2 by the inverse water-gas shift reaction starting at about 450°C was observed on both LSF and STF. Generally, the catalytic performance for the water-gas shift equilibrium is heavily influenced by the extent of pre-reduction in hydrogen. Catalytic methane reforming reactivity or decomposition was observed on neither of the two materials, only total oxidation of methane to CO_2 with reactive lattice oxygen on initially fully oxidized powder samples. In general, the catalytic activity of both perovskite-type oxides is strongly dependent on the degree of reduction and the associated reactivity of the remaining lattice oxygen. Structure-wise, high-resolution high-angle annular dark-field electron microscopy images (Figure 1, right) show that after a catalytic reaction both perovskites still appear SrO-terminated (Figure 1, left). Raman measurements on STF reveal a reversible modification of the Fe/Ti-O structural entity upon treatment in the water-gas shift reaction mixture at 600°C as deduced from according changes in the Fe/Ti-O stretching vibration. Generally, combining XRD and Raman measurements, a clear difference in the surface and bulk reactivity of the two perovskite-type oxides results.

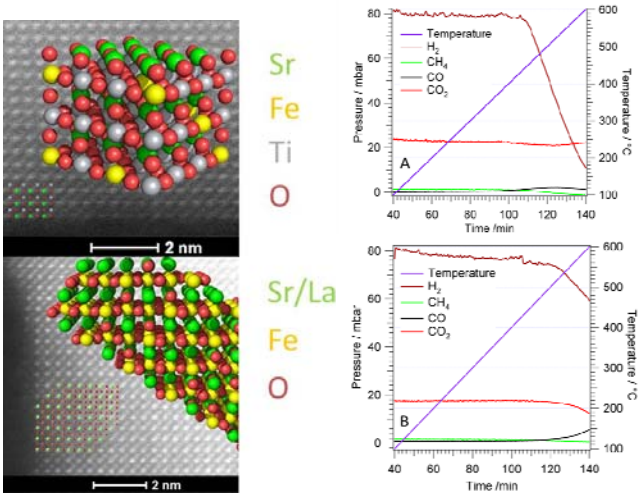

Fig. 1. Left: High-resolution STEM-HAADF images of STF (above) and LSF (below) after an inverse water-gas shift reaction (iWGSR) cycle up to 600°C with overlaid crystallographic structures showing the exact position of each atom in the structure and at the surface. Right: Reaction profiles of the iWGSR on STF without (panel A) and with (panel B) pre-reduction in hydrogen at 600°C (1 h, 1 bar).

4 Conclusions

As the most important parameter highly influencing the reactivity, the reduction degree could be determined: it controls the oxygen reactivity and the specific oxidation and reduction capability of the active sites in the working state of the perovskitic catalysts. The presented results in turn allow for the first time the direct correlation of a catalytic profile measured on a perovskite system to bulk and surface structural changes occurring during each step of catalytic pre-treatments and catalytic reaction.

Facile Redispersion of Sintered Au Nanoparticlces with Controllable Size for Catalytic Application

Duan X., Tian X., Ke J., Yuan Y.*

State Key Laboratory of Physical Chemistry of Solid Surfaces and National Engineering Laboratory for Green Chemical Production of Alcohols-Ethers-Esters, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, China

* yzyuan@xmu.edu.cn

Keywords: Au, catalyst, sintering, redispersion, particle, size, acetylene, hydrochlorination

1 Introduction

Catalysis with supported gold nanoparticles (Au NPs) has become a focus of intense research, which is wildly used in energy conversion, chemicals production, *etc*. However, sintering of Au NPs is one of the most common events leading to deactivation of Au based catalysts. Although several reports have conducted to minimize or reverse the Au catalyst deactivation owing to sintering [1–3], controlling the Au particle size associated with the mechanism of redispersion is still ambiguous. Herein, we firstly established the correlation between the C–X bond dissociation energy (BDE) of alkyl halides and relative redispersion efficiency. Time-dependent XRD patterns and TEM images illustrate the procedures of redispersion, following a mechanistic discussion. The catalytic test of acetylene hydrochlorination was conducted to show the performance of regenerated Au catalysts.

2 Experimental

The catalyst 1 wt.% Au/C was prepared by the impregnation method. Analytic reagent of alkyl halides were employed to treat the sintered Au/C catalysts under established conditions. The samples before and after redispersion are characterized by means of various techniques like BET, XRD, TEM, *etc*. The acetylene hydrochlorination was carried out in a fixed bed reactor. The gas phase products were analysed on-line by GC with a FID detector equipped a GDX-301 column.

3 Results and discussion

The TEM image in Fig. 1a shows that the sintered Au/C catalyst has an average size of 30 nm. After the sintered Au/C catalyst was treated in CHI_3 at 40 °C for 5 min, the TEM image in Fig. 1b indicates that there are some smaller Au NPs in the periphery of larger particle on the catalyst surface, which likely taking place a reverse agglomeration or reverse Ostwald ripening process. After 30 min, the Au NPs can be readily redispersed to less than 3 nm (Fig. 1c). Fig. 2 (*Left*) shows plots of the redispersion efficiency against BDE of C–X (X = I, Br, Cl). CHI_3 exhibits the highest redispersion efficiency for its minimum C–I BDE. The results suggest that the C–X BDE of alkyl halides might be served as a descriptor for the reverse agglomeration of sintered Au/C.

Further experimental results indicate that the high dispersed Au NPs with mean particle sizes of *ca.* 0.8, 2.6, and 6.8 nm can be obtained after the sintered Au/C catalysts were treated with CHI_3, C_6H_5I and $C_5H_{11}I$ at 40 °C for 3-7 days, respectively. The findings may pave the way for the facile regeneration of sintered Au-based catalysts for practical applications. In fact, the regenerated Au/C catalyst can almost recover its activity for the hydrochlorination of acetylene (Fig. 2, *right*).

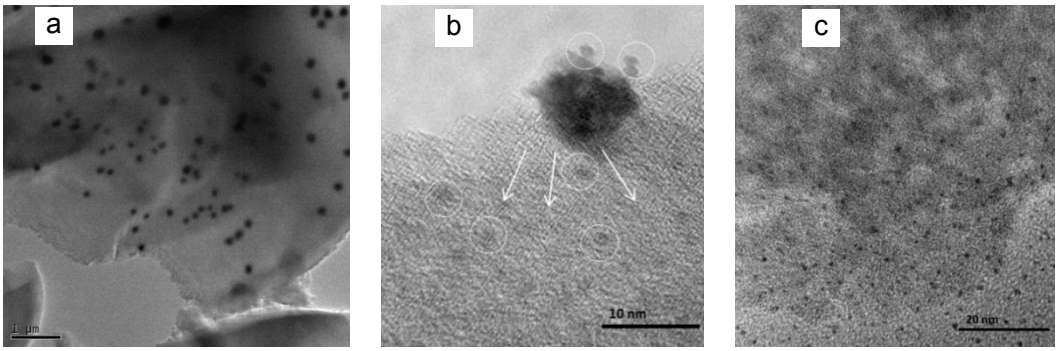

Fig. 1 TEM images of Au/C catalyst. (a) sintered Au/C; (b) and (c) the sample (a) treated in CHI_3 at 40 °C for 5 min and 30 min, respectively.

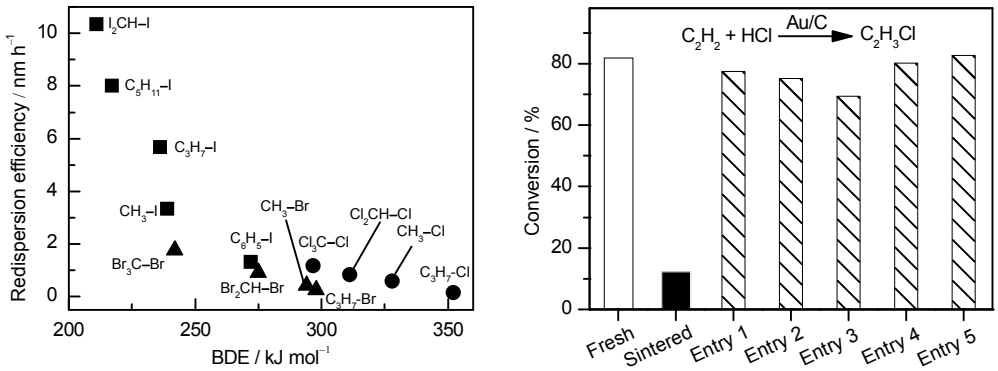

Fig. 2 *Left*: correlation between redispersion efficiency with C–X (X = I, Br, Cl) BED of alkyl halides; *Right*: acetylene hydrochlorination over the Au/C catalyst before and after reactivation. Reaction conditions: P = 0.1 MPa, T = 180 °C, GHSV (C_2H_2) = 600 h^{-1}.

4 Conclusions

We have demonstrated a facile and rapid protocol for the redispersion of sintered Au/C catalysts. The correlation of C–X BDE of alkyl halides with redispersion efficiency revealed that the alkyl halides with lower BDEs are able to redisperse the sintered Au/C efficiently. The method is also able to facilitate the redispersion and/or regeneration of Au-based catalysts until the desired sizes of Au NPs are obtained. The proposed mechanism may help formulate a molecular-level understanding of the critical interfacial events. The forthcoming work will put weight on adjusting to weaken and elongate the C–X bond with a functional donor that would benefit the dispersion efficiency and size/shape controlling of supported Au NPs.

Shape Effect of TiO_2 on the Performance of VO_x/TiO_2 Catalysts for NH_3-SCR

Shi Q., Li Y., Zhan E., Ta N., Shen W.*

Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China

* shen98@dicp.ac.cn

Keywords: TiO_2, shape effect, nanosheets, nanospindles, VO_x/TiO_2 catalysts, NH3-SCR

1 Introduction

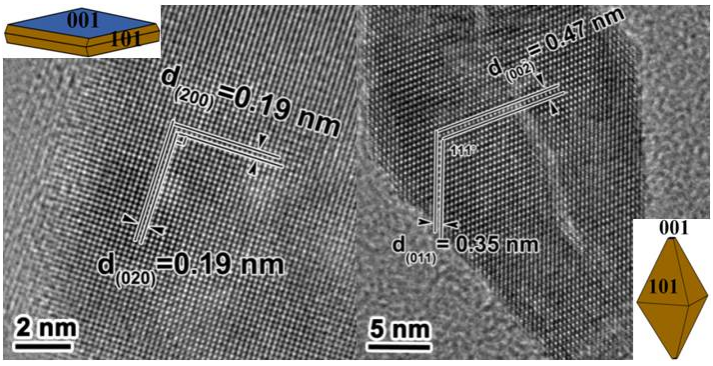
VO_x/TiO_2 catalysts have been industrially used for selective reduction of NO with NH_3 in abating polluting emission from power plant [1]. It is generally viewed that VO_x monolayer on titania are the most active species and their interaction with underlying TiO_2 largely determine the catalytic performance [2]. The {001} facet of TiO_2 favors a monolayer dispersion of vanadium oxide species [3], but this reactive facet grew very fast under synthetic conditions and the commonly used TiO_2 particles are dominantly enclosed by the thermodynamically stable {101} facet [4]. Here, we examined the shape effect of TiO_2 particles, in terms of the exposed crystalline facets, on the dispersion of VO_x species in VO_x/TiO_2 catalysts.

2 Experimental

TiO_2 nanosheets (TiO_2-S) and nanospindles (TiO_2-P) were prepared by a hydrothermal method with the aid of F^- and CH_3COO^-, respectively. The VO_x/TiO_2 catalysts with a V_2O_5 loading of 8.2 wt% were prepared by an impregnation method; they were calcined at 673 K in air before characterizations and catalytic tests. Structural analysis was conducted by Raman spectroscopy, XPS, NMR, XRD and TEM techniques. Selective reduction of NO with NH_3 was performed with a continuous-flow fixed-bed quartz reactor at atmospheric pressure. The typical reaction conditions are 100 mg catalyst, 1000 ppm NO /1000 ppm NH_3/ 3 vol% O_2 / He (60 mL min^{-1}), and 303-673 K.

3 Results and discussion

XRD patterns of the TiO_2 nanoparticles showed characteristic diffraction lines of anatase TiO_2. The (200) diffraction line in the TiO_2-S sample intensified remarkably while the (004) diffraction line weakened considerably, suggesting a predominant exposure of the {001} facet [5]. The TiO_2-P sample showed enhanced diffraction intensity in the (004) plane and a decrease in the (200) line, indicating the exposure of the {101} facet. TEM observation revealed that the TiO_2-S exhibited a sheet-like morphology with the thickness of 7 nm and the side length of 40 nm. It consisted of 74% {001} facet on the square surface and 26% {101} facet on the isosceles trapezoidal surface. The TiO_2-P had a spindle-like shape with 50 nm in length and 20 nm in



diameter; and it was enclosed by 81% {101} facet on the isosceles trapezoidal surface and 19% {001} facet on the top surface.

The VO_x/TiO_2 catalysts maintained almost the original size and morphology of the TiO_2 supports. STEM observation and EELs analysis confirmed that the VO_x species were dispersed at monolayer level in both cases but their atomic coordinations strongly depended on the shape of TiO_2. XPS profiles and Raman and NMR spectra indicated that TiO_2-S, predominantly exposed the reactive {001} facet, favored a selective deposition of vanadia species in octahedral coordination, whereas TiO_2-P, enclosed with the {101} facet, induced the generation of tetrahedral VO_x species. The {001} facet is terminated with 50% Ti_{5c} atoms and 50% Ti_{6c} atoms, whereas the {101} surface is composed by 100% unsaturated Ti_{5c} atoms [5]. Accordingly, vanadia presented as octahedral-coordinated state on the {001} facet but tetrahedral-coordinated environment on the {101} facet [6]. Therefore, it can be concluded that the dominantly exposed facets of TiO_2 nanoparticles tuned the dispersion of vanadia species and their interactions with TiO_2.

On the VO_x/TiO_2-S catalyst, the conversion of NO reached 50% at 465 K and approached 100% at 560 K. However, the temperatures for the corresponding NO conversions over the VO_x/TiO_2-P catalyst shifted to 496 at 608 K, respectively. The reaction rate on the VO_x/TiO_2-S catalyst was 1.71×10^{-6} mol g^{-1} s^{-1} at 503 K; but it decreased to 7.05×10^{-7} mol g^{-1} s^{-1} over the VO_x/TiO_2-P catalyst. The turnover frequency, based on the amount of vanadium, was 1.90×10^{-3} s^{-1} on the VO_x/TiO_2-S catalyst and 7.82×10^{-4} s^{-1} over the VO_x/TiO_2-P catalyst. TPSR of pre-adsorbed NH_3 further evidenced the superior activity of the VO_x/TiO_2-S catalyst, over which NO consumption occurred at 353-543 K with the production of significant amounts of N_2 and H_2O. On the VO_x/TiO_2-SP catalyst, however, the temperature window for NO consumption shifted to 553-673 K, forming much less of N_2 and H_2O. All these results demonstrate that vanadia species with an octahedral coordination on the reactive {001} facet of TiO_2 are intrinsically more active for the selective reduction of NO with ammonia.

4 Conclusions

Anatase TiO_2 nanosheets and nanospindles were applied to support vanadia species for selective reduction of NO with ammonia. The preferential exposure of reactive {001} crystal facet on TiO_2 nanosheets favored the selective deposition of octahedral vanadia species; whereas TiO_2 nanospindles that were dominated by the {101} facet induced the formation of tetrahedral VO_x species. This finding demonstrates the importance of morphology in the preparing efficient VO_x/TiO_2 catalysts.

Keywords: 3DOM, materials, platinum, nanoparticles, TMO, core-shell, structure, soot combustion

1 Introduction

Soot particle emitted from diesel engine vehicles is one of probable precursors to damage the human health. Development of catalysts, which decrease the emission amount of diesel soot, is one of the focus research topics in the field of environmental catalysis. To design a synthesize high-performance material of catalytic activity, understanding the properties affecting catalytic performance is of great importance. The key challenge is to find effective catalysts for soot combustion that operates at low temperatures. A number of researches show that transition metal oxides (TMO: Ti, Mn, V, Cr, Fe, Co, Ni, Cu, Zn, Ce, etc.) are one of the key components in auto-exhaust treatment catalysts. 3DOM structure oxides will be a valuable and promising catalyst system not only for diesel soot combustion due to their good catalytic properties and big pore sizes but also for catalytic oxidation of hazardous macromolecule organic compounds. However, the catalytic performance is limited by the intrinsic activity of metal oxide. Noble metal nanoparticles are possible choices for enhancing the intrinsic catalytic activety of 3DOM metal oxides. Among the reported catalysts for soot oxidation, Pt-based catalysts are still the best catalytic system, and are also only currently commercialized for practical conditions. The catalytic performance of Pt nanocrystals can be finely tuned by transition metal oxides (TMO) due to the strong metal-oxides interaction. Thus, the shape-controlled synthesis of Pt-TMO nanoparticles over 3DOM Al_2O_3 support is a promising route for enhancing their catalytic activities.

2 Experimental

Synthesis of monodispersed PMMA microsphere, assembly template, and preparation of 3DOM Oxide (e.g., Al_2O_3, ZrO_2) supports by colloidal crystal template (CCT) were method described previously [1-4]. 3DOM Al_2O_3-supported Pt-TMO nanoparticle (NPs) catalysts were synthsized by one-pot process of the gas bubbling-assisted membrane reduction-precipitation (GBMR/P) method just developed in our lab. The typical preparative procedures were described as follows: 3DOM Al_2O_3 support and TMO precursor were also introduced into the H_2PtCl_6 solution (Beaker I). The mixture solution was driven by a peristaltic pump. A reductant solution ($NaBH_4$) in Beaker II was injected to the membrane reactor with two ceramic membrane tubes (Φ 3 mm × 160 mm) by a constant flow pump. Meantime, the hydrogen gas was also injected by the two other membrane tubes. The $NaBH_4$ solution was infiltrated through the abundant holes (d=40 nm) on the wall of the ceramic tubes into the glass tube reactor, where the reduction of metal ions occurred immediately when the two solutions met. After complete consumption of the $NaBH_4$ solution, the precipitation agent ($NH_3 \cdot H_2O$) was added into Beaker II and was injected to the membrane reactor same as the reductant agent by a constant flow pump. The synthesis process was stopped after complete consumption of the precipitation agent solution. The final products were calcined in an oven at 500 ^oC for 1 h and the desired 3DOM Pt-TMO/oxide catalysts were obtained.

3 Results and discussion

Fig. 1 shows SEM (A), TEM (B), STEM (C) and HRTEM (D) images of 3DOM Pt-$CeO_{2-\delta}$/oxide catalysts. The SEM image exhibits that the macroporous material contains a skeleton surrounding uniform close-packed periodic voids with the average diameter of 260±10 nm. The wall thicknesses observed from SEM images are 30±5 nm. 3DOM structures with overlapped pores can be also clearly observed by TEM and STEM images in Fig. 1(B-C). The spherical platinum nanoparticles are anchored evenly over the surface of 3DOM oxide host, and all Pt particles are highly dispersed (Fig. 1C). One Pt nanoparticles on the surface of 3DOM oxide were covered by the $CeO_{2-\delta}$ nano-sheet and formed the core-shell structural Pt-$CeO_{2-\delta}$ nanoparticles (Fig. 1D). The ordered nanostructure with Pt-$CeO_{2-\delta}$ core-shell-type nanoparticles would provide abundant catalytic active sites with low- coordinatively unsaturated ceric cation duo to the maximal contact region of $CeO_{2-\delta}$(shell)-Pt(core)-oxide (support) nanojunction system. Therefore, 3DOM Pt-$CeO_{2-\delta}$/oxide catalysts show high catalytic activities (T_{50}, 340 ^{o}C) for diesel soot combustion under the loose contact between soot and catalysts.

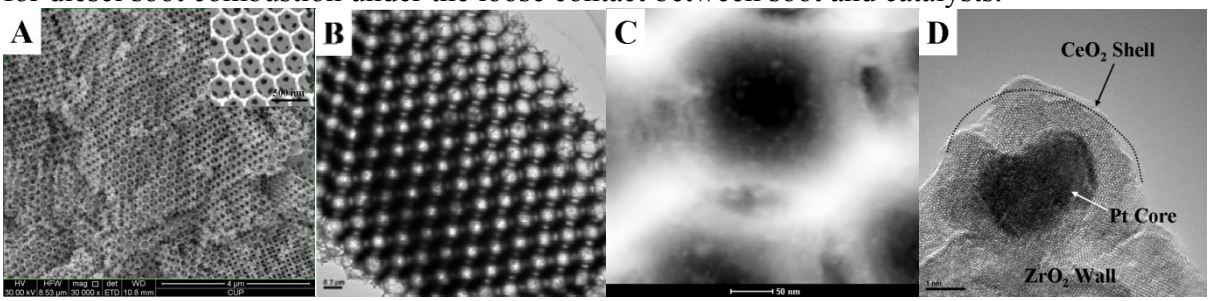

Fig. 1 SEM (A), TEM (B), STEM (C) and HRTEM (D) images of 3DOM Pt@$CeO_{2-\delta}$/oxide catalysts.

4 Conclusions

The catalysts of 3DOM oxides-supported Pt-TMO nanoparticles were synthesized successfully by one-pot GBMR/P method. The mutifunctional materials, which combine both advantages of 3DOM structure and nanoparticles with the maximal contact region of TMO(shell)-Pt(core)-oxides(support) nanojunction system, may be useful for fundamental research on metal-support synergetic effect and potential practical applications in the catalytic oxidation of solid particles.

Keywords: methane, oxidation, OCM, perovskite, crystal, structure

1 Introduction

Substituted rare-earth perovskites with the general formula $A_xA'_{1-x}B_yB'_{1-y}O_{3-\delta}$ (A – rare-earth; A' – Ca, Sr, Ba; B, B'– Mn, Co, Fe, Ni) display a wide variety of fascinating electric, magnetic, optical and catalytic properties. They are particularly promising for total and partial oxidation of hydrocarbons, oxygen conducting media for catalytic membrane reactors, CO and hydrogen generation, electro-, photocatalysis and fuel cells.

It is known, that the perovskite structure allows a large number of ionic substitutions to form new compounds - solid solutions or complex oxide compositions. Such substitutions may result in the formation of A/B-site ordered or completely/partially disordered states giving rise to specific properties not inherent to ABO_3 perovskites. In particular, lead-based complex perovskites belong to a special family of substituted materials (called ''relaxors'') which have extraordinarily high dielectric constants due to the formation of nanoscale ordered regions in a disordered matrix [1].

As to catalytic applications it is generally accepted that the nature of B-site ions is crucial for catalysis on perovskites, while A-side ions have moderate influence on performance. That is why there are numerous papers considering the interrelation between catalytic and physico-chemical properties of B-site cation (including order–disorder phenomena on B-site) but to the best of our knowledge, there is only limited information on correlations between the peculiarities of A-site ion distribution and catalytic performance of $A_xA'_{1-x}BO_{3-\delta}$ mixed perovskites [2]. The aim of this work is the synthesis of A-site ordered and disordered Gd-Sr-cobaltates and the comparison of their catalytic properties in the reaction of CH_4 oxidative conversion.

2 Experimental/methodology

Samples of *annealed* perovskite were prepared by a conventional solid phase ceramic synthesis from Gd_2O_3 (99.99 %), Co_3O_4 (99.7 %) and $SrCO_3$ (99.99 %) powders. The compounds were ground in an agate mortar with ethanol, pressed into pellets and calcined at 1200°C for 12 h in air with intermediate re-grinding and re-pelleting. The final ceramic pellets were ground to the particle size of 100-160 microns, annealed additionally at 1200 °C in air for 1 h and cooled down with cooling rate of 2 °C·min^{-1}.

Samples of *quenched* perovskite with A-site disordered Gd^{3+}/Sr^{2+} ions were prepared from the annealed samples, which were additionally calcined at 1200 °C for 1 h in air and quenched from 1200 °C to room temperature, an estimated ramp rate from 1200 °C to 900 °C was about 30 °C·s^{-1}.

Phase compositions of perovskite catalysts were characterized by X-ray powder diffraction; the full-profile crystal structure analysis was done using the Rietveld method with the derivative difference minimization refinement [3]. Simultaneous thermal analysis (STA) experiments were

performed on a NETZSCH STA 449C analyzer equipped with an Aeolos QMS 403C mass spectrometer. The oxygen content and non-stoichiometry index δ were calculated using the value of mass loss *(Δm*, %) measured by the thermogravimetric reduction. Tests for catalytic activity were carried out in a fixed-bed 4 mm i.d. quartz reactor under atmospheric pressure with an on-line gas chromatographic analysis of the feed and the product gases.

3 Results and discussion

Crystall structure. XRD patterns of the annealed samples of $Gd_xSr_{1-x}CoO_{3-\delta}$ (x=0.8, 0.9) corresponded well to superstructures with ordered Gd^{3+}/Sr^{2+} ions over A-sites (Fig.1) and anion vacancies over O-sites, similar to that published previously for x=0.8 [4]. In situ high-temperature XRD analysis showed that above 1100°C the superstructure reflections disappeared due to a phase transition to the cubic perovskite phase with randomly distributed Gd/Sr sites and anion vacancies. DSC measurements of annealed samples (20%O_2-Ar, 10°s^{-1}) reveal reversible endo-effects with T_m temperatures at 1074, 1013 and 990 °C for x=0.5, 0.8, 0.9, respectively, which may be ascribed to the cation order–disorder transition. Quenching the samples (x=0.5-0.9) from 1200°C resulted in the preservation of the Gd/Sr-disordered cubic phase which is stable under oxidative conditions (5–20% O_2) at least up to 850°C and slowly transfers to the ordered tetragonal superstructure upon heating above 900°C.

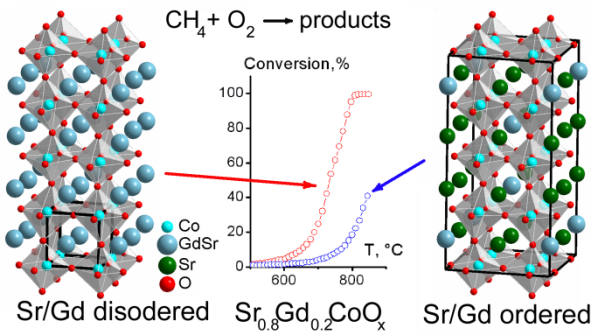

Fig.1 Ordered and disordered structures of $Gd_{0.8}Sr_{0.2}CoO_{3-\delta}$ and light-off curves for oxidation of methane. Feed, CH_4:O_2:He =27:13:60.

Catalytic activity. Thus prepared samples of $Gd_xSr_{(1-x)}CoO_{3-\delta}$ with ordered (annealed) and disordered (quenched) distribution of Gd^{3+}/Sr^{2+} ions demonstrated completely different catalytic activity in CH_4 oxidation, the quenched samples being up to 5 times more active than annealed one (Fig.1) At 360-600°C reaction of deep oxidation of CH_4 prevailed and CO_2 was the only product of CH_4 oxidation but at T>650°C reaction of oxidative coupling of methane (OCM, conversion of CH_4 to C_2-hydrocarbons) starts. The selectivity of methane conversion to ethane+ethylene was found to be higher for samples with ordered Gd^{3+}/Sr^{2+} ions distribution. Kinetic studies of methane oxidation reaction at 360-600°C, O_2 TPD and TPR in hydrogen make it possible to conclude that the observed difference in catalytic behavior of ordered and disordered structures caused by the presence of weakly bound mobile oxygen, which is responsible for deep oxidation of methane on disordered (quenched) perovskites.

4 Conclusions

Cubic perovskite phases with disordered Gd/Sr cations were found to be up to five times more active in the reaction of methane combustion and less selective in OCM than tetragonal perovskite phases with ordered distribution of Gd^{3+}/Sr^{2+} ions over the A-sites of the crystal lattice. Gd^{3+}/Sr^{2+} ion site ordering in Gd/Sr-cobaltates results in the oxygen vacancy ordering. The difference in catalytic performance is attributed to weakly bound mobile oxygen, presented on A-site disordered perovskites, and results from the structure-directed increase in both the amount of mobile oxygen and its mobility in the crystal lattice.

Keywords: *in situ* XPS, Pt/ Al_2O_3 nitric oxide neutralization

1 Introduction

The elucidation of the mechanisms of catalytic reactions as well as mechanisms of catalyst activation and deactivation can be a key to the design of the new improved catalysts. In the sphere of heterogeneous catalysis the investigation of the processes taking place under reaction conditions on the surface of the catalyst demands involving powerful *in situ* surface science techniques such as *in situ* XPS (X-ray photoelectron spectroscopy). At the same time the set of methodical issues has to be resolved when *in situ* XPS is applied. This can be done by using the special constructed systems that model real catalysts.

In the present work, the results of *in situ* XPS study of the NO involved reactions modeling processes of car exhaust neutralization are presented.

2 Experimental/methodology

Thin alumina film with thickness of 1.2 nm formed on the surface of FeCrAl alloy foil was used as support for preparation of model Pt catalysts suitable for *in situ* XPS experiments [1, 2]. γ-Al_2O_3 (specific surface area 225 m^2/g) from Sasol was used for preparation of Pt on alumina catalysts for kinetic experiments. On the surface of both model and porous alumina platinum was deposited from $H_2[Pt(OH)_6]/HNO_3$ aqueous solutions with subsequent reduction in H_2. Samples were characterized by XPS, scanning tunneling microscopy (STM) and transmission electron microscopy (TEM). Pt foil and Pt(100) single crystal were used as bulk catalyst models.

NO decomposition, NO+CO and NO+C_3H_6 reactions were chosen as model processes of NOx neutralization. *In situ* XPS experiments were performed in a VG ESCALAB HP photoelectron spectrometer equipped with a special gas cell (gas phase pressure up to 1 Pa) and a photoelectron spectrometer at the ISIS Beam Station (BESSY II, Berlin) (up to 15 Pa). STM experiments were carried out in a SPM1000 system (RHK Technology). TEM experiments were carried out on a JEOL JEM-2010. ^{15}N isotopic kinetic studies were performed in a static reactor equipped with mass-spectrometry gas phase analysis.

3 Results and discussion

XPS study of NO adsorption on the surface of Pt(100) single crystal at NO pressure 10^{-7} mbar indicates formation of the single nitrogen-containing surface state with N1s line binding energy (BE) of 400.9 eV. According to literature this state can be identified as NO_{ads} [3]. Using XPS gas cell NO pressure was raised up to 0.01 mbar, approaching to the conditions interesting from the stand point of car exhaust neutralization. At this pressure in addition to NO_{ads} the new state shifted to the higher BE at ~1.2 eV and assigned to $(NO)_{2,ads}$ was found [4]. No other nitrogen-containing surface species were observed under NO pressure up to 0.015 mbar in

temperature range from 320K to 670K.

The next step on the way of catalytic car exhaust neutralization investigation would be *in situ* XPS study of the Pt nanoparticles on porous alumina. Unfortunately due to sample charging effect XPS peaks of surface nitrogen-containing species overlap with N1s peak of gas phase when standard X-ray gun is used. As result spectrum deconvolution needs some additional information. Application of XPS with synchrotron radiation is impossible in this case due to the same surface charging effect.

So special constructed model system Pt/AlOx/FeCrAl was used for *in situ* XPS studies of NO decomposition and NO+CO, NO+C_3H_6 reactions. Obtained data were compared with results of static reactor catalytic tests. Only N_2 and N_2O were found as nitrogen-containing products of considered reactions on Pt/γ-Al_2O_3 and Pt foil under static reactor conditions up to 90-100% NO conversion. It was found that NO pre-treatment of the catalysts improves the activity of the supported catalysts, activating the systems. At the same time Pt foil was deactivating gradually after a few cycles of NO decomposition runs when Pt on alumina was still active.

According to *in situ* XPS data three nitrogen-containing surface species, described as N_{sup}, N_{ads} and N_2O_{ads}, were found on the surface of model Pt/AlOx/FeCrAl samples in the presence of NO in gas phase. Interesting that no NO_{ads} was recorded in the case of Pt/AlOx model catalyst as contrasted to Pt(100) single crystal. So the principal difference of surface layer composition between supported and bulk catalysts is found. Supposedly NO activation and decomposition take place on metal particles; N_{sup} forms by the spillover of N_{ads} on the support. Basing on obtained data it can be assumed that nitrogen-containing species of alumina support are involved into reactions. *In situ* XPS study of NO decomposition on Pt foil and Pt(100) single crystal indicates on the accumulation of oxygen (product of NO decomposition) which can be described as oxygen introduced into sub-surface layer of Pt. Used reaction temperature is not enough to remove this oxygen effectively. The observed accumulation results in the fast deactivation of Pt bulk catalysts under NO decomposition conditions.

So under reaction condition the adsorbed layer composition is completely different for supported and for bulk Pt catalysts. Results of investigation of single crystals and foils can't be applied to the real catalytic car exhaust neutralization process directly. As it was shown to get practically important information using powerful *in situ* XPS techniques special model systems should be applied bridging the gap between model and real catalysts.

4 Conclusions

On the base of comparison of *in situ* XPS data obtained for special model catalysts Pt/AlOx/FeCrAl with isotopic kinetic studies of DeNOx reactions on Pt/γ-Al_2O_3 the details of catalyst activation, deactivation and catalytic reactions were studied and the explanations of obtained effects were proposed. Applied approach bridges the pressure and material gap between model and real catalysts and provides information very useful for the practical catalysis.

Keywords: zeolite, SSZ-13, mesopore, surfactant

1 Introduction

Porous materials with the chabazite pore topology containing 6.7 Å × 10.9 Å-sized cavities interconnected by 8-membered rings with pore apertures of 3.8 Å are the preferred catalysts for the Methanol-To-Olefins (MTO) process. Industrially, the Si-substituted AlPO form is used. The use of the more acidic/active aluminosilicate SSZ-13 would be beneficial in practice, if rapid coke formation could be suppressed. One of the approaches to improve stability of SSZ-13 in the MTO reaction is to introduce mesopores in the crystals. Wu et al. [1] succeeded in this by combining TMAdaOH and an expensive diquaternary ammonium type surfactant $C_{22\text{-}4\text{-}4}Br_2$, and the lifetime of mesoporous SSZ-13 was three times higher than that of conventional SSZ-13.
In this study, we present a much simpler, cheaper and industrially scalable dual-templating strategy [2]. It is based on a simple-to-prepare amphiphilic surfactant containing a single N-methylpiperidine head group as quaternary ammonium center (C_{16}MP). We show how it can be used in concert with conventional zeolite structure-directing agents (SDAs) to efficiently downsize microporous domains in SSZ-13 zeolite. This approach is not only very effective as only small amounts of the template need to be added to the synthesis gel, but it also leads to materials with the highest catalytic MTO performance reported so far.

2 Experimental/methodology

In a typical synthesis of conventional SSZ-13 (denoted by SSZ-13-bulk), Ludox AS40, $Al(OH)_3$, NaOH (50 wt%), TMAdOH (25 wt%), and distilled water were mixed to obtain a gel composition of 20 TMAdOH : 7.5 Na_2O : 2.5 Al_2O_3 : 100 SiO_2 : 4400 H_2O. The resulting gel was stirred at room temperature for 2 h and crystallized at 160 °C for 8 days. The hierarchical SSZ-13 (named by SSZ-13-C_{16}MP) was synthesized by the same way, the calculated amount of C_{16}MP was added into the gel and stirred for 2 hours, the final gel was transferred to the autoclave and crystallized statically at 160 °C for 8 days. After crystallization, the zeolite product was filtered, washed with distilled water and dried at 110 °C. The product was calcined at 550 °C for 10 h under flowing air and ion-exchanged three times with 1.0 M NH_4NO_3 solutions followed by calcination at 550°C for 4 h in order to obtain its proton form. Methanol-to-olefins was performed in a fixed-bed reactor at 350°C at a WHSV of 0.8 g $g^{-1}h^{-1}$. The products were analyzed by online gas chromatography.

3 Results and discussion

As shown in Fig. 1, low-voltage scanning electron microscopy (LV-SEM) images show the decreased size of the microporous domains in SSZ-13-C_{16}MP. The zeolite consists of particles with dimensions in the range of 200−500 nm made up from stacked three-dimensional intergrowths of cubic crystals with sizes much smaller than 100 nm. These images also show

mesoporous voids between the primary particles. The mesopores can also been seen by TEM. On contrary, SSZ-13-bulk consists of micrometer-sized crystals with very smooth surfaces.

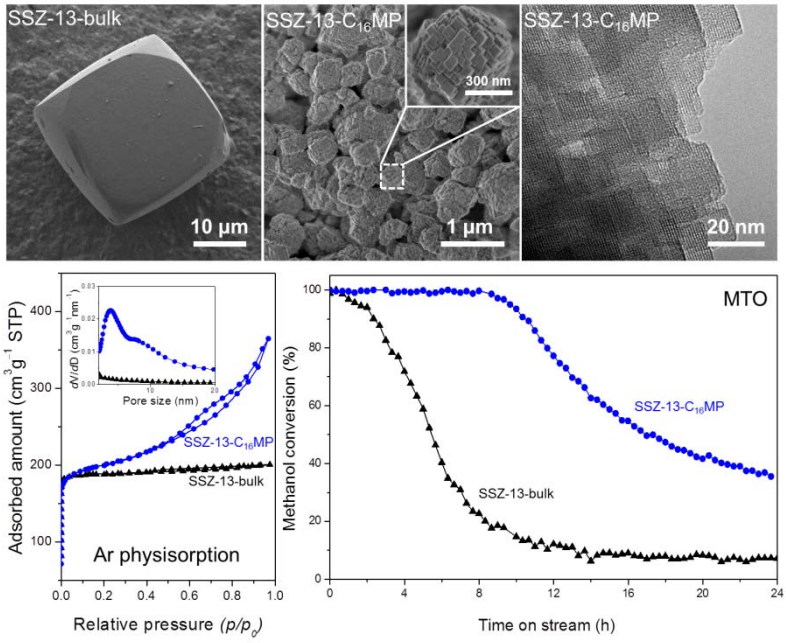

Fig. 1. Morphology, textural, and catalytic properties of SSZ-13-bulk and SSZ-13-C_{16}MP.

The Ar physisorption isotherm of SSZ-13-bulk has the usual type I shape of microporous materials. The additional presence of mesoporosity in SSZ-13-C_{16}MP is evident from the type IV shape of isotherm. The potential of mesoporous SSZ-13-C_{16}MP in acid catalysis was evaluated in the MTO reaction. The catalyst lifetime is defined as the time to reach 50 % of methanol conversion. Initially, all catalysts convert the methanol feed completely. Deactivation of bulk SSZ-13 was rapid and its lifetime was only 5 h. For SSZ-13-C_{16}MP methanol conversion only started decreasing after 9 h. The rate of deactivation was much slower and the lifetime of SSZ-13-C_{16}MP was 17 h. The greatly improved performance is attributed to the smaller microporous domains in the hierarchical zeolite, effectively reducing molecular trafficking distances. Catalyst lifetime of SSZ-13-C_{16}MP was also substantially better than for other mesoporous SSZ-13 reported earlier by us [1]. The total methanol conversion capacity improved from 6 to 24 $g_{methanol}/g_{catalyst}$ for SSZ-13-bulk and SSZ-13-C_{16}MP. Further synthesis efforts show that the C_{16}MP mesoporogen can also be used to generate mesoporosity in ZSM-5 zeolite using diaminohexane as the SDA. However, with tetrapropylammonium as SDA bulk zeolite is obtained. Molecular modeling is used to explain this subtle difference.

4 Conclusions

Hierarchically structured SSZ-13 zeolite has been successfully synthesized using the novel mono-quaternary ammonium surfactant as mesoporogen. The resulting zeolite is highly mesoporous and thus exhibits the highest catalytic performance in the MTO reaction reported so far. Our approach should be generally applicable to other zeolite topologies.

Keywords: cerium, ordered mesoporous alumina, redox, catalysis, isotopic, exchange

1 Introduction

Cerium-based materials are extensively studied because of their remarkable properties that make them interesting for a wide scope of catalytic applications [1]. The importance of CeO_2 is linked to its oxygen storage capacity and mobility, due to the two stable valence states of the Ce^{4+}/Ce^{3+} couple. These properties are improved when the crystallite size of ceria decreases since over pure ceria the phenomenon is limited to the surface and sub-surface layers. In the present study, we performed a series of cerium-doped mesoporous alumina employing the Evaporation Induced Self Assembly (EISA) route [2] and we particularly investigated the redox behaviour of these large surface mixed oxides by using advanced characterization techniques.

2 Experimental/methodology

The materials (Al_2O_3 and CeXAl where X represents the $n_{Ce}/(n_{Ce}+n_{Al})$ molar ratio and correspond to 2, 5, 10, 15 and 20%) were prepared employing a methodology close to the one described by Yuan et al. [2]. The as-synthesized materials were calcined at 400°C under air atmosphere. High surface ceria provided by Rhodia was studied as reference material for comparison.

The samples were characterized by: ICP-OES, XRD, TEM, low temperature N_2 adsorption/desorption isotherms. Redox behaviour and oxygen mobility was evaluated by temperature-programmed-reduction (TPR), oxygen storage capacity complete (OSCC), oxygen isotopic exchange $^{18}O/^{16}O$ techniques, High Field Solid State NMR and X-ray Absorption Near Edge Structure (XANES).

3 Results and discussion

BET surfaces and contents of Ce are reported in Table 1. Pure Al_2O_3, with 322 $m^2\ g^{-1}$ BET surface exhibits mesoporous morphology with hexagonal symmetry as characterized by N_2 adsorption/desorption isotherms and low angles XRD patterns. CeXAl mixed oxides also display amorphous walls and high specific surface area values which decrease when the content of Ce increases. Up to 20 wt% Ce, the mesoporosity is preserved although the hexagonal symmetry of the mesopores disappears progressively on diffractograms and TEM pictures.

Table 1. BET surface area and Ce loading of the CeXAl samples.

Samples	Al_2O_3	Ce2Al	Ce5Al	Ce10Al	Ce15Al	Ce20Al
S_{BET} (m^2 g^{-1})	322	355	350	316	254	256
Ce content (wt%)	-	6.0	11.0	20.8	29.3	35.5

The values of H_2 consumption during TPR as well as the values of CO_2 produced during OSCC are significantly superior to the ones expected based on the behavior of commercial high surface ceria. However the mobility of the oxygen in these samples does not match with the behavior of pure cerium oxide. Combining $^{17}O/^{16}O$ isotopic exchange technique and ^{17}O solid state NMR (Fig.1), we demonstrate that the mobility of oxygen atom from the alumina lattice is improved by the presence of cerium. EXAFS and XANES analyses permit to propose a hypothesis to explain the strong reducibility based on a reversible reaction between amorphous mesoporous Al_2O_3 and very small ceria crystallites (Fig.2).

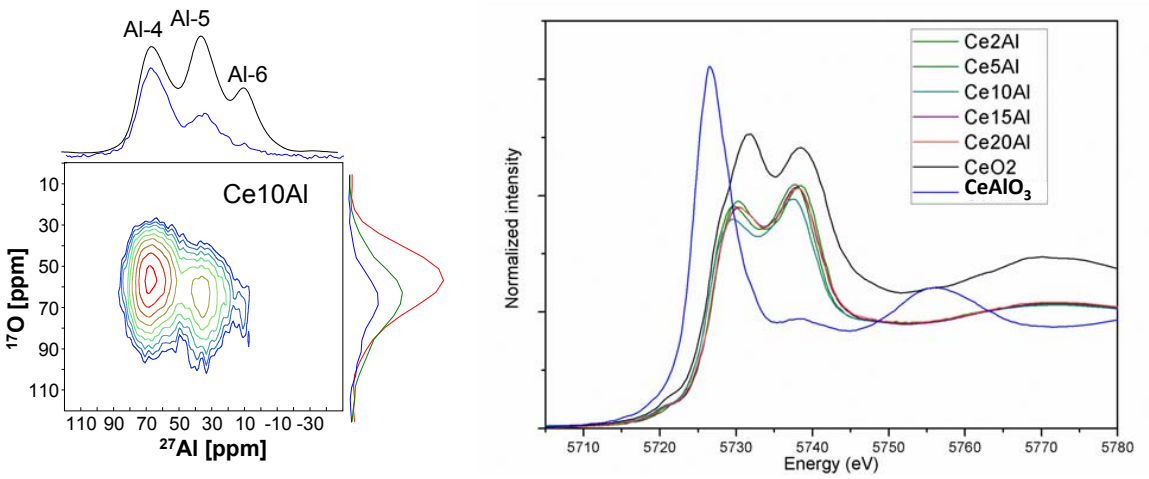

Fig. 1. ^{27}Al-^{17}O heteronuclear correlation spectra of ^{17}O-exchanged Ce10Al sample; b) XANES spectra for the CeXAl samples under oxidation (5%O_2/He) atmosphere.

4 Conclusions

In the present work, cerium-doped large surface alumina samples have been produced. We demonstrated by XANES and OSCC techniques that the high reduction rate of the solids observed at 400°C is reversible. Such properties make these mixed oxides very interesting supports of catalysts for selective oxidation reactions.

Keywords: support functionalization, particle, growth, methanol synthesis

1 Introduction

Metal particle growth is one of the main reasons for catalyst deactivation in commercial copper catalysts for methanol synthesis. The extent of particle growth depends next to the reaction conditions upon the characteristics of the catalysts, e.g. initial metal particle size, support geometry and metal-support interaction [1, 2]. It is difficult to decouple the effects of these characteristics on particle growth, especially for commercial-like catalysts under industrial conditions. In our contribution we report on the sole effect of support functionalization on copper particle growth in the methanol synthesis reaction.

2 Experimental/methodology

Non-porous silica spheres of 30-50 nm in diameter were synthesized and subsequently functionalized with aminopropyltriethoxysilane (APTES) [3, 4]. One weight percent of copper was deposited via incipient wetness impregnation of copper nitrate followed by drying and calcination in N_2 (A) or 2% NO/N_2 (B) gas flow [5]. The extent of surface functionalization was determined with diffuse reflectance infrared spectroscopy (DRIFTS) and ICP. Copper oxide particle sizes were determined with TEM. The temperature at which the copper oxide particles were reduced to metallic copper was determined with temperature programmed reduction (TPR). The wetting of the copper particles was investigated with *in-situ* TEM. The catalytic performance of the copper catalysts in the methanol synthesis reaction was investigated at 40 bars at 260 °C for 10 days. Second order deactivation fits were used to calculate the deactivation constants ($K_{D,2}$).

3 Results and discussion

Functionalization of silica with APTES led to the introduction of amine groups and a loss of free silanol groups on the silica surface as shown by DRIFTS and ICP. Incipient wetness impregnation with copper nitrate followed by calcination led, for the functionalized silica, to a higher copper dispersion. Similar copper particle size distributions for the unfunctionalized and the amine-functionalized silica were, however, obtained when the N_2 flow during calcination of the former was changed to a 2% NO/N_2 flow for the latter catalyst (Figure 1B, D). The subsequent reduction of the copper oxide particles to metallic copper was retarded from 180 to 230 °C in the presence of amine groups, indicating a strong interaction between the copper oxide particles and the support. The wetting of the copper particles after reduction, determined with *in-situ* TEM was identical, indicating similar adhesion of the particles to the support.
The initial activity of both catalysts in the methanol synthesis reaction was similar, but copper on functionalized silica remained more active over time (Figure 1A). Electron microscopy on

the spent catalysts showed significant particle growth for copper on unfunctionalized silica and very limited particle growth for copper on functionalized silica (Figure 1C, E). The most probable particle growth mechanism for these catalysts was Ostwald ripening, since the particles were small (2-3 nm) and relatively distant (>5 nm) to each other [2]. Since the thermodynamic driving force for particle growth was the same for both catalysts, it was concluded that either the formation of mobile copper species or their mobility was slowed down due to the presence of amine groups.

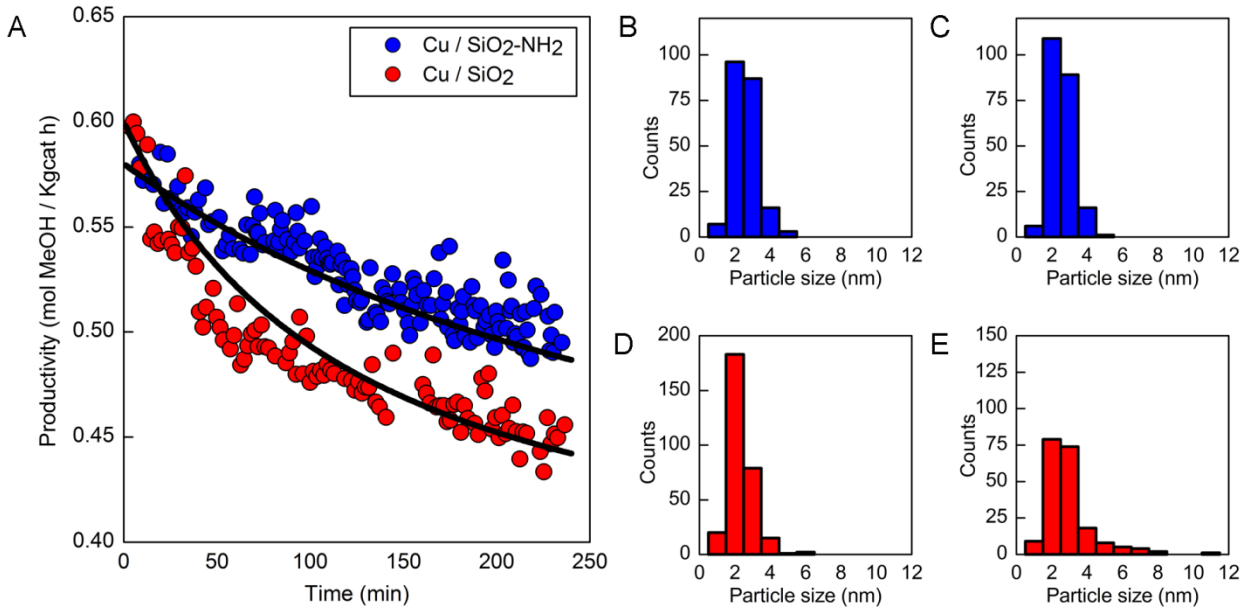

Fig. 1. (A) Catalytic performance of copper on silica (red) and copper on amine-functionalized silica (blue). (B, C) Copper particle size distributions of copper on silica before and after methanol synthesis reaction. (D, E) Copper particle size distributions of copper on functionalized silica before and after methanol synthesis reaction.

4 Conclusions

Functionalizing a silica support with amine groups retarded copper particle growth in the methanol synthesis reaction.

Selective Hydrotreating of FCC Gasoline on K_x-CoMoS/Al_2O_3 Catalysts

Ishutenko D.I.*, Nikulshin P.A., Pimerzin A.A.

Samara State Technical University, Samara, Russia

* dasha.ishutenko@gmail.com

Keywords: FCC gasoline, KCoMoS, HDS/HYD, selectivity hydrotreating, octane, number

1 Introduction

Nowadays in Russia the ecological requirements are moving towards limiting the amount of benzene and aromatic hydrocarbons in gasoline what leads to redistribution of fractions in gasoline pool – the amount of catalytic reforming product decrease and the amount of fractions coming from FCC.

FCC gasoline is characterized by great amount of olefins (to 40 wt.%) and high level of sulfur content (to 1.5 wt.%) [1]. One of the most efficient way of upgrading FCC gasolines is hydrotreating. But unsaturated hydrocarbons are quite reactive in hydrotreating conditions what leads to hydrogenation and reduction of octane number consequently. The solution of this problem is selective hydrodesulfurization which allows to reduce total sulfur content and to minimize octane loss. Conventional hydrotreating (HDT) catalysts, sulfided Co(Ni)Mo/Al_2O_3, possess both HDS and HYD activities which levels are high. So HDS/HYD selectivity of such catalysts is low and does not satisfy the requirements for hydrotreating of FCC gasoline. Therefore, design of catalyst with high HDS and low HYD activities (i.e. with high HDS/HYD selectivity) is greatly desired. One of the effective method to improve HDS/HYD selectivity of TMS catalysts is modification with alkali metalls [2].

The aim of the work was the comparison of catalytic properties of industrial and laboratory (K)-CoMoS/Al_2O_3 catalysts synthesized with the use of molybdenum heteropolycompound (HPC) in HDS of FCC gasoline.

2 Experimental

Catalysts were synthesized by means of the incipient wetness technique via impregnation of the alumina with the aqueous solutions of precursors ($H_3PMo_{12}O_{40}$, $CoCO_3$, citric acid and KOH) with following drying and liquid-phase sulfidation.

Physical-chemical characteristics of catalysts were determined with the use of the following techniques: low-temperature nitrogen adsorption, Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), high-resolution transmission electron microscopy (HRTEM), NH_3-TPD, H_2-TPR.

Catalytic activity examination was carried out in a bench-scale flow reactor in hydrotreating of heavy fraction of FCC gasoline under the following conditions: temperature of 240-320 °C, pressure of 1.5 MPa, LHSV of 4.5-10.0 h^{-1}, H_2/feed ratio of 100 nl/l. The performance of synthesized catalysts was estimated with conversions of sulfur and olefinic compounds and HDS/HYD selectivity that calculated as a ratio of HDS and HYD rate constants.

3 Results and discussion

Modifying catalyst with potassium leads not only to significant changes in physical-chemical properties but also to considerable changes in catalytic activity and HDS/HYD selectivity. Thus, with the growth of the process temperature we observed increase of both HYD

and HDS activity on all catalysts, but process temperature over modified sample impacted less significant than for unmodified and industrial ones. Besides sulphur conversion levels on K-$CoMoS/Al_2O_3$ catalyst were comparable with the results obtained on industrial and unmodified samples, whereas HYD activity was sufficiently lower. That resulted in maximum of HDS/HYD selectivity at 280°C over modified catalyst. Meanwhile industrial sample showed HDS/HYD selectivity around laboratory $CoMoS/Al_2O_3$ catalyst and about 2.5 times lower than modified one.

For all three catalysts kinetic characteristics such as reaction order, activation energy and preexponential factor were calculated (Fig.1). It was established that in hydrotreating of FCC gasoline on CoMo catalysts HYD reactions are described by first order kinetic equation, whereas HDS reactions are described by kinetic equation of 1.33 order what is in agreement with data published earlier [3]. Both activation energy and preexponential factor of HDS as well as HYD for unmodified catalyst were higher than similar for industrial sample, what can indicates the formation of active centres with different nature during preparation stage. Modifying with potassium led to decrease of activation energy and preexponential factor of HDS and HYD, so it can be conclude, that using alkali metal promotes changing the nature and amount of both types of active sites.

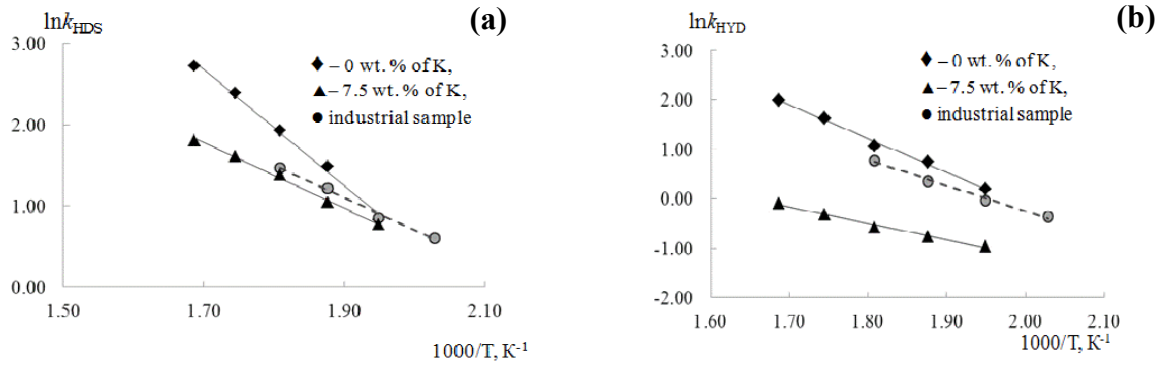

Fig. 1. Arrhenius plots of rate constants of HDS (k_{HDS}, wt.$^{-0.33}$·% h^{-1}) (**a**) and HYD (k_{HYD}, h^{-1}) (**b**) over K_x-$CoMoS/Al_2O_3$ catalysts

Changing the strength of HDS and HYD active sites connected with the reduce of apparent activation energy for both reactions what evidently is a result of donor properties of alkali metal. Decreasing the active centers amount is conformed with the reduction of preexponential factor for K-$CoMoS/Al_2O_3$ catalyst in comparison with $CoMoS/Al_2O_3$ sample. Besides, it can be mentioned that apparent activation energy and preexponential factor of HDS reactions for modified catalyst is similar to industrial sample whereas for HYD reactions all that characteristics are lower.

4 Conclusions

Modifying TMS catalysts with alkali metal leads not only to changing of physical-chemical characteristics but also catalytic properties and kinetic characteristics as well. Using potassium in catalyst synthesis results in changing of both active sites nature and amount.

Immobilized Grubbs Catalysts on Mesoporous Materials: New Insights into Support Characteristics and their Impact on Catalytic Activity and Product Selectivity

Dewaele A., Van Berlo B., Dijkmans J., Jacobs P., Sels B.*

Center for Surface Chemistry and Catalysis, KU Leuven, Leuven, Belgium

* bert.sels@biw.kuleuven.be

Keywords: heterogeneous, catalysis, ring-opening, ring-closing, metathesis, ruthenium, mesoporous materials, macrocycles

1 Introduction

Since the discovery of ordered mesoporous silica (OMS), this research area has developed greatly over the years leading to materials with unique opportunities for applications in heterogeneous catalysis, including the immobilization of Ru metathesis catalysts. Recently a new and practical immobilization strategy of Hoveyda-Grubbs complexes on silica supports by non-covalent adsorption was reported by Van Berlo *et al*. [1]. Later, this adsorption concept was studied and expanded successfully by others on OMS (e.g. MCM-41, SBA-15) [2-7]. Despite the evaluation of some silica materials as support structure for the physisorbed immobilization of Grubbs complexes in different studies, no profound study concerning the influence of the different textural and structural characteristics of mesoporous silica and of the immobilization process on the catalytic performance has been done since. In search for the ideal catalyst for the ring-opening ring-closing metathesis (RO-RCM) of cyclooctene to form macrocycles, we here extent this research area by systematically investigating in detail the impact of several textural and structural parameters of the support like pore size, pore architecture, surface area and morphology on the catalytic activity and product selectivity of the immobilized Hoveyda-Grubbs 2nd generation catalyst (HG 2). The optimal support-catalyst system is used to unravel the reaction pathways of RO-RCM of cyclooctene to cyclic oligomers under heterogeneous catalysis conditions.

2 Experimental/methodology

Immobilization of the mesoporous support was performed by adding a solution of HG 2 in toluene (1.57 mM, 2.5 mL) to the support (0.1 g). After 30 min. of stirring, the heterogeneous catalyst was thoroughly washed with hexane and dried. RO-RCM reactions of cyclooctene (0.05M) were performed in glass reactor vials in hexane (5 mL) with 50 mg of the immobilized catalyst at 35 °C. The reaction mixture was analysed by GC and GPC.

3 Results and discussion

The best support characteristics for immobilization of the HG 2 catalyst were defined to obtain a maximal activity in the RO-RCM of cyclooctene. This was accomplished by scrutinizing on one hand textural and structural parameters of the support, as well as investigating surface properties like surface adsorption, silanol density and catalyst loading. Hereby typical heterogeneous aspects such as pore diffusion limitations were examined. Immobilized ordered mesoporous silica MCM-41 and TUD-1 were found to answer these conditions best, and resulted in highly active catalysts. The activity of both supports was greatly improved by a temperature treatment prior to immobilization in order to obtain a high amount of free surface silanols, which are used as anchoring points during the immobilization. Among

these two supports, TUD-1 has a higher affinity for HG 2 than MCM-41 at low Ru loadings due to a greater fraction of geminal silanols on the former structure. Furthermore, since MCM-41 has smaller pores, it is more prone to diffusion limitations compared to TUD-1 at high Ru loadings. This phenomenon originates from linear polymer obstruction and is even more pronounced in cage-like pore systems. As a consequence, this affects product selectivity.

With an optimized catalytic system the ideal conditions to obtain a high selectivity to C16-C56 cyclic oligomers, valuable intermediates in *e.g.* lubricant and fragrance industry, under batch conditions were investigated. Unraveling the reaction pathways of the RO-RCM of cyclooctene, the mechanistic understanding led to optimal conditions for synthesizing macrocyclic oligomers (Fig. 1). At low monomer concentrations (0.05 M), performing reactions under a kinetic regime (low Ru loadings of 0.3 wt%), and at full conversion, selectivities of 70 % to the C16-C56 cyclic oligomeric fraction were obtained.

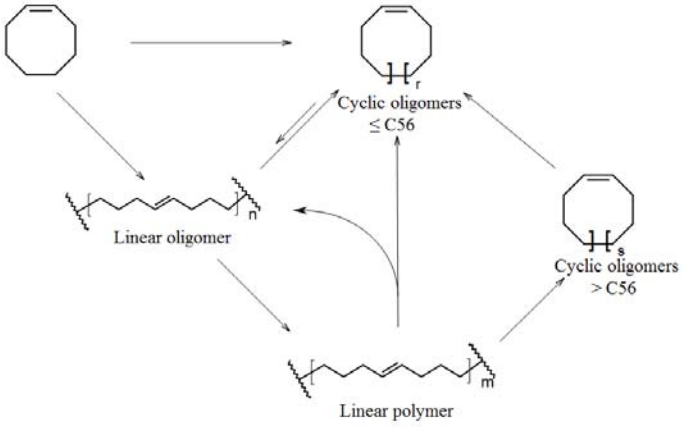

Fig. 1. Proposed reaction scheme for the ring-chain equilibrium of cyclooctene with HG 2/MCM-41.

4 Conclusions

Screening of OMS and study of the immobilization process brought on one hand new insights into the support characteristics and treatment needed for an economically favorable RO-RCM reaction. On the other hand it led to a better understanding of the reaction mechanism of the RO-RCM of cyclooctene under heterogeneous conditions to direct the reaction to the desired end product.

Keywords: nanoreactors, 4-nitrophenol, mechanism, AuPd, nucleus, shell

1 Introduction

The selective hydrogenation of the nitro groups is an important transformation since many produced aromatic amines have multiple industrial applications. Among different tested catalytic systems, Au-based catalysts showed high performance in the reduction of 4-nitrophenol (4NP) into 4-aminophenol (4AP) [1, 2]. It has been reported a catalytic enhancement in this reaction when Pd and Au are combined [3]. On the other hand, the encapsulated nanoparticles (nuclei) into porous matrices (shells) have become attractive due to their high catalytic stability. These relatively new structures have been called as nanoreactors (NRs) and are encoded as nucleus@shell [4]. There are only few reports in the literature dedicated to the encapsulation of AuPd NPs into porous oxide shells [5, 6]. Till now, no data about the reduction of nitro compounds over AuPd@Oxide NRs is presented in the literature.

This paper is devoted to the analysis of the 4NP reduction into 4AP over AuPd-based NRs.

2 Experimental protocol

The bottom-up route was used for the synthesis of AuPd-based nanoreactors with shells of PVP, SiO_2 or ZrO_2. Briefly, free AuPd NPs with different Au:Pd molar ratios (20:1 and 3:1) were prepared using Au NPs as seeds as in [7]. AuPd@PVP NRs were obtained by AuPd NPs treatment in PVP (Mw=10,000). AuPd@SiO_2 composites, synthesized using a modified Stöber method to encapsulate AuPd NPs into silica, were exposed to a surface protecting etching with a concentrated base for the synthesis of AuPd@SiO_2 NRs or used as a hard template for AuPd@ZrO_2 NRs [8].

The reduction of 4NP was carried out under magnetic stirring at 25°C in a quartz cuvette (1 cm of optical path) placed into temperature controlled holder (CUV-UV/VIS-TC, Avantes). UV-Vis spectra were recorded every 2 seconds using set-up including light source (AvaLight- DHS, Avantes) and UV-Visible spectrometer (Ava- Spec-2048, Avantes). Before injection of aqueous suspension of nanoreactors (28-100 µL, 7.1 10^{-3} µmol Au) the reaction mixture of 4NP (10 µL, 30 mM), $NaBH_4$ (3.7 mL, 1 mM) and H_2O (290 µL) was stirred during 15 min. The individual spectral components were resolved by the principal component analysis method [9] from the experimental UV-Vis spectra collected during the reaction.

3 Results and discussion

It was revealed that the reduction of 4NP over obtained NRs (Fig. 1, left) proceeds through:

1) direct reduction to 4AP and 2) indirect reduction via condensation of intermediates of 4NP partial reduction with their consequent reduction to 4AP. Kinetic constants (Fig. 1, right) were estimated by the fitting of experimental profiles for 4NP, 4,4-azobiphenol and 4AP with simulated ones. The deposition of Pd on the surface of Au NPs favored the steps of reduction. Encapsulation of NPs into the PVP shells affected the mass transport in particular for Au-based NRs. PVP diminished the contribution of the indirect route while ZrO_2 shell drastically increased it. Interestingly, activity for Au_3Pd_1@PVP NRs was higher than that for free Au_3Pd_1 NPs. The latter seems to be related with the partial surface reconstruction of Au_3Pd_1 nuclei due to the contact with PVP shell.

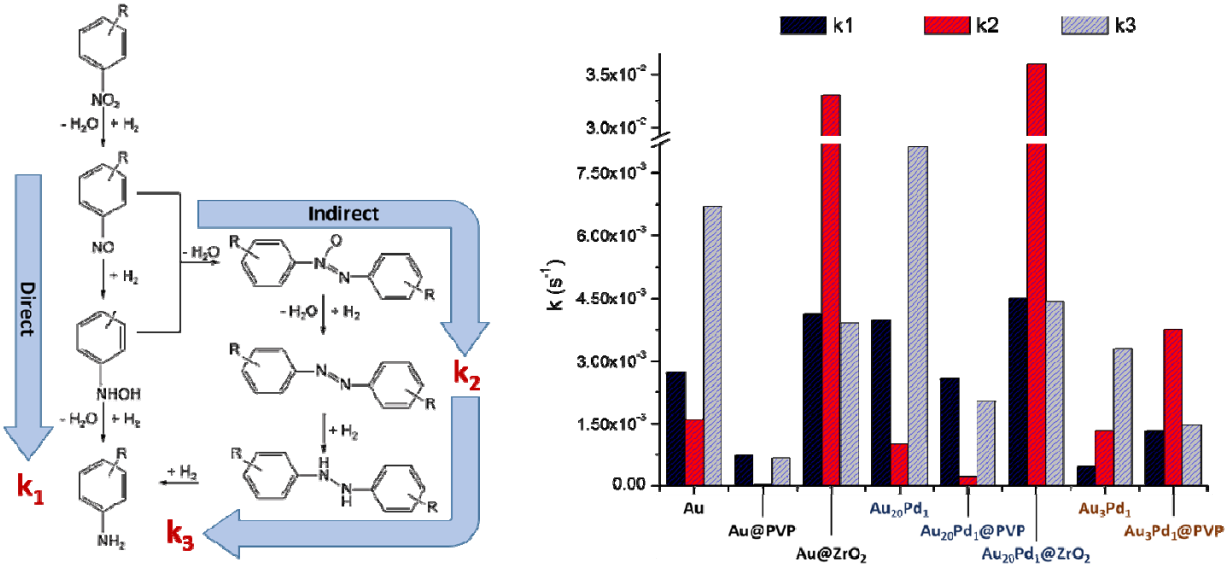

Fig. 1. Reaction scheme for the reduction of aromatic nitro compounds proposed by Haber [10] (left). Estimated reaction rate constants (k_1, k_2 and k_3 for scheme on left) for the 4NP reduction over free NPs, NPs@PVP and NPs@ZrO_2 NRs (right).

4 Conclusions

The presence of AuPd species on the surface of nanoreactor's nuclei favors the reduction steps while oxide shell participates in the reaction mechanism provoking indirect route of the 4-aminophenol formation through condensation of intermediates.

1 Introduction

Today the necessity for propylene is rapidly increasing due to the increasing demand of polypropylene, propylene oxide, etc. Today increased propylene production is one of the most significant objectives in petroleum chemistry. Deep-cracking [1], metathesis of ethylene and 2-butenes [2] and the direct conversion of ethylene to propylene are applied and suggested for solving this problem. Direct conversion of ethylene to propylene without any addition of other hydrocarbons is the most desirable route, but no single catalyst with high ethylene conversion and propylene selectivity has been found so far. In our previous reports, NiO-Re_2O_7/B_2O_3-Al_2O_3 and PdO-Re_2O_7/B_2O_3-Al_2O_3 bimetallic catalysts [3, 4] showed good performance for direct conversion of ethylene to propylene with high propylene selectivity. The explanation was given by a mechanism that consist of three steps in which ethylene dimerization on Ni or Pd sites affords 1-butene that can be isomerized to 2-butene on acidic sites as the first and the second steps followed by metathesis reaction of the 2-butenes and non-reacted ethylene on Re sites. In earlier reports [5] it was shown that supported PdO catalysts can be highly active in ethylene dimerization at low temperatures (25°C). This fact is determined by the Pd application in the preparation of catalysts for the direct conversion of ethylene to propylene. The aim of our studies is preparation a new PdO-Re_2O_7 catalyst, based on SO_4^{2-}/ZrO_2 for the direct conversion of ethylene to propylene at mild conditions (reaction temperature up to 100°C, atmospheric pressure). Special attention is paid to the influence of the supported metal oxide (PdO, Re_2O_7) content, to the support nature and to the several the preparation procedures of PdO-Re_2O_7/SO_4^{2-}/ZrO_2 catalysts: impregnation with aqueous solutions of H_2PdCl_2 and $HReO_4$ in different order.

2 Experimental

A series of supported PdO catalysts with different Pd loading (between 0.2 and 5 wt. %) were prepared by the impregnation of SiO_2-Al_2O_3 (12% Al_2O_3) with an aqueous solution of H_2PdCl_4, followed by calcination in air at 550°C. A series of catalysts based on supports with different supports nature (SiO_2, t-ZrO_2, γ-Al_2O_3, B_2O_3-Al_2O_3, SO_4^{2-}/Al_2O_3, SO_4^{2-}/ZrO_2) containing 1 wt. % PdO were prepared also by the impregnation and were characterized by HRTEM/EDX, TPR and XPS. Ethylene dimerization over supported PdO catalysts was carried out in a fixed bed reactor at 50 and 100°C, atmospheric pressure and WHSV of 0.5 h^{-1}. Three series of catalysts for direct ethylene to propylene conversion were prepared by impregnation of SO_4^{2-}/ZrO_2 with aqueous solutions of H_2PdCl_4 and $HReO_4$ in different order, each impregnation being followed by calcination in air at 550°C. These series of catalysts are loaded 1 wt. % of PdO and 2, 5, 10 wt. % of Re_2O_7 (in nominal). Direct conversion of ethylene to propylene over PdO-Re_2O_7/SO_4^{2-}/ZrO_2 catalyst was also carried out in a fixed bed reactor at 40 and 80°C, atmospheric pressure and WHSV of 0.5 h^{-1}. The products of the reaction were analyzed with online gas chromatography.

3 Results and discussion

At 1 wt. % PdO loading, ethylene conversion and 2-butene selectivity over PdO/SiO_2-Al_2O_3 had

maximum: 80.0 % and 20.0 %, respectively. Considering this data, influence of supports nature for the dimerization and isomerization functions on Pd-containing catalysts was studied. The PdO/SiO_2, PdO/Al_2O_3 and PdO/ZrO_2 showed low conversion (at the most of 4-6 %) in ethylene dimerization. As well as PdO/SiO_2-Al_2O_3 catalyst, the catalysts based on anion-modified supports ($PdO/SO_4^{2-}/Al_2O_3$, PdO/B_2O_3-Al_2O_3, $PdO/SO_4^{2-}/ZrO_2$) indicated high ethylene conversion: from 60.0 to 79.0 %. High ethylene conversion can be attributed to stable Pd cationic form and highly-dispersed Pd-containing particles on the surface with different supports nature (XPS, and TPR analysis data). Maximum selectivity of 2-butene (up to 90%) is achieved with $PdO/SO_4^{2-}/ZrO_2$ catalyst. Thus, SO_4^{2-}/ZrO_2 support was used for preparing a new catalyst for the direct conversion of ethylene to propylene at mild conditions. Influence of the preparation method and Re_2O_7 content in the PdO-$Re_2O_7/SO_4^{2-}/ZrO_2$ system was studied. Optimal method of catalyst preparation is impregnation of support by solution of palladium precursor and then by solution of rhenium precursor, each impregnation being followed by calcination in air at 550°C (a series of Pd-Re catalysts). The maximum yield of propylene (62.1 wt. %) was achieved on the PdO-$Re_2O_7/SO_4^{2-}/ZrO_2$ catalyst with 4.1 wt. % Re_2O_7 at the temperature of 80˚C (Table 1).

Table 1. Catalytic performance of PdO-$Re_2O_7/SO_4^{2-}/ZrO_2$ catalysts (at 80°C).

Catalyst	Composition (wt.%)			Reaction time (h)	Conversion of ethylene (%)	Yield of propylene (wt.%)	Selectivity (%)		
	Re_2O_7	PdO	SO_4^{2-}				Propylene	2-butene	C_{5+}
Pd-Re-10	4.1	1.1	7.3	0.2	81.9	62.1	75.8	10.1	14.0
				1	48.9	17.9	36.6	46.6	16.8
Pd-Re-5	3.6	1.1	7.3	0.2	81.9	49.8	60.8	7.2	32.0
				1	56.3	25.3	44.9	37.7	17.4
Pd-Re-2	1.9	1.1	7.3	0.2	86.1	56.3	65.4	26.5	8.0
				1	62.6	27.9	44.6	38.1	17.4

4 Conclusions

A series of Pd-Re catalysts, which was prepared with the impregnation of support by solution of palladium precursor and then by solution of rhenium precursor, exhibited ethylene conversion, lower than for other two series. But at that a series of Pd-Re catalysts showed high propylene yield (42.4-55.2 wt. % at 40°C and 49.8-62.1 wt. % at 80°C), and that the initial activity depends on the Re_2O_7 content in the catalysts. Thus, PdO-$Re_2O_7/SO_4^{2-}/ZrO_2$ catalyst exhibits a higher propylene yield in the direct conversion of ethylene to propylene at mild conditions (reaction temperature up to 100°C, atmospheric pressure).

1 Introduction

Process Intensification (PI), which is defined as "any chemical engineering development that leads to a substantially smaller, cleaner, safer and more energy efficient technology", is likely to be the next revolution of the chemical industry [1]. The technology of membrane reactor plays an important role in PI and is based on a device combining a membrane based separation and a catalytic chemical reaction in one unit. DEMCAMER - DEsign and Manufacturing of CAtalytic Membrane Reactors by developing new nano-architectured catalytic and selective membrane materials" is a large scale collaborative project including 18 European organizations as consortium participants. The aim of DEMCAMER is to develop innovative multifunctional Catalytic Membrane Reactors (CMR) based on new nano-architectured catalysts and selective membrane materials to improve their performance, durability, cost effectiveness and sustainability (lower environmental impact and use of new raw materials) over four selected chemical processes for pure hydrogen, liquid hydrocarbons and ethylene production [1]:

- Autothermal Reforming, (ATR)
- Fischer-Tropsch Synthesis, (FTS)
- Water Gas Shift, (WGS)
- Oxidative Coupling of Methane, (OCM)

DEMCAMER will bring the proof of concept of these novel CMRs by the set-up and validation of pilot prototypes relevant for each process [1]. The research activity of the team from Boreskov Institute of Catalysis (BIC) focused on the development of novel catalyst materials for ATR of CH_4 and OCM processes as well as quantum-chemical modeling. These studies will be applied to understand the structure-property-performance relationships.

2 Experimental

For each process four different catalyst generations have been developed. For each catalyst generation, 8-10 catalyst formulations have been prepared varying the type of support, the nature of the active phase, the addition of promoters and/or the method of preparation. The effect of following parameters on the physicochemical properties of catalysts and their performance in the reaction were studied:

ATR of CH_4:

- active component (Ni, Pt, Rh, Pd)
- support composition (La_2O_3, $Ce_xZr_{1-x}O_y$, $Ce_xGd_{1-x}O_y$, $La_2O_3/Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$,)
- promoter type (Mo, Re, Sr, Sn, Pt, Pd)
- method of preparation (citrate sol-gel method, Pechini method, impregnation)
- calcination, pre-treatment and ATR reaction conditions

OCM:

- type of catalyst system (catalysts based on tungsten and promoted with manganese and rare earths and supported on conventional silica carrier; catalysts based on rare earth and alkaline earth metal oxides)
- metal contents
- promoter type (La, Ce, Zr, S, P, Cl)
- preparation mode (citrate sol-gel method, sequential impregnation, mixture slurry method)
- calcination, pre-treatment and OCM reaction conditions.

Moreover, some catalysts have been also prepared by the POSS® nanotechnology implemented by Hybrid Catalysis. In order to identify the Red-Ox, textural, surface and structural characteristics of catalysts influencing catalytic activity and stability detailed characterization of catalyst systems in both fresh and used state has been performed by a complex of methods (N_2 adsorption, XRD, TPR, HRTEM-EDX, TG-DTA, XPS and ESDR). The design and assembling of the kinetic setup for the studies of catalytic activities in ATR and OCM process have been done. The screenings of prepared catalysts as well as stability tests (up to 100 h) have been carried out. The optimal reaction conditions to achieve the maximum efficiency in the hydrogen production from ATR and C_2 hydrocarbon production from OCM were determined.

3 Results and discussion

Detailed physicochemical characterization of fresh and used catalysts combined with catalytic activity measurements have allowed to determine the correlation between composition, preparation conditions and activity and stability of the developed catalysts [1-4]. From catalyst screenings and durability tests in the laboratory set-up, the final optimal catalyst composition and preparation mode were selected, with emphasis on the catalyst nanostructure control, as final catalyst generation for scale-up and conformation for testing at pilot scale. For ATR of CH_4 the $NiPd/Ce_{0.5}Zr_{0.5}O_2/Al_2O_3$ catalyst prepared by Pd/Ni sequential impregnation showed high activity (methane conversion > 90%, hydrogen yield > 80% at 850^{o}C), resistance to carbon formation and deactivation by sulfur during 100 h of operation under reaction feed containing 50 ppm of H_2S. $MnNaWLa/SiO_2$ catalyst prepared by sequential impregnation method at optimized conditions showed high activity (methane conversion > 50%, C_2 yield > 18%) during 24 h of the OCM reaction at 800^{o}C.

4 Conclusion

The rational preparation procedures and perspective composition of catalysts for ATR of CH_4 and OCM have been developed. Final catalyst generation developed for each processes showed high values of activity, selectivity and stability in compliance with the DEMCAMER targets.

Keywords: TAP, Reactor, MOFs, intraparticle, diffusion, porous, transport, transient, kinetics

1 Introduction

Metal organic frameworks (MOFs), formed from metal complexes joined by organic linking structures, are a distinctive class of nanoporous material with high surface area and pore volume. While zeolites have greater thermal and chemical stability, MOFs offer a greater degree of flexibility for pore size and surface chemistry according to the selection of the linking molecule. The TAP (Temporal Analysis of Products) vacuum pulse response technique [1,2] offers a unique characterization of adsorption kinetics and intraparticle transport in nanoporous materials [3,4] with a number of advantages. In particular, the measurement is made at low pore occupancy where molecules can freely diffuse and processes occurring on the external surface can be distinguished from processes that take place in the porous confines. Here we present a probe molecule filtering that results under TAP conditions where only molecules that have a finite surface lifetime gain access to the pore. This offers an advanced tool for materials characterization that can distinguish properties that are not observable with conventional techniques.

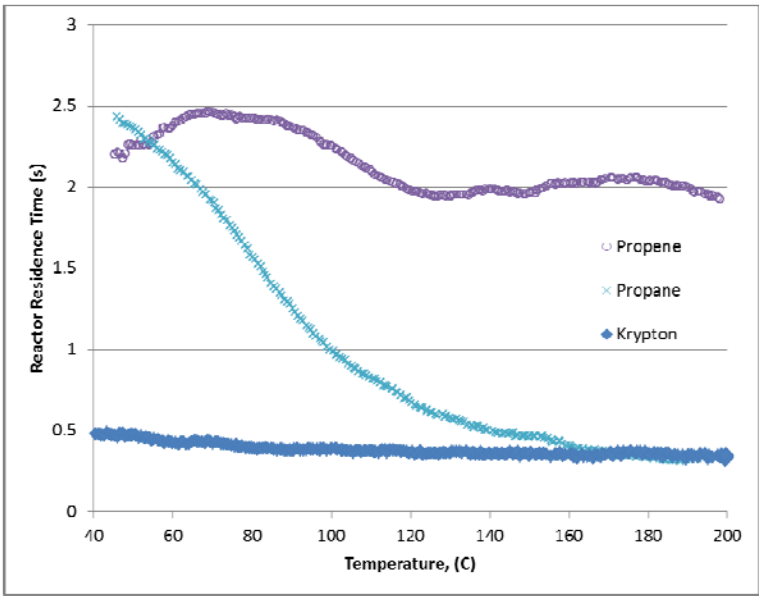
2 Experimental/methodology

A TAP pulse response experiment, described elsewhere [5], starts with a very small (10 nmol) pulse of probe molecule/inert molecule mixture at the entrance of a microreactor packed in three zones with two larger sections of inert (SiC) particles separated by a thin zone of active material. At the exit of the microreactor (10^{-8} torr) a mass spectrometer collects the pulse response. 6 mg of a commercial sample of the HKUST-1, $Cu_2(C_{12}H_4O_8)$, MOF produced by BASF under the tradename Basolite®C300 was tested in the TAP reactor using various probe molecules (methane, ethane, propane, propene, butane, butene, krypton, etc.). The reactor temperature was slowly (2 °C/min) decreased from 200 – 20 °C while pulsing every 10.1 seconds. The evolution of the pulse response curves with temperature was collected. Data was analyzed using the moment-based technique and applied to an adsorption model of porous diffusion using the basic kinetic coefficient approach to the state-defining experiment as described by Shekhtman et al. [6].

3 Results and discussion

Due to the low number of collisions in the gas phase during a TAP experiment, when the kinetic diameter of the diffusing species is similar to the pore diameter, only molecules with a finite lifetime on the external surface will have the opportunity to enter the intraparticle space. The evolution of reactor residence time is shown in Figure 1 when propene, propane and krypton are pulsed over the HKUST-1 material in separate experiments as the temperature changes. At temperatures above 180 °C the reactor residence time for propane and krypton is

similar and is generally governed by diffusion through the particle bed: $D \propto \sqrt{8RT/\pi M_w}$. Propane and propene, being of similar molecular weight should exhibit similar Knudsen transport but the presence of a double bond results in a much higher reactor residence time. As the temperature decreases the residence time for krypton follows the dependence for Knudsen transport through the reactor but the residence time for propane dramatically increases indicating a kinetic process. The dependence for propene is characterized by two plateaus that can be explained by a strong interaction of the double bond with the catalyst and a significant contribution of intraparticle diffusion.



We present a kinetic model describing the competing processes of entering the pore and desorbing from the external surface. Applying this kinetic model to the TAP experimental configuration we can distinguish time delays in pulse response curves that are due to the residence time in pores from those caused by adsorption on the external surface.

Fig. 1. Reactor residence time as a function of temperature for different probe molecules (propene, propane and krypton) pulsed over the HKUST-1 material.

4 Conclusions

Under TAP pulse response conditions, when the size of the probe molecule is similar to that of the pore size, an energy barrier exists for entrance to the porous confines that can be described as a kinetic process. This enables a measurement of properties *intrinsic* to the material structure and surface chemistry that are not observable under standard conditions. Characteristics unique to the external surface and internal confines can be used to better distinguish different candidate materials for applications development.

Keywords: CoPd/AlOOH catalysts, Capping agent, Formic acid, Hydrogenation, Succinic acid

1 Introduction

In the current era of energy crisis, researchers are striving to develop technologies to maintain a balance between conventional petroleum feedstock and renewable biomass resources through catalytic approaches. Various studies on the catalytic dehydrogenation of formic acid (FA) into hydrogen is an appreciable contribution to these developments [1]. FA, a convenient hydrogen storage material [2], can be obtained from biomass in high yields [3]. Despite of amazing research attainments in FA dehydrogenation, limited efforts were made to substitute dangerous and difficult-to-handle H_2 under greener conditions. The Pd-based catalysts were found to be effective in promoting the dehydrogenation of FA [4], where the dehydrogenation catalysis can be enhanced by doping a transition metal (such as Co) to promote the 2-electron oxidation pathway of FA [5]. It has also been understood that the chemical, physical and geometrical properties of metallic NPs can be considerably influenced in the presence of capping agents to have a marked impact on their catalyses [6]. In this contribution, we demonstrate the synthesis of boehmite (AlOOH) supported capped CoPd NPs for the hydrogenation of maleic anhydride (MAn) using FA as a hydrogen source [7].

2 Experimental

Material synthesis: A homogeneous solution containing requisite amounts of $Co(OAc)_2 \cdot 4H_2O$ and/or $Pd(OAc)_2$ with/without capping agent were added to AlOOH (S_{BET}: 465 $m^2\ g^{-1}$) dispersed in water. A hydrothermal treatment of the resulting mixture at 453 K afforded mono-/bi-metallic catalysts after drying *in vacuo* overnight at room temperature.

Catalytic activity: In a general reaction procedure, maleic anhydride (MAn, 0.5 mmol) in deionized water (5 mL) and catalyst (25 mg) were weighed in a Teflon vessel (50 mL). After addition of FA (1.9 mmol), the autoclave was sealed and heated at 353 K for 3 h. The conversion and yields were determined with a calibration curve method by HPLC (Waters 600 using Aminex HPX-87H column).

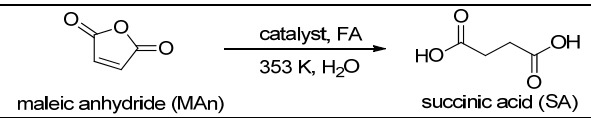
As-prepared catalysts were characterized minutely using TEM, XRD, XPS and XAS [KEK-PF (2013G586): BL-9C (Co K-edge) and BL-9A (Pd L_3-edge); SPring-8 (2013B1478 and 2014B1472): BL01B1 (Pd K-edge)] to explain their catalytic performances.

3 Results and discussion

We found that among various CoPd catalysts, *N*,*N*-dimethyldodecylamine *N*-oxide (DDAO)-capped bimetallic CoPd NPs supported on AlOOH (CoPd-DDAO/AlOOH) exhibited superior catalysis for the hydrogenation of MAn to succinic acid (SA) using FA as a sustainable hydrogen source (Table 1, entries 1-4). CoPd-DDAO/AlOOH emerged as a robust catalyst and can be reused effectively by preventing the cobalt leaching as compared to non-capped CoPd/AlOOH (entries 1-2). The catalysis did not progress in the absence of either catalyst or FA (entries 5-6). The supported CoPd NP catalysts were characterized thoroughly to comprehend their catalytic activity. The electron microscopy confirmed the uniform distribution of Co and Pd

within each CoPd NP throughout the CoPd-DDAO/AlOOH catalyst. XRD, XPS and XAS supported the Co-Pd interactions, whereas, XPS and XAS advocated the electron exchange in Co-Pd-capping to control the electron density on Pd in the CoPd catalysts. Also, the composition of CoPd NP was deciphered as CoPd alloy along with cobalt oxides from XPS and XAS analyses. The absence of any widely-used reducing agent during the preparation of catalyst was considered as the main reason for the presence of cobalt oxides. From these results, it was expected that the alloying of Co with Pd in the presence of DDAO, afforded electron rich Pd (that enhanced the adsorption/dissociation of substrates) and modified the Pd-Pd bond distance to facilitate the better alignment of metal d-orbital with the carbonyl π-orbitals onto the catalyst surface.

Table 1. Hydrogenation of Maleic anhydride (MAn) using Formic acid (FA).



Entry	Catalyst	Co[a] / wt%	Pd[a] / wt%	Conv.[b] / %	Yield[b] / %
1	CoPd-DDAO/AlOOH	0.75, 0.71[c]	2.53, 2.52[c]	>99, >99[c]	>99, >99[c]
2	CoPd/AlOOH	0.94, 0.39[d]	2.44, 2.41[d]	72	56
3	CoPd-CTAB/AlOOH	0.63	2.49	52	36
4	CoPd-PVP/AlOOH	0.55	2.51	49	35
5[e]	CoPd-DDAO/AlOOH	0.75	2.53	0	0
6	blank	0	0	0	0

Reaction conditions: MAn (0.5 mmol), FA (1.9 mmol), Catalyst (25 mg), H_2O (5 mL), 353 K, 3 h, Teflon lined autoclave. [a]Determined by ICP-AES analysis. [b]Calculated by HPLC. [c]After 5th catalytic run. [d]After 1st catalytic run. [e]Without FA. CTAB; cetyltrimethylammonium bromide. PVP; poly(*N*-vinyl-2-pyrrolidone).

4 Conclusions

In conclusion, we found that CoPd-DDAO/AlOOH acts as a robust catalyst for the hydrogenation of MAn using FA as hydrogen source without additive/base. The characterization of various capped CoPd catalysts evidences the superior catalysis of CoPd-DDAO/AlOOH because of enhanced stability (metal leaching inhibition) and electronic/geometric modifications in Pd states in the presence of Co and DDAO.

In-Situ TEM and Electron Tomography: Revealing the Location and the Mechanism of Formation of Copper Particles

Van Den Berg R.[1*], Elkjaer C.F.[2], Gommes C.J.[3], Sehested J.[2], De Jongh P.E.[1], De Jong K.P.[1], Helveg S.[2]

Keywords: particle formation, *in-situ* TEM, electron, tomography

1 Introduction

Two of the main industrial routes to synthesize supported metal catalysts are incipient wetness impregnation and co-precipitation followed by calcination and reduction. It is unclear, however, how metallic particles form during the reduction of a co-precipitated sample and which of the two routes leads to a more thermally stable catalyst. Two advanced TEM techniques, namely *in-situ* TEM and electron tomography (ET), were employed to unravel the mechanism of formation and to determine the exact location of the metal nanoparticles with respect to the support for Cu/SiO_2 methanol synthesis catalysts.

2 Experimental/methodology

Copper on silica catalysts were synthesized via incipient wetness impregnation with copper nitrate followed by drying, calcination and reduction, and via reduction of a co-precipitated copper phyllosilicate [1, 2]. The formation of an ensemble of metallic copper particles during reduction of the copper phyllosilicate was imaged in real time with *in-situ* TEM. The number, size and location of the emerging copper nanoparticles were tracked over time. For both catalysts, the 3D location of the copper particles after reduction with respect to the silica support was determined with electron tomography. The stability of the copper catalysts was investigated in the methanol synthesis reaction at 40 bars at 260°C for 10 days.

3 Results and discussion

In-situ TEM showed that copper particles forming during the reduction of a co-precipitated copper phyllosilicate were not mobile, indicating that growth occurred via diffusion of copper species to the nucleated particles (Figure 1). As soon as a new particle appeared it grew first very fast and then slower, expectedly as the copper ion concentration in the surrounding copper phyllosilicate was gradually depleted. As a result, particles that nucleated early during reduction grew, on average, larger than particles that nucleated later.

Electron tomography revealed the 3D location of the copper particles with respect to the silica support. After reduction of the copper phyllosilicate, the particles were partially entrapped in the silica, since the copper particles and the silica support were formed at the same time (Figure 2A). For copper on silica gel, prepared via incipient wetness impregnation of an existing support, the copper particles were located on the surface of the silica (Figure 2B).

Copper on silica, prepared via reduction of a co-precipitated copper phyllosilicate, showed an improved stability in the methanol synthesis reaction compared to copper on silica prepared via incipient wetness impregnation. Both catalysts had similar initial particle size distributions and particle-particle distances.

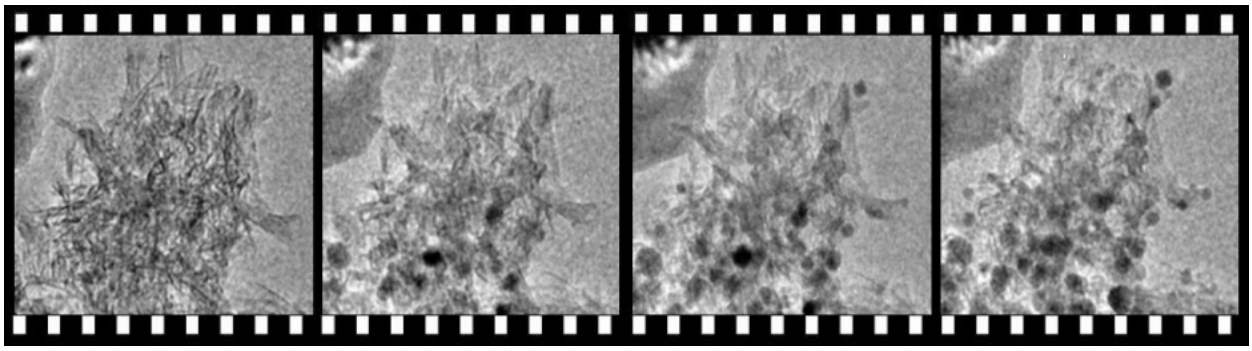

Fig. 1. *In-situ* TEM images (170 x 170 nm) taken of the same location during reduction of a co-precipitated copper phyllosilicate.

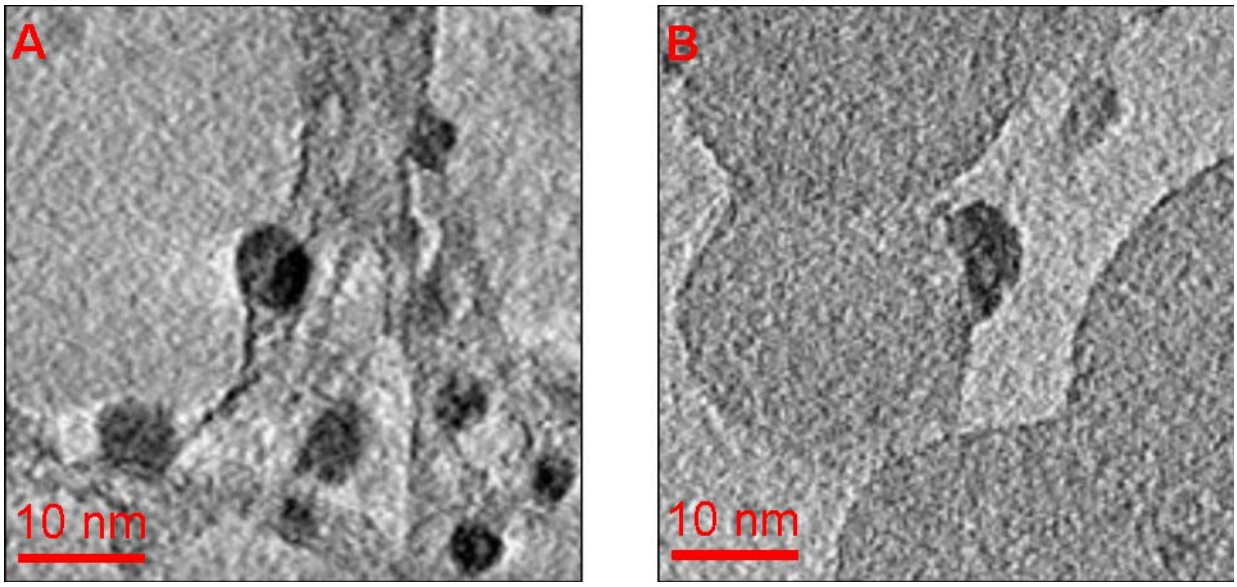

Fig. 2. TEM tomogram sections of copper on silica prepared via co-precipitation followed by reduction (A) and via incipient wetness impregnation of copper nitrate (B).

4 Conclusions

Copper particles formed during reduction of a co-precipitated copper phyllosilicate were partially entrapped in the silica support. These entrapped particles proved more stable against growth in the methanol synthesis reaction compared to a Cu/SiO_2 catalyst prepared via incipient wetness impregnation where copper particles were located on the convex surface of the silica spheres.

Keywords: palladium, iron, alloy, TEM, WGS

1 Introduction

Nano-sized particles continue to attract interest for heterogeneous catalysis, especially alloy nanoparticles, due to their unique catalytic properties. These nanomaterials have been studied to improve the catalytic activity in reactions for hydrogen production. We report the synthesis of Pt@ZnO and Pd@ZnO core-shell nanostructure that form alloy after mild reduction [1]. For the methanol steam reforming, the formation of the PtZn and PdZn alloy increase the CO_2 selectivity compare to the metal catalysts. Another, important reaction is the water gas shift ($CO + H_2O \rightarrow CO_2 + H_2$). The addition of Fe was found to increase WGS rates of Pd catalysts but not for other metals such Pt and Rh [2]. The enhancement associated with addition of Fe to Pd catalysts is due to the PdFe alloy.

In this work, we present the synthesis of Pd/Al_2O_3 and $PdFe/Al_2O_3$ nanocatalysts. We studied the effect of adding Fe to Pd in the catalysis of water gas shift reaction. The PdFe alloy improve the rates of the WGS reaction compared to Pd catalyst. Also, the $PdFe/Al_2O_3$ catalysts have similar activation energy than Pd/CeO_2 [2]. These findings are important for tailor the alloys synthesis for applications in heterogeneous catalysis.

2 Experimental/methodology

The controlled synthesis of the PdFe alloy nanoparticles were done by co-reduction of $Pd(acac)_2$ and $Fe(acac)_2$, similar to previously reported procedures [3]. The PdFe alloy nanoparticles were deposited on Al_2O_3 support for a metals loading of 1-wt%. Also, Pd nanoparticles were prepared by reduction of $Pd(acac)_2$ and deposited on Al_2O_3 support. For comparison, conventional Pd/Al_2O_3 and $PdFe/Al_2O_3$ catalysts with 1-wt% metal were prepared by impregnation of the support with aqueous solutions of $(NH_3)_4Pd(NO_3)_2$ and $Fe(NO_3)_3 \cdot 9H_2O$, respectively. The dried powders were calcined in air at 773 K for 6 h. The catalysts were characterized by TEM and CO chemisorption. The water gas shift reaction rates were measurement by placing 0.10 g of the sample in a tubular reactor and flowing CO and H_2O at a partial pressures of 25 torr and 25 torr, respectively, with He as carrier.

3 Results and discussion

The 1-wt% Pd/Al_2O_3 and 1-wt% $PdFe/Al_2O_3$ catalysts were prepared to study their catalytic activity towards water gas shift (WGS) reaction. TEM images of the PdFe alloy show uniform nanoparticles of approximately 5 nm in diameter. In the CO chemisorption measurements, the $PdFe/Al_2O_3$ show low palladium dispersion that can be due the formation of alloy. The $PdFe/Al_2O_3$ catalyst show higher rates compared to Pd/Al_2O_3 catalysts. It is noteworthy that these catalysts have the same particles sizes, so the increase in the catalytic

activity for the $PdFe/Al_2O_3$ catalyst can be attribute to the Fe present in the sample.

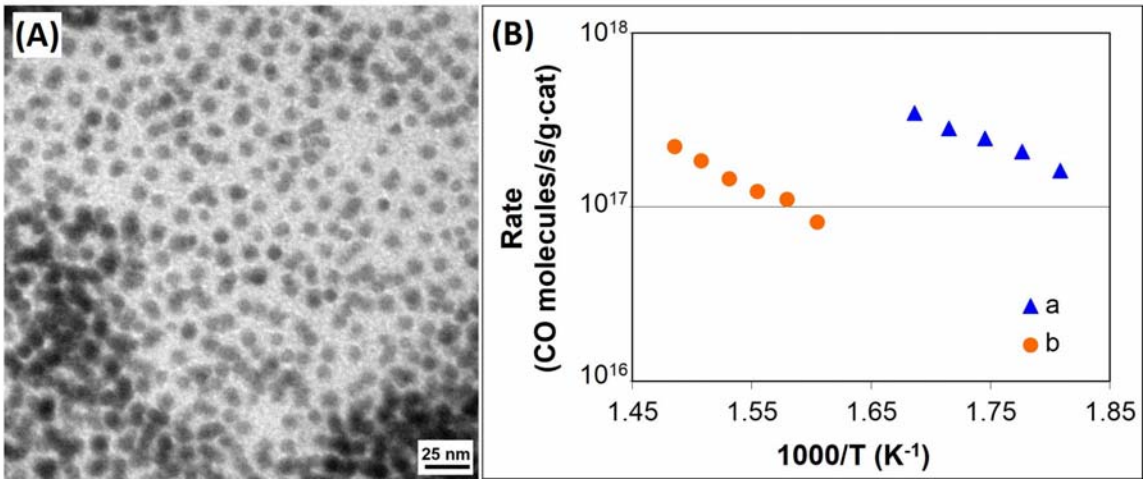

Fig. 1. (A) Transmission electron microscopy (TEM) image for the PdFe alloy nanoparticles. (B) Rates for the water gas shift (WGS) reaction over (a) $PdFe/Al_2O_3$ and (b) Pd/Al_2O_3 catalysts.

4 Conclusions

We successfully demonstrated the synthesis of PdFe alloy nanoparticles and deposited on alumina. The addition of Fe to Pd catalysts increase the rates for WGS reaction compared to Pd catalysts. These findings were important because can lead to better understanding of the alloy effect in catalytic reactions.

Architecting Acid-Mediated Synthesis of Ordered Mesoporous Aluminosilicates

Nunna V.K., Parasuraman S.*

National Centre for Catalysis Research and Department of Chemistry, Indian Institute of Technology, Chennai, India

* selvam@iitm.ac.in

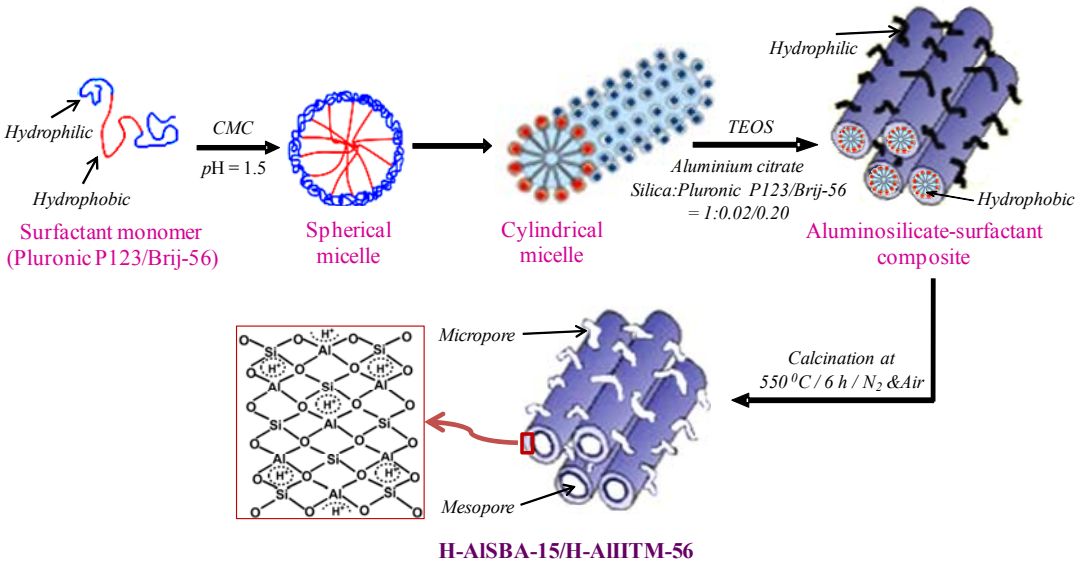
Keywords: ordered mesoporous aluminosilicates, intrinsic, hydrolysis, method, moderate, solid, acids

1 Introduction

Ordered mesoporous aluminosilicates (OMAs) with moderate Brønsted acidity have great potential as heterogeneous acid catalysts. However, the synthesis of acid-mediated OMAs such as H-AlSBA-15 and H-AlIITM-56 is difficult owing to: (i) existence of trivalent aluminium under acidic conditions; (ii) differences in the hydrolysis rates of both silicon and aluminium sources and (iii) easy dissociation of Al–O–Si bonds. Hence, it is a big challenge to incorporate trivalent aluminium in the tetrahedral silicate framework [1,2]. For this purpose, we have developed a novel (intrinsic) hydrolysis method in which the hydrolysis rates of source materials are matched using precursors.

2 Experimental

A 4.0 *g* of Pluronic P123/ Brij-56 surfactant was added to 30 *mL* of water and stirred till a clear solution was obtained. Thereafter, 70 *mL* of 0.086 *M* HCl was added and stirred for 2 *h* and *p*H was adjusted to 1.5. Then, 8.30 *g* of TEOS and aluminium citrate was added at 2 *h* interval to this mixture and the resultant gel was stirred at 40°*C*/50°*C* for 22 *h*. The mixture was transferred to a teflon-lined autoclave for hydrothermal treatment (100°*C* for 24 *h*). The obtained precipitate was filtered, washed, dried at 60°*C* for 6 *h* and calcined at 550°*C* for 1 *h* in nitrogen, and 5 *h* in air with a heating rate of 1°*C* min^{-1}. The final samples were designated as H-AlSBA-15/H-AlIITM-56 [3]. Scheme 1 illustrates the methodology for the preparation.



Scheme 1. Acid-mediated synthesis of OMAs by intrinsic hydrolysis method.

3 Results and discussion

Figure 1 depicts XRD, N_2 sorption isotherms and ^{27}Al MAS-NMR spectra of OMAs. It can be seen from this figure that a well-ordered, narrow-pore sized and tetrahedral coordinated H-AlSBA-15/H-AlIITM-56 could be achieved with our novel intrinsic hydrolysis method. In addition, for the first time, this method allows us to incorporate high aluminium content in the silicate matrix. Table 1 summarized the structural and textural properties of the samples.

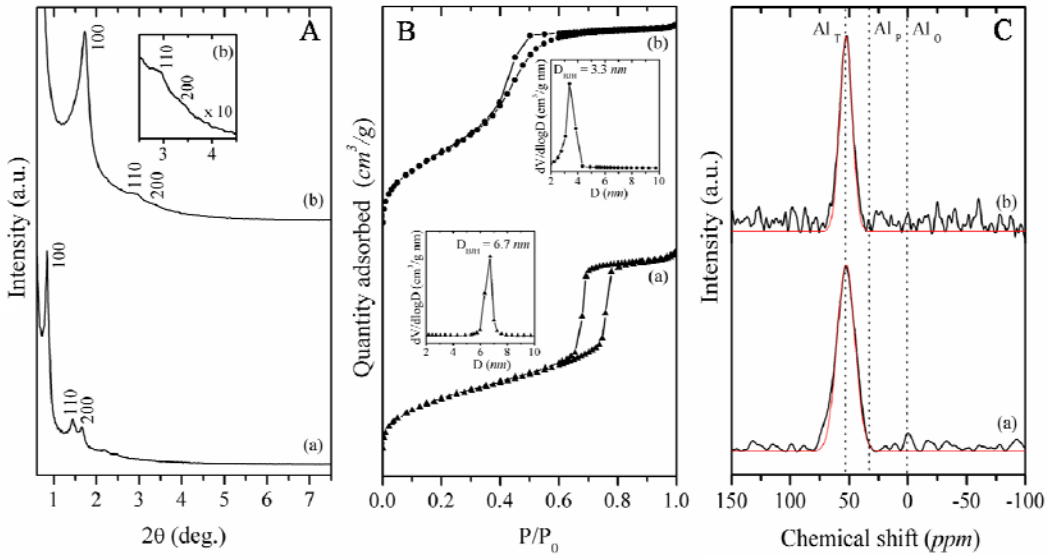


Fig. 1 Low angle XRD patterns (A), N_2 sorption isotherms (B), and ^{27}Al MAS-NMR spectra (C) of: (a) H-AlSBA-15; (b) H-AlIITM-56.

Table 1. Structural, textural and compositional characteristics of acid-mediated OMAs.

	as-syn.	calc.	gel	product				
H-AlSBA-15	12.4	12.0	30	85	599	6.7	0.76	5.3
H-AlIITM-56	6.2	6.0	30	80	818	3.3	0.79	2.7

[a] n_{Si}/n_{Al} determined by XRF; [b] Wall thickness, $h_w = a_0 - D_{BJH}$.

4 Conclusions

For the first, we could successfully achieve the incorporation of trivalent aluminium in the ordered mesoporous silicate matrix under acidic condition. The catalysts, viz., H-AlSBA-15 and H-AlIITM-56, exhibit moderate acidity and show promise for acid catalysed reactions, e.g., tertiary butylation of phenol [4].

Atomic Scale Understanding of Hydrodesulfurization Catalysis Using High-Pressure Scanning Tunneling Microscopy

Mom R.V.[1*], Frenken J.W.M.[1,2], Groot I.M.N.[1]

Keywords: hydrodesulfurization, scanning tunneling microscopy, model, catalyst, *operando* studies

1 Introduction

During hydrodesulfurization (HDS), sulfur is removed from crude oil using hydrogen over a Co or Ni promoted MoS_2 catalyst, typically supported on Υ-Al_2O_3. The catalyst is generated *in situ* from a MoO_3 precursor using a sulfur-rich feedstock (sulfidation). In recent years, the requirements on sulfur levels in fossil fuels have become stronger while the quality of crude oil is decreasing. This has inspired continuing interest in improved understanding and rational design of the catalyst.

While a combination of spectroscopy and microscopy methods has generated a good understanding of the atomic structure of the catalyst and its precursor, little is known about their dynamics under reaction conditions. *Ex situ* studies reveal that the precursor is highly dispersed, with single MoO_3 units being the dominant species [1]. During sulfidation, small crystalline islands of MoS_2 are formed. Studies using model systems have shown that several stable edge structures exist [2], and that these are the active sites for HDS.

Here, we show our efforts to extend the model approach for hydrodesulfurization. We have developed a new model system, MoO_3 on an alumina film on NiAl(110), which allows us to study the detailed nature of the MoO_3–alumina bond using a scanning tunnelling microscope (STM). With our high-pressure STM [3], we have performed *operando* experiments, following the dynamics of the atomic structure of the catalyst under reaction conditions.

2 Experimental

In order to create well defined model catalysts, we prepared single-crystal supports under ultra-high vacuum conditions (see figure 1). We have employed NiAl(110) and Au(111) crystals. Both were cleaned by cycles of Ar^+ bombardment and annealing, after which they were checked

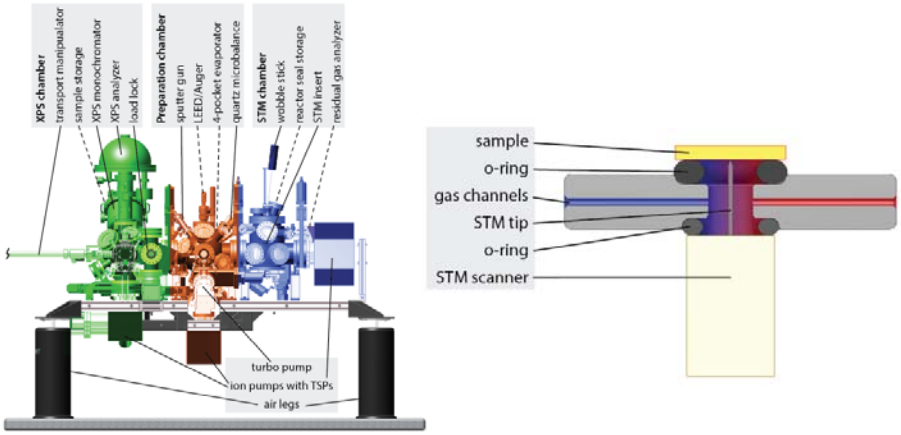

Fig. 1. The ReactorSTM [3]. Left: Ultra-high vacuum apparatus Right: Reactor geometry with STM

for impurities using X-ray photoelectron spectroscopy (XPS) and low-energy electron diffraction (LEED). To grow an alumina film on NiAl(110), the NiAl sample was exposed to a controlled amount of oxygen. This resulted in an alumina film thickness of 0.5nm. Thickening of the alumina film was accomplished by subsequent exposure to NO_2. The crystallinity of the film was checked using LEED and STM. MoO_3 was deposited onto the substrate by heating a Mo evaporation source in the presence of oxygen. MoS_2 could be deposited on Au(111) in a similar fashion, by Mo deposition in the presence of H_2S.

After preparation the catalysts were characterized by XPS and transferred to the STM chamber. By pressing the sample onto a polymer o-ring on top of the STM, the sample and STM scanner are sealed off from the ultrahigh vacuum environment, enclosing the reactor volume (see figure 1). With this geometry, experiments at pressures up to 6bar and temperatures up to 300 ºC can be performed. A dedicated gas supply system was used to control the composition, flow and pressure in the reactor (not shown in figure 1).

3 Results

We have established that the Al_2O_3/NiAl(110) model support is stable under high-pressure conditions, although some sensitivity towards H_2O was found. The deposition of MoO_3 on Al_2O_3/NiAl(110) results in a highly dispersed catalyst precursor (see figure 2). Polymerized MoO_3 coexists with the expected isolated MoO_3 species. *Operando* studies using the model catalysts will be discussed.

Keywords: nanostructured, catalysts, Ce-Pr mixed oxide, supercritical, carbon dioxide, green solvent, CO oxidation

1 Introduction

The synthesis of materials using supercritical carbon dioxide (scCO2) has received growing attention in recent years [1]. The specific properties of scCO2, which include tuneable density, gas-like viscosity, low surface tension and high diffusivity, can enable the synthesis of nanostructured materials with unique morphologies and features [2, 3]. Moreover, CO2 is a green solvent, since it is renewable, inexpensive, non‐toxic and can be easily removed from the reaction mixture upon depressurisation, thus enabling the straightforward separation from the products. Here, we present the synthesis of nanoscaled Ce-Pr mixed oxide by using a novel method employing supercritical CO2 as reaction medium, and the application of these materials as heterogeneous catalysts for the oxidation of CO.

2 Experimental

Ce-Pr mixed oxide was prepared with a new methodology based on a tailored design of the reactor that allows bringing in contact a solution containing the metal precursors [$Ce(NO_3)_3$ and $Pr(NO_3)_3$, in ratio 3:1] with an aqueous alkaline solution, only in the presence of supercritical CO_2 fluid. The two solutions are originally placed in separate vessels and they mix only once the supercritical CO_2 conditions are reached. For comparison, the same mixed oxide was prepared with conventional methods, or in $scCO_2$ but in a single vessel. Also pure CeO_2 and PrO_2 were prepared as references. All materials were calcined at 500 □C. The oxides were characterised by means of TEM, XRD, N_2-physisorption and H_2-TPR. The catalytic oxidation of CO was performed in a cylindrical fixed-bed reactor at atmospheric pressure and with a total flow rate of 50 ml/min (1000 ppm CO + 5 % O_2 + He balance; GHSV = 12000 h^{-1}), operated in the range 25-500 ºC. The gas composition was analysed by GC.

3 Results and discussion

The novel synthesis method developed in this work employs supercritical CO_2 as a solvent to bring in contact two solutions, containing the metal precursors and a base, respectively. Under these conditions, the precipitation of the oxide occurs when the two solutions come in contact. The supercritical CO_2 medium promotes the formation of a highly-dispersed precipitate with an intimate contact between the two metal species by:

(i) creating a homogeneous, low-density solution of the two metal precursors

(ii) favouring the rapid precipitation of the oxides, due to their low solubility in $scCO_2$.

The obtained Ce-Pr mixed oxide ($Ce_{0.75}Pr_{0.25}O_2$_$scCO_2$) consists of interconnected nanoparticles with a typical size of 6-7 nm (see TEM in Fig. 1) and presents much higher surface area

compared to its counterparts synthesised with conventional methods or in $scCO_2$ but in a single vessel (Fig. 1). The H_2-TPR profile of $Ce_{0.75}Pr_{0.25}O_2$_$scCO_2$ shows a single peak at relatively low temperature (below 500 ºC, see Fig. 1), indicating that the desired high dispersion of Pr within the mixed oxide was achieved. These features are promising for the catalytic properties of the Ce-Pr mixed oxide in the oxidation of CO. Indeed, $Ce_{0.75}Pr_{0.25}O_2$_$scCO_2$ displayed much superior catalytic performance compared to pure CeO_2 and PrO_2 synthesised with the same approach, and also compared to oxides with the same composition but prepared with a conventional synthesis method, or in $scCO_2$ but in a single vessel (Fig. 1).

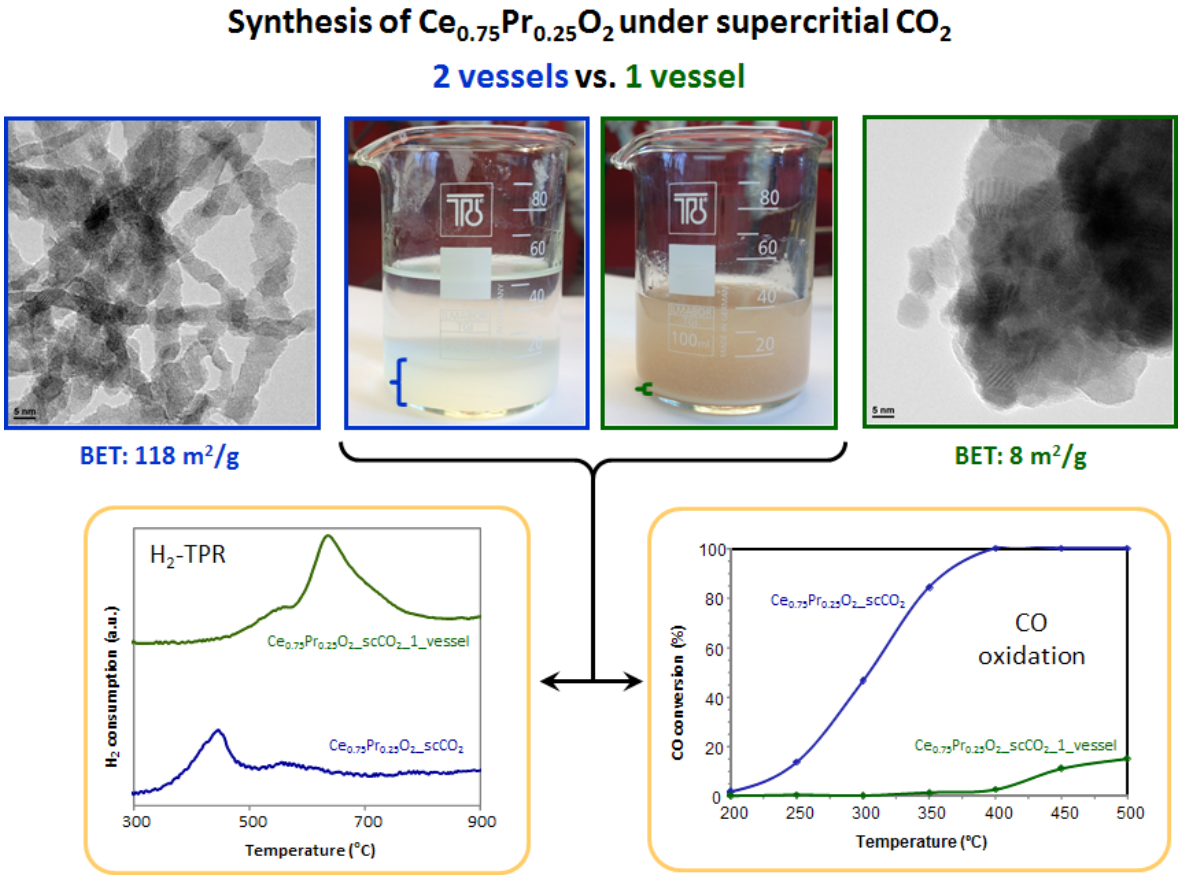

Fig. 1. Comparison between Ce-Pr oxides prepared in $scCO_2$ using a 2-vessel or 1-vessel reactor design.

4 Conclusions

The use of supercritical CO_2 as reaction medium was coupled to a tailored reactor design to produce a nanostructured Ce-Pr mixed oxide with high surface area and with enhanced catalytic activity in the oxidation of CO. This novel synthesis method is of general applicability and, therefore, is also promising for the preparation of other mixed oxide catalysts.

Synthesis and Regeneration of Differentcatalysts with the Supercritical Fluid Technology

Bilalov T.R.[1], Zakharov A.A.[1], Jaddoa A.A.[1,2], Gabitov F.R.[1], Gumerov F.M.[1*]

Federal State Budgetary Educational Institution of Higher Professional Education "Kazan National Research Technological University", Kazan, Russia
Technological University, Baghdad, Iraq

* t.bilalov@yandex.ru

Keywords: supercritical fluids, catalist, synthesis, regeneration

1 Introduction

Supercritical fluid technologies based on the use of working environments in sub- and supercritical fluid states are currently one of the most promising innovative scientific and technological areas. Supercritical fluids, while combining the advantages of gaseous and liquid states of working environments, greatly intensify heat and mass transfer processes. Diffusivity (binary diffusion, self-diffusion) of supercritical fluid media is 1-2 orders of magnitude higher than the figure for the same liquid organic solvents. In the case of supercritical fluid media, there are no phase boundary, surface tension, and, therefore, capillary effect. This define their high penetrability into the porous structure and important perspectives, including within the objectives of the synthesis and regeneration of heterogeneous catalysts. The effectiveness of this approach has been repeatedly confirmed not only by numerous studies, but also by industrial implementations.

2 Experimental/methodology

Synthesis of a palladium chloride benzonitril complex is carried out according to the method described in work [17]. For synthesis the following materials are used: carbon dioxide with 99.995% volume maintenance of CO_2 (GOST 8050-85, certificate of quality № 2052); palladium chloride purity of 99.99% and the pure for analysis benzonitril with the main component maintenance not less than 99.7%. Kinetics research of SC-CO_2-impregnation process and aluminum oxide impregnation by a benzonitril complex on the basis of palladium chloride has been carried out on experimental unit, described in [1]. Supercritical fluid CO2-impregnation process in the static mode is described in [1]. Activity of the prepared catalysts samples study has been carried out on the microcatalytic experimental unit of flowing type which has been described in [2, 3].

Regeneration of the spent catalyst was performed at supercritical fluid extraction system that allows performing the regeneration in a dynamic mode [4]. Spent catalyst, used in present work, was nickel-molybdenum catalyst deposited on alumina "Criterion514" and "DN 3531" brands, manufactured by *"Criterion Catalyst and technology"*. Carbone dioxide, used in regeneration process, was with 99.995% volume maintenance of CO_2 (GOST 8050-85, certificate of quality № 2052).

3 Results and discussion

Results of impregnation process, compared with solubility of palladium chloride benzonitrile complex at T=308.15 K is given in Figure 1. The results confirm results of earlier carried out research of palladium chloride benzolnitrile complex solubility in supercritical carbon dioxide [2, 3]. The study shows, that preferable range of SC-CO_2-impregnation process parameters are 19.0 - 21.0 MPa and 313.15˚K - 318.15˚K.

Another important task is regeneration of spent catalyst with the use of supercritical fluids. In this work the spent "Criterion514" and "DN 3531" catalysts manufactured by *"Criterion Catalyst and technology"* were regenerated with the use of pure and modified supercritical carbon dioxide. The regeneration process was held at temperatures range from 323,15 to 383,15 K and pressures 20 and 30 MPa. Results are shown in Figure 2.

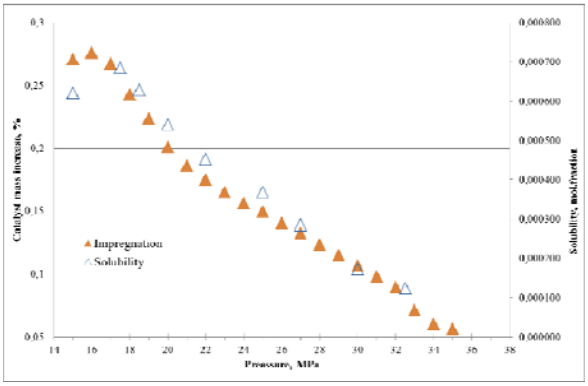

Fig. 1. Increase in mass of the catalyst carrier as a result of implementation SC-CO2-impregnationprocess. Comparison to nature of impregnation material solubility change in supercritical carbon dioxide at a temperature T = 308,15 K

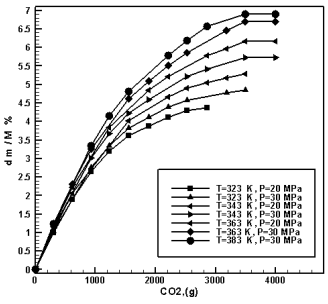

Fig. 2. Nickel-molybdenum catalyst mass change - pure SC-CO_2 mass relationship

4 Conclusions

The data obtained suggest that the synthesis and regeneration using supercritical carbon dioxide modified with various polar additives allows getting various types of catalysts, with characteristics that are not inferior to industrial counterparts. In this case, the regeneration is carried out at significantly lower temperatures as against the commonly used methods of regeneration, which has a beneficial effect on the overall performance of catalysts and on the energy consumption associated with regeneration thereof, which ultimately leads to lower cost of the finished products.

Solvation Shell of Platinum Complexes in Solutions According to EXAFS Data

Kanazhevskiy V.*, Chesalov Yu., Kochubey D.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* v.kanazhevskiy@mail.ru

Keywords: EXAFS, Raman, spectroscopy, solvation, shell, hexachloroplatinate, water, solution, DMSO

1 Introduction

Using EXAFS and Raman spectroscopy the structure of the solvation shell of hexachloroplatinate complexes in dimethylsulfoxide (DMSO) and water solutions over a wide range of concentration and aging time up to six months were studied. The experimental results clearly reveal that chlorine atoms are in the platinum atoms surrounding. Hydrolysis processes and direct interactions of platinum atoms are not observed. The Pt-Cl bond length is 2.3 Å. The chlorine coordination number is 6. No metal-metal bonds through bridging chlorine atoms are also observed. A tightly bound solvation shell covers the platinum complexes. Regardless of the solvent origin, solution concentrations and aging times, EXAFS curves of radial distribution function (RDF) exhibit maximums in the region 3.7-4.4 Å. These maximums belong to oxygen atoms of the solvation shell. The shell is likely to contain cations H_3O^+, $H_5O_2^+$ and molecules of DMSO, depending on the solvent type and platinum concentration.

2 Experimental/methodology

Two sample series were studied: solutions of a hexachloroplatinate acid in water (concentration from 0.0031 up to 0.4 M) and DMSO (0.02 and 0.2 M).

The samples were prepared using H2PtCl6×6H2O (pure grade), distilled water, benzene (chemically pure) and DMSO (chemically pure). The initial commercial complexes were used without additional purification or modifications. Solutions of hexachloroplatinate were treated in a shaded room; the samples were stored and aged away from light to prevent hydrolysis (photolysis).

Aqueous solutions were prepared immediately before spectra recording. Hexachloroplatinate was preliminary dissolved in water to achieve an initial sample concentration of 0.4 M. The rest samples in the series were prepared by successive two-times dissolution of the previous sample at each step.

To prepare solutions in DMSO, a hexachloroplatinate sample was preliminary flood with benzene in order to reduce water content of the complex. EXAFS spectra suggest that platinum complexes do not dissolve in benzene. On standing in benzene, orange crystals of H2PtCl6×6H2O converted to yellow “needles” of H2PtCl6×2H2O. After 7 days, benzene was decanted from the two-phase mixture. Raman spectra confirm a decrease in a number of the water molecules coordinated to the complex, resulting from drying of the initial complex placed into benzene. Dried hexachloroplatinate was dissolved in DMSO to a concentration of 0.2 M. The following dilution resulted in a 0.02 M H2PtCl6 solution. According to Raman spectra, the as-prepared solutions contain small amounts of benzene.

The solutions were held in DMSO away from sunlight, at standard conditions during 5 month and at 80°C during 5 hours.

Sharp EXAFS maximum at 2.32 Å and three vibrational lines at 343, 320,161 cm-1 indicated regular Oh-symmetry of [PtCl6]2- ion clearly showed the absence of the hydrolysis (photolysis) in water and DMSO solutions studied.

3 Results and discussion

EXAFS and vibrational spectroscopy were used to study the structure of complexes H_2PtCl_6 in water and DMSO solutions in the wide range of concentrations and ageing times to 5 months.

Our data confirm the earlier suggestion that platinum atoms are surrounded by chlorine atoms. The Pt-Cl bond length is approximately 2.3 Å. The chlorine coordination number is six. No traces of hydrolysis (photolysis) were observed in the studied samples. Platinum atoms are not directly bound to each other. There are no metal-metal bonds through bridging chlorine atoms.

We were the first to show that the platinum complexes are surrounded by a tightly bound (>10 kcal/mole) solvation shell. The EXAFS RDF curves exhibit maximums in the range 3.7-4.4 Å irrespective of solvent type, solution concentration and ageing time. These peaks belong to the atoms involved in the solvation shell. It is likely that the solvation shell of the complex used in prepared platinum solutions is formed by H_3O^+, $H_5O_2^+$ and DMSO molecules, depending on the solvent type and platinum concentration. For DMSO solutions, the solvation shell involves cations H_3O^+, $H_5O_2^+$, "crystal" water and solvent molecules. The number of oxygen atoms, which were related by EXAFS to the solvation shell of the complex in a DMSO solution, is small due to inclusions of larger solvent molecules in it.

Studied changes in concentration of the water solutions do not yield alterations in nuclearity of the complex. For several solution concentrations, we observed a hints of the solvation shell reconstruction manifested as a change in symmetry of the platinum surrounding with chlorine.

After a half-year storage of the solutions in DMSO at normal conditions, the symmetry of the coordination surrounding of platinum with chlorine decreases, which is associated with an effect of the solvation shell. It was established that the solvation shell radius decreases after a semi-annual sample storage. The reasons of "tightening" of the solvation shell call for additional investigations. Note that after storage of solutions for 5 hours at 80°C, the surrounding of platinum with chlorine does not change.

Probable binding of platinum complexes into associates by a solvation shell is not excluded with our data. In this case, Pt-Pt distances should approach the detection limit of EXAFS and be missed in spectra for two reasons: first, the distance between two atoms should exceed 6 Å; second, intensity of the maximum should be low due to high lability of the complex [1].

4 Conclusions

Using EXAFS and vibrational spectroscopy a tightly bound solvation shell of H_2PtCl_6 in DMSO and water solutions is established. The shell contains H_3O^+, H_5O^{2+} and DMSO molecules, depending on the solvent type. EXAFS suggests O-atoms of the shell are located at a distance of 3.7-4.4 Å from Pt. Complexes' structure was studied in wide concentration range DMSO and water solutions. The complexes are mononuclear and unhydrolyzed. Combining via the shell is possible.

Keywords: mesoporous aluminosilicates, sol-gel, synthesis, oligomerization of 1-octene

1 Introduction

In the last time in heterogeneous catalytic conversion of the acid-base type of various organic substances intensively studied the catalytic properties of mesostructured mesoporous aluminosilicate [1]. Their synthesis base on coprecipitation of the inorganic component with surfactant. They were supposed to be used for the catalytic conversion of large organic molecules. However, despite the fact that since the first report on the synthesis of these materials [2] has been more than 20 years in the literature, in practice, there is no information on their use as industrial catalysts and carriers for them. This situation is explained by the fact that the synthesis of catalytically active mesoporous materials is complex and multistage. In this case, use the templates expensive.

More accessible way to prepare the mesoporous catalytically active aluminosilicates can be sol-gel synthesis using silicon alkoxides and aluminum. The method allows to adjust the porous aluminosilicate structure in a wide range and provides a uniform distribution of Al^{3+} cations in the silica matrix [3].

The present work deals to method of sol-gel synthesis of catalytically active mesoporous aluminosilicates with a narrow pore size distribution.

2 Experimental/methodology

Mesoporous aluminosilicates are prepared by sol-gel synthesis using oligomeric esters of orthosilicic acid (ES-40) and an alcoholic solution of aluminum nitrate. Synthesis was carry out in two stages. The first stage is gelation at pH = 3, the second at pH = 10.

The phase composition of the obtained aluminosilicate was characterized by: X-ray diffraction; IR spectroscopy and MAS NMR ^{27}Al and ^{29}Si.

The acidity of the surface was characterized by TPD of NH_3 and IR spectroscopy of CO adsorption of probe molecules.

The porous structure was characterized by low-temperature nitrogen adsorption-desorption and transmission electron microscopy.

Catalytic properties of the obtained mesoporous aluminosilicates tested in the oligomerization reaction of 1-octene. The reaction is carried out continuously in rotating autoclaves under the following conditions: the content of catalyst per olefin is 10-30 wt%, T = 150-200 °C, τ = 3-5 h. Qualitative and quantitative analysis of the products of the oligomerization reaction of 1-octene was carried out by high performance liquid chromatography and ^{1}H and ^{13}C NMR spectroscopy.

3 Results and discussion

In this paper we study the effect of the ratio of SiO_2/Al_2O_3, SiO_2/H_2O and the pH of the precipitation on the porous structure, phase composition and surface acidity. It has been shown

that carrying out synthesis in acidic medium before gelation point and then to the alkaline allows synthesizing mesoporous aluminosilicate (SiO_2/Al_2O_3 = 20) with relatively narrow pore size distribution of from 3 to 5 nm of Fig. 1 and a high proportion embedded in an aluminum silicate framework (Fig.2). When this change of the specific surface area of 450 to 720 m^2/g, specific pore volume - from 0.5 to 1.2 cm^3/g, a pore diameter - from 0.17 to 7 nm and a total acidity of ammonia - ranging from 100 to 750 μmol / g.

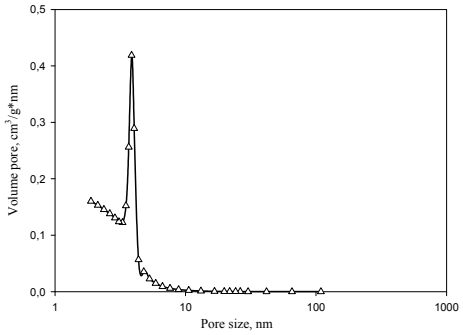

Fig. 1. The pore size distribution

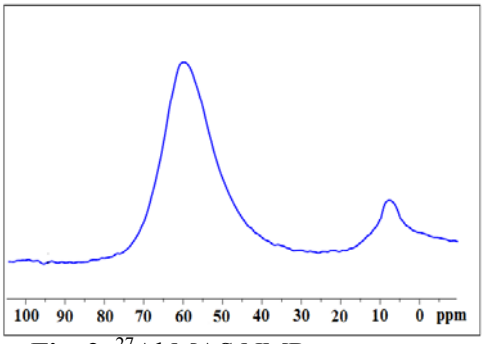

Fig. 2. ^{27}Al MAS NMR spectrum

It was found that the conversion of 1-octene in conditions studied achieves 90%, the selectivity to dimers - 40 ÷ 55%, trimers - 25 ÷ 38%, tetramers - 5 ÷ 17%. Products oligomerization of 1-octene in the presence of mesoporous aluminosilicates catalysts are oligomers with a degree of oligomerization n = 2-4. The formation of higher molecular weight products not were detected.

4 Conclusions

Developed a method of sol-gel synthesis of mesoporous aluminosilicate based on the use of oligomeric esters of orthosilicic acid (ES-40) and an alcohol solution of aluminum nitrate. The method allows to obtain mesoporous aluminosilicates having a narrow pore size distribution. Obtained aluminosilicates exhibit high catalytic activity in the oligomerization of 1-octene with a high yield of trimers.

Keywords: Cu, Zr, inverse, model, system, methanol steam reforming, water, activation, surface, redox, chemistry

1 Introduction

To prepare an active "inverse" methanol-reforming Zr^0-(pre)-catalyst on Pd- and Cu-metal substrates, a novel ALD/CVD approach was followed and compared to results of previous experiments using a self-developed sputter device . The latter, sputter-based experimental series already showed that H_2O activation sites exist in the Zr(ox)-Cu system, combining Zr redox activity ($ZrO_2 \leftrightarrow ZrO_{2-x}$) with water activation . The ALD/CVD technique using organometallic Zr precursors was originally used to prepare thin insulating layers of ZrO_2, aiming to scale down microelectronic devices. This ALD/CVD system was now adopted for inverse model catalyst synthesis. However, different kinds of interaction between precursor, Zr and catalytically active substrate have been observed for different metals leading to various active sites for MSR.

2 Experimental/methodology

ALD/CVD preparation of Zirconium-t-butoxide (ZTB) was investigated on Cu(111) and Pd(111) single crystals using in-situ and ex-situ XPS, STM, HREELS and LEED. The aim was to prepare a metallic Zr (sub-) monolayer film on a metal substrate as an inverse pre-catalyst to maximize potential bi-functional sites induced by ZrO_x segregation under reaction conditions. Alternatively, a ZrO_2/ZrOH layer with a high number of active interface sites can already be formed via organic precursor hydrolysis and/or oxidation. The Zr results were compared with Al on Pd(111), using tri-methyl-aluminum (TMA) as a precursor. Differences in particle topography and size result in significant differences in redox activity of Al and Zr.

3 Results and discussion

Temperatures between 300°C and 550°C are required for Zr^0 deposition via decomposition of the volatile ZTB compound on Pd(111). The organic moieties of the precursor can easily be removed by heating in vacuum, leading to subnanometer Zr^0 clusters of a few atoms. These clusters behave very different as bulk Zr^0 with respect to redox activity. The subnano-Zr can be oxidized or hydroxylated reversibly and, by annealing in vacuum at 400°C, it can be very easily reduced to Zr^0 again. This highly redox active state has been characterized with in-situ XPS and was also found to be active for methanol decomposition. The unusual Zr-redox behavior on Pd was not observed for Al, according to STM, because no sub-nano Al-clusters but rather big particles were formed on Pd(111).

4 Conclusions

In the Cu-Zr "real" and "inverse" UHV model catalyst study with high pressure catalysis experiments not only "good" but also "bad" active sites that trigger methanol dehydrogenation

towards CO have been identified. To design a CO_2-selective catalyst these sites need to be avoided, while simultaneously active sites for water activation need to be provided. We showed that the degree of hydroxylation of Zr is crucial for catalyst stability and CO_2-selectivity.

Keywords: manganese oxide, reactive, mechanical, grinding, catalytic oxidation, VOC

1 Introduction

Seeking for effective and low cost materials for low temperature Volatile Organic Compounds (VOCs) removal remains an important industrial challenge. Manganese oxides have been identified as promising materials for the total formaldehyde (HCHO) oxidation [1]. Recent attentions have been paid to the tunnel-type structures, due to their excellent catalytic performances for VOCs oxidation. Among these structures, cryptomelane (α MnO_2) showed the best catalytic activity in VOCs oxidation [2], underlining the important effect of the material morpho-structural properties. Specific surface area and porosity, crystal size, surface reducibility, *etc.* are parameters to control to maximize material catalytic performance [1]. Great efforts have been made to produce metal oxides with low particle size and high surface area. A promising synthesis route, recently reported for the preparation of mixed metal oxides, is to use the activated reactive synthesis (ARS) process [3,4]. This solvent free synthesis process involves the restructuring of a pre-crystallized metal oxide *via* reactive grinding process, to generate nanostructured materials with high surface area. In the present work, the advantages of the reactive mechanical grinding process, applied to the pure cryptomelane, are presented.

2 Experimental

Commercial α-MnO_2 (Mn_C), cryptomelane-type oxide, from Sigma Aldrich, was used for the synthesis of activated oxides by ARS process. The process involves two successive steps, including a first high energy ball milling (Mn_HEBM materials), and a second low energy ball milling (Mn_ LEBM materials). The first step was conducted under 2 hours of milling time using SPEX laboratory mill, whereas the second step was performed under different milling times (0.5, 1 and 2 h), using attrition mill.

XRD, N_2 physisorption, TEM, XPS and H_2-TPR experiments were conducted to elucidate structural, textural, surface and redox properties of materials obtained at the different synthesis stages. Total catalytic oxidation under air of two VOCs (formaldehyde and toluene) was studied to assess the benefit of reactive mechanical grinding process for manganese oxides activation.

3 Results and discussion

XRD analyses confirmed the presence of the cryptomelane phase (α-MnO_2, PDF n°44-0141) for the Mn_C, Mn_HEBM and Mn_LEBM samples.

After the high-energy ball milling, XRD reflections became less intense and more broadened. The average crystal size decreased from 19 nm (Mn_C) to 10 nm (Mn_HEBM). The specific surface area was not significantly improved (10 $m^2.g^{-1}$), despite the decrease in crystal

domain size. The generation of micron-size aggregates, exhibiting a high degree of agglomeration after high-energy ball milling treatment, is awaited.

The crystallite size remained constant after the low energy ball milling, whatever the milling time applied. However the second milling step was efficient to increase the specific surface area of the Mn_HEBM sample. After only 30 min of the LEBM treatment, the specific surface area value was two times higher than that of the untreated sample, this value being still increasing with the milling time (Fig. 1).This result can be related to the de-agglomeration of the aggregates (Fig. 2), resulting in substantial increase of the accessible surface area.

The Average Oxidation Number of Mn was not significantly modified by the ARS process. Values of 3.2 and 3.6 were obtained from H_2-TPR and XPS analyses, respectively, suggesting that the surface was more oxidized than the bulk cryptomelane. Redox properties were found to be affected by the material microstructure since the reduction of Mn species in Mn_HEBM and Mn_LEBM was promoted at low temperature.

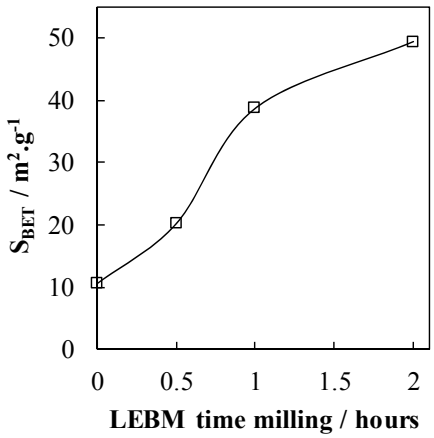

Fig. 1. SSA evolution with LEBM time.

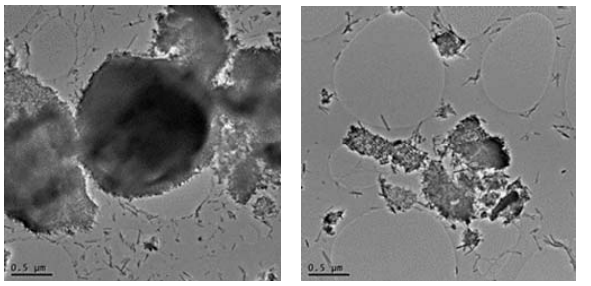

Fig. 2. TEM images recorded on the initial sample, and after 2 h of HEBM.

Specific activity of cryptomelane in formaldehyde or toluene oxidation was enhanced when the LEBM process was applied to the catalyst. The specific activity can be ranked as follows : Mn_LEBM > Mn_HEBM ~ Mn_C. Increase of low energy ball milling time led to an increase in specific activity, owing to the improvement of textural and redox properties of the corresponding materials.

4 Conclusions

The activated reactive synthesis process has been successfully applied for the cryptomelane activation. Improved textural, redox and catalytic properties have been measured, especially after particles de-agglomeration step occurring during the low energy ball milling.

Keywords: interstitial nitrides, ammonia synthesis, isotopic, exchange

1 Introduction

Interstitial metal nitrides are a range of materials that are increasingly of interest as heterogeneous catalysis[1,2]. For ammonia synthesis, some literature exists on the application of ternary metal nitrides including Co_3Mo_3N and Ni_2Mo_3N which have been reported to display high efficacy [3]. Of these two systems, it seems that Co_3Mo_3N is the more active, however there has been little investigation into rationalizing these findings within the context of structure/activity relationships. A theoretical study has invoked a synergy between Co and Mo for N_2 adsorption where one species binds N too strongly and the other too weakly – resulting in a material that has the optimal N_2 adsorption enthalpy [4]. This study also suggests surface sensitivity. The activity of Ni_2Mo_3N could also be rationalized in a similar manner. In addition, the extension of the ternary Co_3Mo_3N and Ni_2Mo_3N systems to yield quaternary systems is also of interest for possibly further improving activity and also improved understanding of the origin of enhanced activity. Previous work has examined Ni_2Mo_3N for ammonia synthesis [5]. The synthetic route employed – ammonolysis of a nickel molybdate precursor - created Ni_2Mo_3N with a residual nickel metal impurity, as dictated by stoichiometry. The ammonia synthesis reaction activity was poor. Accordingly sol-gel based routes aimed both at the preparation of phase pure Ni_2Mo_3N which is free from the presence of Ni and also well-defined quaternary $Ni_{2-x}Co_xMo_3N$ systems have been developed in this study. A specific advantage for the ternary nickel molybdenum system is that it can be prepared by direct reaction of the oxide precursor with N_2/H_2 by-passing the ammonolysis step necessary for the cobalt system[6].

2 Experimental/methodology

Ni (M) + Ni_2Mo_3N was prepared by drop-wise addition of 400 ml of a 0.25 M aqueous solution of $Ni(NO_3)_2.6H_2O$ to a 150 ml solution of $Na_2MoO_4.(H_2O)_2$. The resulting precipitate was then calcined at 700 ^oC for 6 hours under a flow of nitrogen gas (5 ml min^{-1}). Nitridation was performed by exposing the calcined material to a high space velocity flow of NH_3 and then heating using the following procedure; ambient to 357 ^oC at 5.6 ^oC min^{-1}, 357 – 447 ^oC at 0.5 ^oC min^{-1}, 447 – 785 ^oC at 2.1 ^oC . The furnace was held at this temperature for 5 hours.

Sol-gel derived precursors were synthesised by calcination of a gel obtained from stoichiometric amount of $(NH_4)_6Mo_7O_{24}.4H_2O$, $M(NO_3)_2.6H_2O$ (M = Ni or Co), citric acid monohydrate (79.35 g) and 600 cm^3 of 8-10 % aqueous HNO_3. The gel was calcined in air at 500 °C (heating rate 60 °C min^{-1}) for 2 hours to obtain the precursor. The precursor was nitrided under NH_3 at 5 °C min^{-1} to the target temperature (600 or 700 °C) and maintained for at least 6 hours, before cooling at 10 °C min^{-1}.

Ammonia synthesis tests involved pre-treating the nitrides at 700 °C with the reactant gas ($3H_2$:$1N_2$) for 2 hours before cooling to the reaction temperature, 400 °C. Ammonia synthesis rates were analysed by flowing the exhaust gas through a solution of H_2SO_4 and measuring the conductivity change of the solution as a function of time.

3 Results and discussion

The powder x-ray diffraction patterns of the Ni_2Mo_3N systems prepared by N_2/H_2 pretreatment of the oxide precursors are presented in Figure 1. Both patterns evidence Ni_2Mo_3N as major phases but in the case of the sample prepared from $NiMoO_4$, the large phase fraction of Ni is clearly visible (*).

Figure 2 presents conductivity plots representing the ambient pressure NH_3 synthesis activities of both systems. In the case of the phase pure Ni_2Mo_3N the rate of ammonia synthesis measured was 330 µmol hr^{-1} g^{-1} (b) whereas it was only < 15 µmol hr^{-1} g^{-1} for the Ni containing sample (a). Nitrogen isotopic exchange pathways have been investigated and related to performance for these systems[6]. This will be discussed within the context of their catalytic performance. In addition, a range of $Ni_{2-x}Co_xMo_3N$ materials have been prepared and screened for activity and the results will be considered in terms of composition-performance relationships.

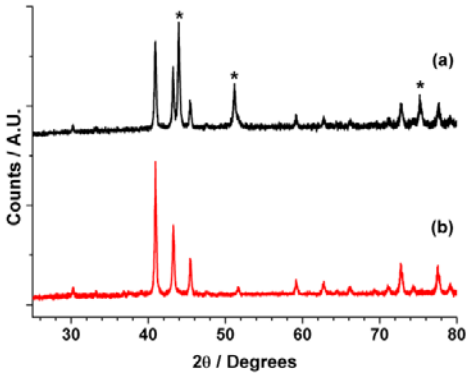

Figure 1. XRD comparison of Ni+Ni_2Mo_3N (a) and Ni_2Mo_3N (b).

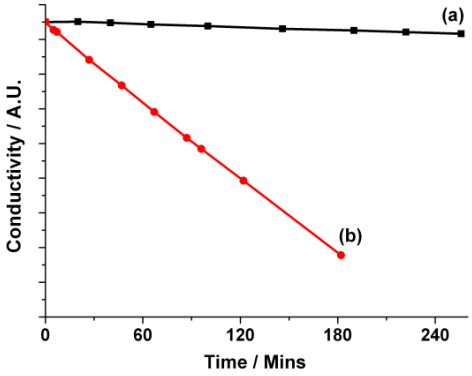

Figure 2. Reaction profiles of Ni+Ni_2Mo_3N (a) and Ni_2Mo_3N (b).

4 Conclusions

This study has shown that different synthesis routes can be employed for successful preparation of Ni_2Mo_3N materials. In particular, the sol-gel route results in a pure-phase Ni_2Mo_3N which is highly active for the ammonia synthesis reaction at ambient pressure. This presentation will also outline the application of N_2/H_2, as opposed to NH_3, for nitridation performance which would be highly beneficial if large-scale synthesis was desired. Furthermore, the access to high quality phase pure quaternary systems demonstrated in this study will provide further insight into the origin of the high activity exhibited by interstitial nitride catalysts.

II-PP14

Kinetic Classification for the Coupled Reactions. New Oportunities of Catalytic Systems Design

Bruk L.G.*, Temkin O.N.

Moscow State University of Fine Chemical Technology, Moscow, Russia

* lgbruk@mail.ru

Keywords: coupled reactions, kinetic classification, mechanism, catalytic system design

1 Introduction

The phenomenologic Shilov's theory of coupled reactions [1] and modern kinetic theory of multiroute reactions allowed us to formulate the principle of kinetic conjugation (PKC) [2,3]. The aproach to catalytic systems design on the base of PKC includes purposeful selection of catalytic systems using information about probable mechanisms of reactions resulted in desirable products formation from available starting reagents [2]. The primary (basic) reaction (according Shilov's terminology) may be source of key intermediate or catalyst which is necessary to obtain desirable products.

2 Experimental/methodology

The kinetic classification of coupled reactions is proposed. This classification includes one-route and multiroute mechanisms. A one-route coupled reaction mechanism includes consecutive elementary steps leading to two (or more) different products. This reaction is described by one stoichiometric equation. The reaction including carbon monoxide oxidation and acetic acid dehydratation [3] may be used, for example:

$$Pd(OAc)_2 + CO = CO_2 + Pd(0) + (Ac)_2O$$

$$Pd(OAc)_2 \xrightarrow{CO} Pd(OAc)(COOAc) \xrightarrow{-CO_2} Pd(OAc)(Ac) \rightarrow Pd(0) + (Ac)_2O$$

Multiroute coupled reactions are described by a number of independed stoichiometric equations and may be chain and non-chain processes. The example of chain coupled reaction is H_2SO_3 and H_3AsO_3 oxidation:

Initiation: $2\ SO_3^{2-} + 0{,}5\ O_2 + 2\ H^+ \rightarrow 2\ SO_3^{\cdot -} + H_2O$

Chain termination: $2\ SO_3^{\cdot -} \rightarrow S_2O_6^{2-}$

The first route of chain propagation:

$$SO_3^{\cdot -} + O_2 \rightarrow SO_5^{\cdot -}$$

$$SO_5^{\cdot -} + SO_3^{2-} \rightarrow SO_4^{\cdot -} + SO_4^{2-}$$

$$SO_4^{\cdot -} + SO_3^{2-} \rightarrow SO_3^{\cdot -} + SO_4^{2-}$$

Stoichiometric equation: $2\ SO_3^{2-} + O_2 = 2\ SO_4^{2-}$

The second route of chain propagation:

$$SO_3^{\cdot -} + O_2 \rightarrow SO_5^{\cdot -}$$

$$SO_5^{\cdot -} + AsO_3^{3-} \rightarrow SO_4^{\cdot -} + AsO_4^{3-}$$

$$\underline{SO_4^{\cdot -} + SO_3^{2-} \rightarrow SO_3^{\cdot -} + SO_4^{2-}}$$

Stoichiometric equation: $SO_3^{2-} + AsO_3^{3-} + O_2 = SO_4^{2-} + AsO_4^{3-}$

The example of multiroute reaction in the catalytic system $PdBr_2$-$CuBr_2$-THF was designed using PKC [4]. Stoichiometric equations of the routes:

$$CO + O_2 + H_2O \rightarrow CO_2 + H_2O_2$$

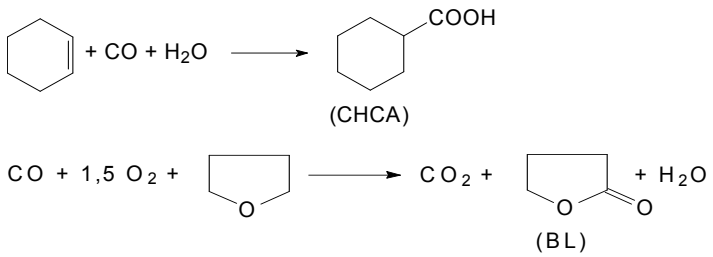

Fig.1. Mechanism of the coupled reactions

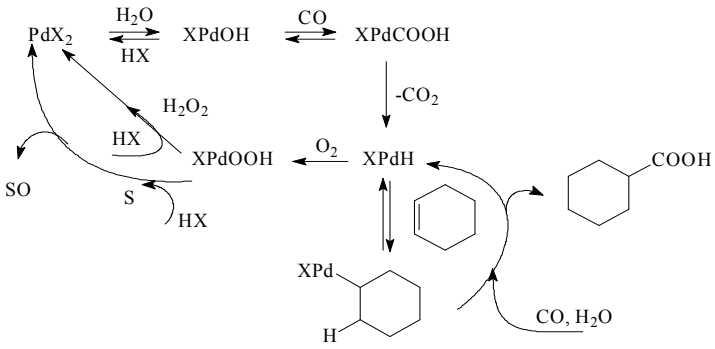

3 Conclusions

The oxidation of different substances (RH, ROH, RCHO, H_2, CO) is the most often used as primary reaction. The mechanisms of the coupled reactions are discussed.

Keywords: palladium nanoparticles, CNFs, nitrogen, doped, formic, acid, nitrobenzene

1 Introduction

Graphite-like carbon nanomaterials have a great potential for practical application in nanoelectronics and catalysis, for the development of advanced composite materials, gas or biosensors and sorbents. Carbon nanofibers (CNFs) having a large number of graphite edges are of specific interest to be used as catalyst supports [1]. Doping of CNFs by nitrogen (N-CNFs) allows to change electrophysical properties of CNFs and create new anchoring sites for catalyst precursors [2-3]. The current paper is devoted to the development and study of the different procedures of the palladium nanoparticles stabilization by means of CNFs and N-CNFs and elucidation of the correlation between particle size, electronic state of Pd and catalytic activity in CO oxidation, formic acid decomposition and hydrogenation of nitrobenzene.

2 Experimental/methodology

CNFs and N-CNFs were synthesized by a procedure described in [2]. Palladium (1-2% Pd) was deposited by incipient wetness impregnation of the carbon nanofibers with palladium nitrate, palladium acetate or a mixture of palladium acetate with triphenylphospine (PPh_3) solutions followed by calcination in hydrogen. The catalysts were characterized by XRD, XPS, TEM and N_2 adsorption methods. The activity of the catalysts was tested in CO oxidation reaction (0.2%CO, 1%O_2, 0.5%Ne and He) by TPR-CO+O_2 method with GHSV = 240000 h^{-1}. Formic acid (2 vol.%) decomposition was investigated in a flow reactor with a catalyst loading of 6.8 mg and total flow rate 51 cm^3. Hydrogenation of nitrobenzene was investigated in a steel reactor loaded by 10 mg of catalyst and 0.3 ml of nitrobenzene at atmosphere pressure under stirring.

3 Results and discussion

The palladium particle size in the catalysts depends on the type of carbon nanofibers and precursor giving bimodal or monomodal distribution and mean particle sizes from 1.5 to 13 nm, Fig. 1. According to XPS, in all catalysts palladium was found in the main metallic (E_b(Pd3d5/2) = 335.6–335.8 eV) and oxidized (E_b(Pd3d5/2) = 337.3-337.8 eV) states.

The catalysts testing showed that activity in CO oxidation reaction did not depend on the type of carbon nanofibers, particle size and palladium content; the temperature of 50% CO conversion changed within the interval of 190-200°C that was typical for palladium supported on alumina. Meantime, a type of the support and precursor strongly influences the activity of catalysts in formic acid decomposition and hydrogenation of nitrobenzene, Table 1. The highest value of activity was demonstrated by the catalysts with the smallest Pd nanoparticles deposited on nitrogen doped carbon nanofibers. The use of N-CNFs led to an increase of selectivity

towards hydrogen formation from formic acid. The best 2%Pd/7%N-CNFs exceeded the activity of Pd/C catalysts in hydrogenation of nitrobenzene reported in literature (~ 2 L H_2/g Pd ·min) by ~ 6 times. Combination of HAADF-STEM and EELS showed that Pd nanoparticles are attached to the surface of N-CNFs via nitrogen species. A study of N-CNFs by XPS allowed to conclude that mainly pyridinic nitrogen atoms are responsible for this binding.

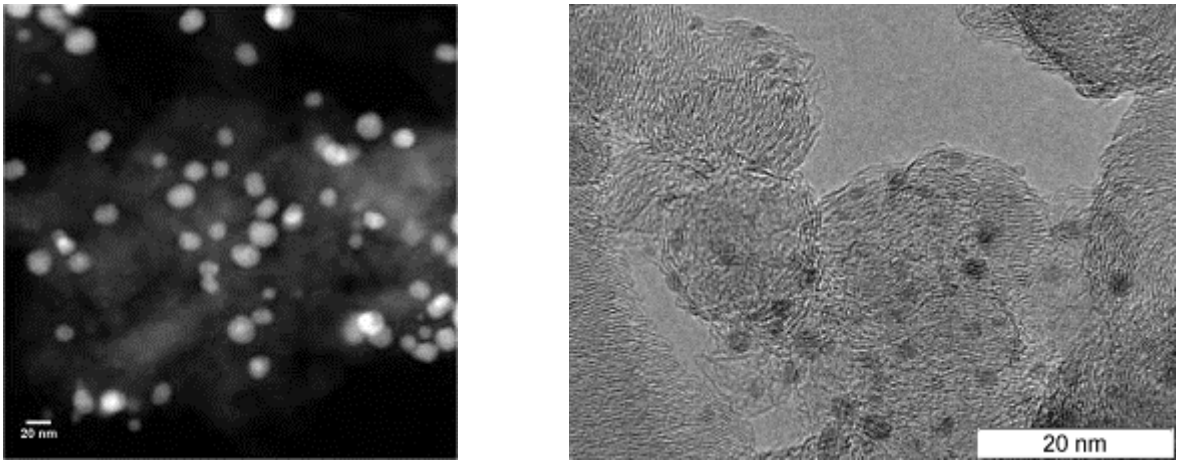

Fig.1. HAADF/STEM image of 1%Pd/7%N-CNFs ($Pd(NO_3)_2$) and STEM image of 2%Pd/7%N-CNFs ($Pd(CH_3COO)_2/PPh_3$).

Table 1. The Pd particle size and activity of catalysts in hydrogenation of nitrobenzene at 40°C and formic acid decomposition reactions (R- reaction rate, T_{50} – temperature of 50% conversion).

Sample	Mean particle size, nm	Precursor	Nitrobenzene hydrogenation R, L H_2/g Pd·min	Formic acid decomposition T_{50}, °C
2%Pd/0%N-CNFs	2	$Pd(CH_3COO)_2/PPh_3$	11.6	
2%Pd/7%N-CNFs	1.5	$Pd(CH_3COO)_2/PPh_3$	13.2	
1%Pd/0%N-CNFs	2.3	$Pd(CH_3COO)_2$		185
1%Pd/7%N-CNFs	2.3	$Pd(CH_3COO)_2$		155
1%Pd/0%N-CNFs	9	$Pd(NO_3)_2$	2.1	255
1%Pd/7%N-CNFs	13	$Pd(NO_3)_2$	3.4	180

4 Conclusions

A combination of a proper precursor and N-CNFs allowed to control the size of supported Pd nanoparticles and improve the activity of catalysts in reactions of formic acid decomposition and hydrogenation of nitrobenzene.

Keywords: diblock, copolymer micelles, ordered, nanoparticle arrays, PdAg

1 Introduction

Bimetallic nanoparticles (NPs) display unique properties drastically different from those of the corresponding single-component particles. These properties are assumed to result from both the electronic and structural effects of the bimetallic NP. As these properties depend also on the preparation conditions, the synthesis of bimetallic NPs with accurately controlled structures and compositions is essential to obtaining advanced materials for electronic, magnetic, optic and catalytic properties. In the present study, 2D ordered arrays of bimetallic PdAg NPs were successfully synthesized via the copolymer micelle approach and characterized by various spectroscopic and microscopic characterization methods. A special focus was laid on the influence of the type of reduction treatments on the chemical nature and the stability of the PdAg NPs. A comparison with the synthesis of single metal (Pd and Ag) NPs obtained by the same method was made.

2 Experimental/methodology

A series of polystyrene-b-poly(4-vinylpyridine) (PS-b-P4VP) diblock copolymers of various compositions and molecular weights was synthesized by nitroxide mediated radical polymerization using an alkoxyamine unimolecular initiator (Styryl-SG1). Intermolecular interactions between the $PdCl_2$ and/or $AgNO_3$ salts and P4VP micellar core and formation of nanoparticles from the micellar complex were investigated by various spectroscopic (UV-vis, XPS) and microscopic (AFM, HRTEM/EDX) characterization methods.

3 Results and discussion

Once the base solutions were made, three ways to produce the final arrays of bimetallic NPs were investigated (Fig. 1). One consisted in using an oxygen-plasma treatment after dip-coating of the SiO_2 surface (Fig. 1a); this method uses the large amount of electrons generated by the plasma to reduce the metallic cations and lead to the formation of the NPs that eventually oxidize under the oxygen-plasma. A second method consisted in introducing a reducing agent (hydrazine) to the base solution (Fig. 1b-path1). The third method consisted on flowing a vapour of the reducing agent (hydrazine) over the film after dip-coating of the SiO_2 surface (Fig. 1b-

path2). Spectroscopic and microscopic characterization of the resulting films before and after reduction showed that the two first methods consistently lead to the formation of rather regular arrays of NPs. In the case of the films before reduction we observe that, for the three methods, the metallic loaded micelles preferentially arrange to form a quasi-hexagonal pattern on the carbon coated copper grid; a close observation of the P4VP cores revealed a fine grain substructure inside every micelle corresponding to ultrasmall (bi)metallic NPs (Fig. 2e). After reduction either by oxygen-plasma or by hydrazine in the solution (Fig. 2) we obtain rather organized arrays of bimetallic NPs. The NPs have uniform sizes (Fig. 2d-insert) and compositions. Unlike the NPs obtained by oxygen plasma, those obtained by hydrazine in the solution are not oxidized. A full characterization of the physicochemical properties of the NPs was enabled by the use of different methods (ICP, AFM, HRTEM/EDX, XPS, UV-Vis).

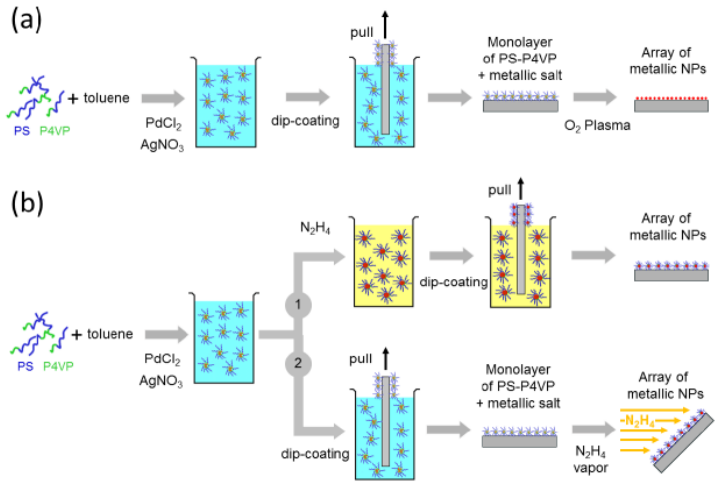

Fig. 1. Methods used to produce the arrays of PdAg nanoparticles: (a) oxygen-plasma; (b) Hydrazine in solution or hydrazine vapour. (see text for details)

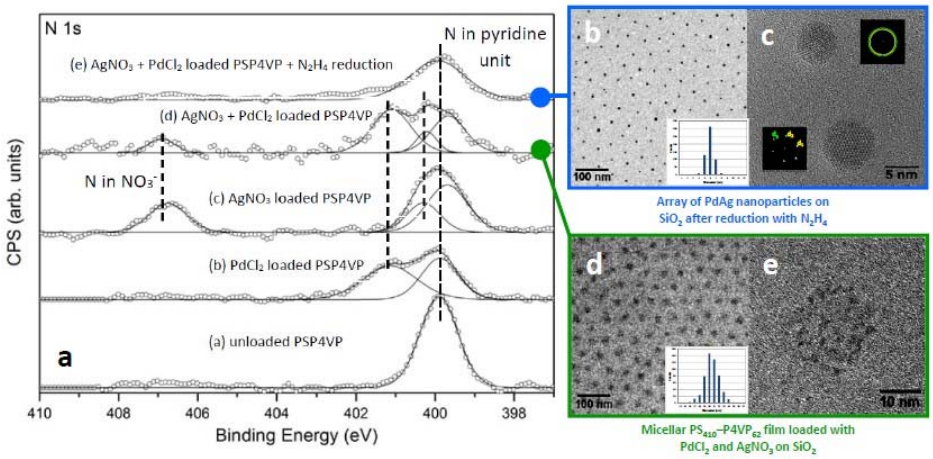

Fig. 2. XPS (a) and TEM (b-e) results for the arrays of PdAg NPs supported on SiO_2 obtained by the method using hydrazine as reducing agent in the solution.

4 Conclusions

The copolymer micelle approach is an excellent method to obtain ordered arrays of bimetallic nanoparticles supported on flat surfaces with controlled sizes, spacing and compositions. These collections of NPs can thus be used as model catalysts (for COV abatement in the case of PdAg) where important parameters that influence their catalytic behaviour can be finely monitored and modulated.

Keywords: layered double hydroxides, platinum anion complexes, anchoring, propane, dehydrogenation

1 Introduction

$Pt/MgAlO_x$ is promising catalytic system for light alkanes dehydrogenation to corresponding alkenes that have high industrial demand. These catalysts could be an alternative to chromia-alumina catalysts that have bad environmental characteristics, and to used nowadays platinum catalysts that have insufficient stability. Layered double hydroxides (LDH) are used as the support precursor for $Pt/MgAlO_x$. The structure of LDH is similar to the structure of brucite where part of magnesium ions is replaced by aluminum ions. The presence of trivalent cations induces excess positive charge of layers, which is compensated by anions located in the interlayer space, where water molecules are also present. The important feature of LDH is moderate and easy adjustable basicity. $Pt/MgAlO_x$ catalysts synthesis is a multistage process, and stage of interaction of platinum complexes with support has a significant effect on properties of resulting platinum sites. Since supported platinum atoms are active sites of alkanes dehydrogenation, to obtain an active catalysts requires understanding of what factors during catalyst synthesis influence the dispersion and electronic state of the platinum sites.

This study investigates the anchoring of platinum complexes with different composition and geometry ($[PtCl_6]^{2-}$, $[PtCl_4]^{2-}$, $[Pt_3(CO)_6]_n^{2-}$) on magnesium – aluminum layered hydroxides with different Mg/Al ratio (Mg/Al = 2, 3, 4). Catalytic properties of $Pt/MgAlO_x$ were tested in propane dehydrogenation.

2 Experimental

LDH-MgAl-CO_3 (with CO_3^{2-} - anions in interlayer space) was synthesized by co-precipitation. LDH-MgAl-OH (with OH^- - anions in interlayer space) was obtained after calcinations of LDH-MgAl-CO_3 at 550 °C and subsequent hydration of mixed oxides in water. Structural features of the synthesized samples of LDH and $MgAlO_x$ mixed oxides were studied by XRD (D8 Advance, Bruker). Elemental analysis of LDH was made by ICP-AES on Varian 710-ES spectrometer, thermal analysis was performed on STA-449C Jupiter (Netzch). Scanning electron microscope (SEM) study performed on JSM-6460 LV (JEOL) microscope equipped with an energy-dispersive X-ray spectrum (EDS).

Anchoring of platinum chloride complexes was carried out on LDH-MgAl-OH and anchoring of platinum carbonyl complexes – on $MgAlO_x$. Chemical composition of adsorbed complexes was investigated by ^{195}Pt NMR and diffuse reflectance electron (DRE) spectroscopy. Platinum dispersion was determined by hydrogen chemisorptions. Transmission electron microscopy (TEM) was recorded on JEM-2100 (JEOL).

Catalytic properties of $Pt/MgAlO_x$ was investigated in propane dehydrogenation under the following conditions: catalyst loading 0.50 g., T = 550 °C, atmospheric pressure, WHSV 8 h^{-1} and H_2/C_3H_8 molar ratio of 0.25. Before reaction, samples were calcined at 550 °C and reduced in hydrogen at 550 °C.

3 Results and discussion

Study of adsorption of $[PtCl_6]^{2-}$ complexes on LDH-MgAl-OH showed that LDH with Mg/Al = 2 and 3 have the largest of adsorption capacity equal to 0.8 – 1.17 mmol/g (16 – 20 wt. % of adsorbed platinum). The intercalation of $[PtCl_6]^{2-}$ complexes into LDH interlayer space was confirmed by XRD and thermal analysis with mass spectrometric identification of the products. According to ^{195}Pt NMR and DRE spectroscopy adsorption of the complexes on LDH (regardless of the Mg/Al ratio) did not lead to significant hydrolysis of the complexes. It was assumed that complexes $[PtCl_6]^{2-}$ fixated in interlayer space by electrostatic interaction with positively charged LDH layers.

When $[PtCl_4]^{2-}$ complexes anchore on LDH-MgAl-OH the greatest number of complexes adsorb on the most basic LDH with Mg/Al = 4. Adsorption capacity equal to 1.37 mmol/g exceeds stoichiometric value. Therefore part of complexes hydrolyzes upon contact with basic support and fixes on its external surface. Absence of signals in the ^{195}Pt NMR spectra for supported complexes suggests the possibility of coordination of $[PtCl_4]^{2-}$ with hydroxyl groups of the LDH-MgAl-OH. According to DRE spectroscopy complexes adsorption leads to their hydrolysis to $[Pt(H_2O)Cl_3]^-$ on the surface. Inversion of intensity of the 003 and 006 peaks on the diffraction pattern of the supported systems indicates to increase in the electron density in interlayer space due to $[PtCl_4]^{2-}$ presence in interlayer space.

No adsorption of platinum carbonyl complexes $[Pt_3(CO)_6]_n^{2-}$ occurred on LDH-MgAl-OH owing to steric difficulties. During adsorption complexes on $MgAlO_x$ their anchoring occurred with saving of structure of mixed oxides (solvent - acetone) as well as with recovery of LDH structure (solvent - acetone + 5 vol. % H_2O). DRE spectroscopy of platinum carbonyl complexes supported on $MgAlO_x$ indicates a decrease in the size of complexes at their contact with basic support.

0.3%Pt/$MgAlO_x$ catalysts obtained using different platinum complexes were investigated in propane dehydrogenation. Propane conversion and propylene yield decrease with increase Mg/Al ratio for catalysts made from chloride precursors. Platinum dispersion decrease with increase Mg/Al ratio too. Herewith catalysts obtained from $[PtCl_4]^{2-}$ were 20-30% more active in comparison to the samples obtained from $[PtCl_6]^{2-}$ due to the larger platinum dispersion. Propane conversion, platinum dispersion and stability of catalysts obtained from platinum carbonyl complexes were above respective characteristics for samples, made using chloride precursors.

4 Conclusions

Composition and geometry of platinum complexes $[PtCl_6]^{2-}$, $[PtCl_4]^{2-}$, $[Pt_3(CO)_6]_n^{2-}$ as well as Mg/Al ratio in LDH-MgAl have a significant effect on anchoring of complexes onto support and on dispersion, electronic state of the platinum sites and their activity in propane dehydrogenation.

An Acidity Study of Encapsulated Heteropolyacids in a Sol-gel Silica Matrix for a Green Friedel-Crafts Alkylation

Pezzotta C.*, Müller K., Gaigneaux E.

Université catholique de Louvain, IMCN Institute of Condensed Matter and Nanosciences, Louvain-la-Neuve, Belgium

* chiara.pezzotta@uclouvain.be

Keywords: Friedel-Crafts alkylation, green chemistry, fine chemistry, pyridine, adsorption and TPD, heteropolyacids, Brönsted, acidity

1 Introduction

Friedel-Crafts alkylation is a key reaction widely used in pharmaceutical and polymer industry for the production of substituted aromatic compounds. Traditionally performed through homogeneous catalysis and in strong acidic conditions, it presents several inconveniences as pollution, difficult product separation, diffuse equipment corrosion and use of hazardous and toxic materials. To solve these problems the transition from homogeneous to heterogeneous catalysis has been attempted [1].

In this work Keggin type tungstophosphoric acid (HPW) was encapsulated in a silica matrix using the sol-gel method. The catalyst obtained was characterized in order to understand the nature of the interaction between HPW and the silica matrix. Then, the samples were tested in the Friedel-Crafts alkylation of resorcinol with methyl-tert-butyl ether to produce 4-tert-butylresorcinol and 4,6-di-tert-butylresorcinol.

Acidity measurements were performed using pyridine adsorption and temperature programmed desorption. The data obtained show the existence of a correlation between acidity and catalytic activity.

2 Experimental/methodology

Preparation: The preparation of the catalysts followed the procedure explained by Kukovecz [2] with some modifications. In a three neck round bottom flask 14 ml of tetraethoxy silane (Sigma-Aldrich, ≥ 99.0%) was added to a mixture of 10 ml of absolute ethanol (Normapur), 7.5 ml of ethylene glycol (Fluka, ≥ 99.5%) and 6 ml of distilled water. A calculated mass of HPW was then added in order to reach 11, 20, 30 and 40% of the total sample mass. The mixture was then magnetically stirred for one hour at 80°C under nitrogen atmosphere. 10 mL of HCl (Sigma-Aldrich, 37% w/w) was then added in order to allow the sol-gel transition to occur after approximately one hour. The transparent gel was then removed from the flask and put in a crystallizer to be dried in air for one day. After that, the catalyst was dried under vacuum at 140°C for three hours and calcined in air for six hours at 450°C. The powder obtained was grinded and sieved to obtain particles between 100 and 200 µm. Before the catalytic test the samples are washed overnight in ethanol in a Soxhlet extractor and dried under vacuum at 100°C for 2h. The catalysts were named: SG (sol-gel) – HPW – XX (HPW weight % on the total sample weight (SiO_2 + HPW)). SG – SiO_2 was the silica matrix without HPW.

Catalytic test: The resorcinol (7 g, Sigma-Aldrich, 99%) alkylation with methyl-tert-butylether (45 ml, Sigma-Aldrich ≥ 99.0%) was carried in air in a three neck round bottom flask connected with a Liebig condenser. After resorcinol dissolution, 0.6 g of catalyst was added and the mixture stirred at 60°C for 21h. The mixture was analysed every 120 minutes with a GC-FID Varian 3800 equipped with an ID-HT5 column. As internal standard 2,4-di-nitrobenzene (Aldrich 97%) was used.

Characterization: Pyridine adsorption and TPD was performed in order to measure the samples surface acidity and to distinguish the nature of the acid sites. Pyridine adsorption was carried on using a wafer of pure catalyst placed in a Pyrex cell equipped with a NaCl window. The wafer was degassed at 300°C and under vacuum for 3h. Then a fixed amount of pyridine vapor was put in contact with the sample. After adsorption, the wafer was left under vacuum for 30 minutes to remove the physisorbed pyridine. After that the sample was heated at 100, 150, 200 and 250°C to desorb the pyridine. A spectrum was taken for each temperature. For the determination of the relative amount of Lewis and Brönsted acid sites, the area of the bands at 1450 cm^{-1} and 1540 cm^{-1} of the spectrum taken at 100°C were integrated.

The interactions between the HPW and the silica matrix were investigated using IR spectroscopy performed with the same instrument.

3 Results and discussion

Although silica is known to have a very high absorption coefficient that can sometimes hide the presence of other compounds, fig. 1 shows the bands related to the W=O and W-O-W vibrations of encapsulated HPW. The weak intensity of these bands could be due to a deep HPW encapsulation into the support pores. Beside this, almost no leaching of HPW in ethanol was observed by UV-vis spectroscopy after the Soxhlet extraction, suggesting that the Keggin structure was firmly incorporated into the silica matrix.

The maximum amount of Brönsted acid sites (55% of the total acidity) was reached in the SG-HPW-30.

Catalytic tests showed activity for all the samples. The SG-SiO2 was tested as reference and showed no activity. The resorcinol conversion increases as the HPW loading increases with the exception of the SG-HPW-40. In that case a drop in the activity was observed. From fig.2 it is visible that in spite of the highest HPA loading, this sample shows a low amount of Brönsted acid sites on its surface. This suggests that the Keggin structures, due to excess loading, may form clusters that reduce the dispersion and consequently the acid sites number on the surface.

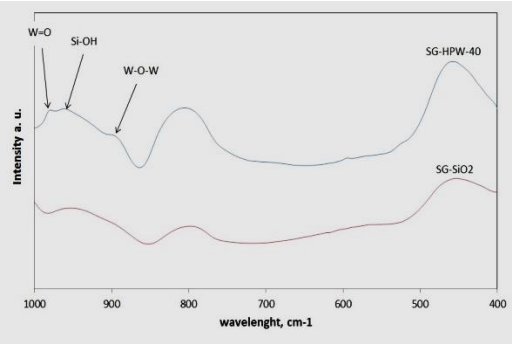

Fig.1 FTIR spectra showing WO band of encapsulated HPW.

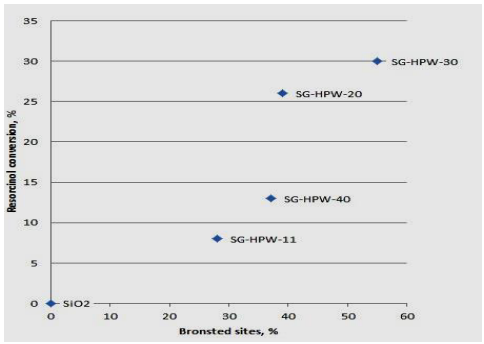

Fig.2 Resorcinol conversion vs Brönsted acidity.

4 Conclusions

A heterogeneous acid catalyst active in the Friedel-Crafts resorcinol alkylation was prepared. The catalytic activity was found to increase with the number of Brönsted acid sites. The heterogenization of HPW using the encapsulation in a silica matrix was successful and led to leaching resistant catalysts that possess promising features for further developments.

1 Introduction

Carbon chemistry represents one of the fastest evolving and expanding research areas primarily due to the extraordinary physicochemical properties of its modifications, especially graphene and carbon nanotube materials [1]. In catalysis, the activity and selectivity of the entire catalytic entitity can be modified by carbon in connection with metal-support interaction [2]. Furthermore, the stability of Ni-based anode materials in Solid Oxide Fuel Cells (SOFC) can be enhanced by carbon management, when they are exposed to hydrocarbon rich fuel gas. Carbon managment requires the understanding of the adsorption, migration, dissolution and resegregation of carbon on the catalyst, as well as of the structural and electronical properties of different scenarios of C-distribution. In particular, the role of the clock-reconstructed Ni(111) surface carbide regarding further C-growth and dissolution is tested and experimental data are compared to the structural models proposed in the literature[3].

2 Experimental

In our work, we focus on the behavior of Carbon on different Nickel systems in the temperature region of 300K to 800 K. The samples were exposed to methane and ethylene under different pressure and temperature condition to observe carbide and graphen/ite formation and dissolution.

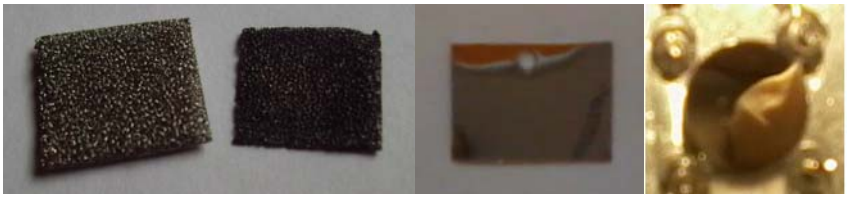

Fig. 1. Ni-Foam(left), -foil(middle) and Ni(111) single crystal(right) used to investigate carbon chemistry.

Experiments were performed at the following beamlines and UHV-systems:

I. In-situ XPS at the beamline ISISS-PGM of BESSY II, Berlin
II. SXRD at the ID03 beamline of ESRF, Grenoble
III. Additional ex-situ experiments in UHV system, Innsbruck [4]

3 Results and discussion

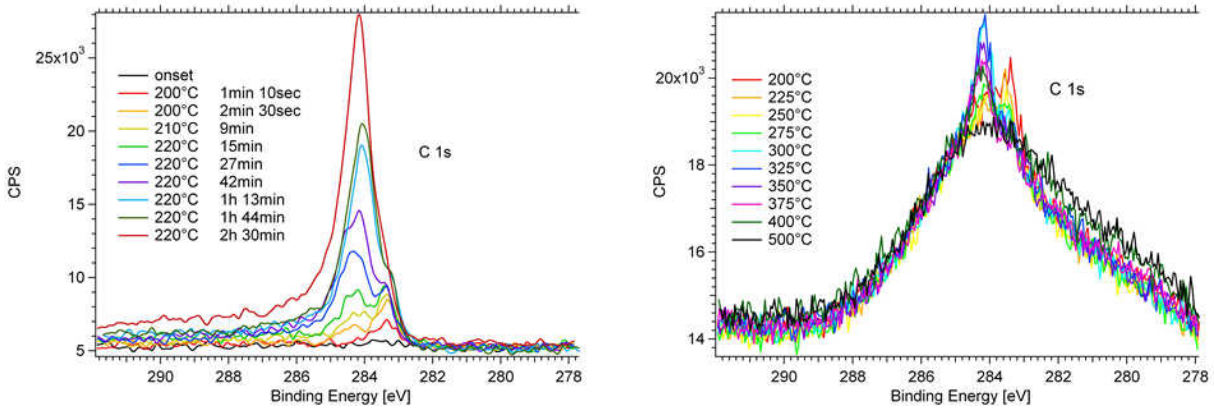

Fig. 2. In-situ XPS spectra of carbide and graphene/ite growth on Ni-foam(left) and Ni-foil(right)

4 Conclusions

As shown in Fig 2, sequential formation of carbide and graphene/ite could be observed both on Ni foam and Ni foil, whereby more amorphous carbon was observed on the latter. In addition, the coexistence of surface carbide and graphene/ite in a certain temperature region was observed as well as the preferential dissolution of the surface carbide at >= 670 K.

Carbide was moreover grown on Ni(111) and the subsequent graphene/ite formation was observed, using similar experimental conditions as on foam/ foil. After thermal dissolution of the carbidic clock-reconstructed $(39)^{1/2}$R16.1°x$(39)^{1/2}$R16.1°phase at 700 K, as indicated by the loss of the related diffraction intensities, the presence of epitaxial and unrotated graphene domains is indicated by the absence of rotated graphene reflections, together with a strong alteration of the specular reflectivity of the surface. These results complement recent structural investigations by STM [5, 6]. Structure modelling of SXRD data to confirm the most plausible configurations of unrotated graphene on Ni(111) will be presented.

Effect of the Preparation Method of $La_{1-x}Sr_xFeO_3$ Perovskites on N_2O Decomposition

Margellou A.*, Petrakis D., Pomonis P.

Department of Chemistry, University of Ioannina, Ioannina, Greece

* amargel@cc.uoi.gr

Keywords: Perovskites $La_{1-x}Sr_xFeO_3$, chiral silica, N_2O decomposition

1 Introduction

N_2O decomposition has been extensively studied over many simple oxides but less over perovskites [1-2]. In this work, the N_2O decomposition has been studied over perovskites $La_{1-x}Sr_xFeO_3$ synthesized through two different methods: (i) sol-gel auto-combustion using glycine as fuel and (ii) wet impregnation of metal nitrates on chiral silica as a substrate.

2 Experimental/methodology

The perovskites $La_{1-x}Sr_xFeO_3/SiO_2$ (x= 0, 0.25, 0.50, 0.75 and 1.0) were prepared using the wet impregnation method of metal nitrates on chiral silica [3]. For the wet impregnation, pre-estimated amounts (mmoles M) of metal nitrates were mixed with citric acid and impregnated on chiral silica. In order to find the optimum amount for the N_2O decomposition, three perovskites $xLaFeO_3/SiO_2$ were synthesized with 0.5, 2.5 and 5.0 mmoles $LaFeO_3$ per g SiO_2. For the sol-gel auto-combustion method, the metal nitrates were dissolved in distilled water and glycine was added with molar ratio Gly/M=1. The solution was heated at 100°C to evaporate the H_2O and then at ~250°C in order to initiate the combustion. All catalysts were calcined at 600°C for 6h and characterized by XRD, N_2 porosimetry and SEM. The catalytic experiments were held in a PFR reactor with total flow 60.0 cc/min and WSHV≈18.000h^{-1}. The analyses of the reactants and products took place in a gas chromatograph GC-15A Shimadzu.

3 Results and discussion

In the $La_{1-x}Sr_xFeO_3/SiO_2$ samples, the XRD patterns at low angles show a peak of MCM-type hexagonal mesostructure. Comparing the impregnated samples with the pure chiral silica, the mesostructure is partially destroyed as the perovskites amount increases and the perovksite phase is formed as seems at XRD patterns at high angles. The calculated d_{100} values from Bragg equation for the synthesized materials are shown on Table 1 and are lower than the pure silica. The substitution of La with Sr is not influence the d_{100}. For the perovskites $La_{1-x}Sr_xFeO_3$ prepared with glycine the XRD pattern confirms the perovskites structure. The crystallite size calculated via the Scherrer's equation (D_{cryst}) shown on Table 1. It seems that the crystallite size is influenced from the Sr addition as it initially decreases with substitution x=0.25, 0.50 and later increases as x=0.75, 1.00.

The N_2 adsorption-desorption isotherms for the $La_{1-x}Sr_xFeO_3$ materials from sol gel auto combustion method correspond to non porous and low specific surface area solids with ssa=12-28 m^2/g. The isotherms of the impregnated correspond to mesoporous materials with high ssa equal to 697m^2/g for $0.5LaFeO_3/SiO_2$, 577m^2/g for $2.5LaFeO_3/SiO_2$ and between 300-500m^2/g for $5.0La_{1-x}Sr_xFeO_3/SiO_2$.

In the SEM images the perovskites system $La_{1-x}Sr_xFeO_3$ prepared with glycine shows a compact

and shapeless structure whereas the impregnated samples maintain the morphology of the chiral silica which does not influenced by the addition of perovskites

Table 1. Properties and catalytic activity of the synthesized materials.

Material	d_{100} XRD (nm)	T_{50} (°C)	Ea (kJ/mol)	Material	D_{cryst} (nm)	T_{50} (°C)	Ea (kJ/mol)
SiO_2	4.1	-	-	$LaFeO_3$	31	507	133
$0.5LaFeO_3/SiO_2$	3.8	-	-	$La_{0.75}Sr_{0.25}FeO_3$	17	487	148
$2.5LaFeO_3/SiO_2$	3.9	612	124	$La_{0.5}Sr_{0.5}FeO_3$	14	495	137
$5.0LaFeO_3/SiO_2$	3.7	587	130	$La_{0.25}Sr_{0.75}FeO_3$	15	500	152

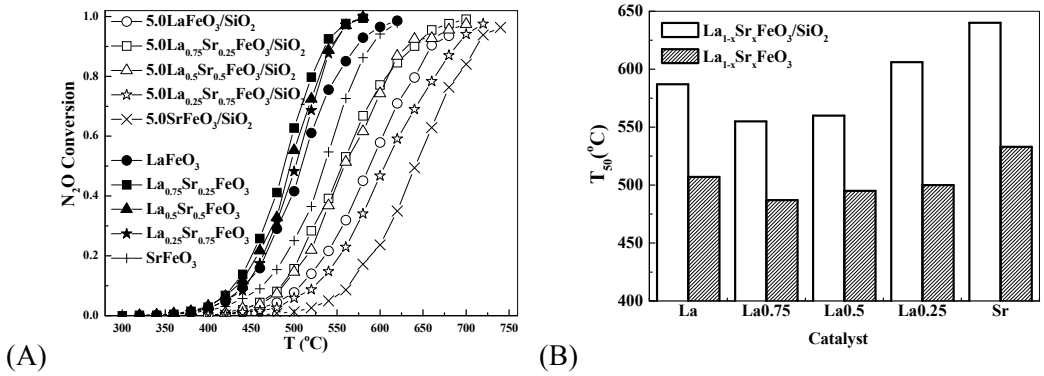
$5.0La_{0.25}Sr_{0.75}FeO_3/SiO_2$	3.6	606	125				
$5.0SrFeO_3/SiO_2$	3.8	640	149				

In the N_2O decomposition the $0.5LaFeO_3/SiO_2$ did not show any activity and the $2.5LaFeO_3/SiO_2$ was less active compare to the $5.0LaFeO_3/SiO_2$ as a result the substitution of La with Sr happened to $5.0LaFeO_3/SiO_2$. The most active catalysts were $5.0La_{0.75}Sr_{0.25}FeO_3/SiO_2$ and $La_{0.75}Sr_{0.25}FeO_3$ (Fig. 1A). From the temperature T_{50} where 50% of N_2O has been converted (Table 1 and Fig. 1B), it can observed that the perovskites synthesized through the sol gel auto combustion method are more active catalysts compared to the impregnated perovskites. The activation energies for all the samples in the range of 130-150 kJ/mol.



(A) (B)

Fig.1.(A) Temperature profiles and (B) Temperature T_{50} of the prepared materials.

4 Conclusions

Perovskites $La_{1-x}Sr_xFeO_3$ were used as catalysts in the N_2O decomposition. The non porous perovskites prepared through the simple, fast and easy method of auto-combustion show high activity towards the N_2O decomposition whereas the mesoporous catalysts $La_{1-x}Sr_xFeO_3/ SiO_2$ showed lower activity. The higher specific surface area and the chiral morphology of the silica support did not improve the catalytic properties of the system $La_{1-x}Sr_xFeO_3$.

Hidden Resources of Electron Scattering at Surface and in the Bulk of a Solid: an Exploratory Research

Cholach A.R.[1*], Asanov I.P.[2]

1 - Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia
2 - Nikolaev Institute of Inorganic Chemistry, Novosibirsk, Russia

Keywords: core level excitation, coupled electron transitions

1 Introduction

The resonant core level excitation makes a crucial impact on an atom and results in specific responses disclosing intrinsic properties of a system which part of an atom is. A fine structure in extended and near above the threshold X-ray absorption spectra revealing the short-range atomic geometry and the density of vacant states were particularly detected and became the grounds of EXAFS and XAS, respectively, while the fine structure in soft X-ray emission spectra near below the threshold disclosing the valence states of a target atom is known as XES [1, 2]. The report highlights similar effects discovered by ordinary techniques of Disappearance Potential Spectroscopy (DAPS) and X-ray Photoelectron Spectroscopy (XPS). Fine structures in extended DAPS spectra reveal the valence states of near-surface atoms and plasmon oscillations, while those in C_2F XPS spectra above both, C and F K-edges are in agreement with the total Density of States (DOS) structure. Events are regarded as a novel route for energy dissipation at surface and in the bulk, the Conjugate Electron Excitation (CEE) which includes a set of independent shake-off and shake-up electron transitions, each coupled with the core level excitation.

2 Methodology

DAPS traces the threshold core level excitations of target atoms by an electron beam of time-based energy [3]. Whenever accelerating *potential* overcomes the core level energy a part of scattered electrons *disappears* from elastic current providing the spectral dip. The capability of DAPS to reveal *any* channel of elastic electron consumption, particularly that related to coupled electron transition has been exploited. DAPS measurements were made on the Pt(100) single crystal of 99.999% purity and (1x1) surface structure around the Pt4d core level [4]. XPS studies were performed on a Phoibos 150 Specs spectrometer under Al K_α excitation. The fluorinated graphite of C_2F stoichiometry was prepared by treating the highly orientated pyrolytic graphite with saturated vapors of a solution BrF_3 in Br_2 [5]. Pt DOS was calculated by the Quantum Espresso package within a *12x12x12* grid. Core electrons were treated with the Perdew-Burke-Ernzerhof ultrasoft pseudopotential [6]; the plane waves were used for a basis set of the valence electron wave function [4].

3 Results and discussion

Spectral features in Fig. 1(a) fit 1π, 5σ and 4σ valent states of the adsorbed CO molecule. Furthermore, a perfect agreement between experimental and theoretical spectra within 5-12 eV gives evidence that CEE readily affects the substrate atoms. Fig. 1(b) displays close similarity between higher energy "tails" in C1s and F1s XPS spectra of C_2F. The satellite at ~ 5 eV corresponds to CEE shake-up $\pi \rightarrow \pi^*$ transition and naturally accompanies the primary C1s peaks since π bond is localized exclusively at the carbon atom. Meanwhile finding similar satellite above F1s seems incredible because F atom has nothing to do with the π bond, but this finding is in line with CEE expectations. The other spectral features are in agreement with the

total DOS structure of C_2F. CEE phenomena developed by DAPS and confirmed by XPS emphasize the strong community of core and outer shell electronic structures and enables to believe that both inelastic scatterings, at surface and in the bulk of a solid follow similar rules.

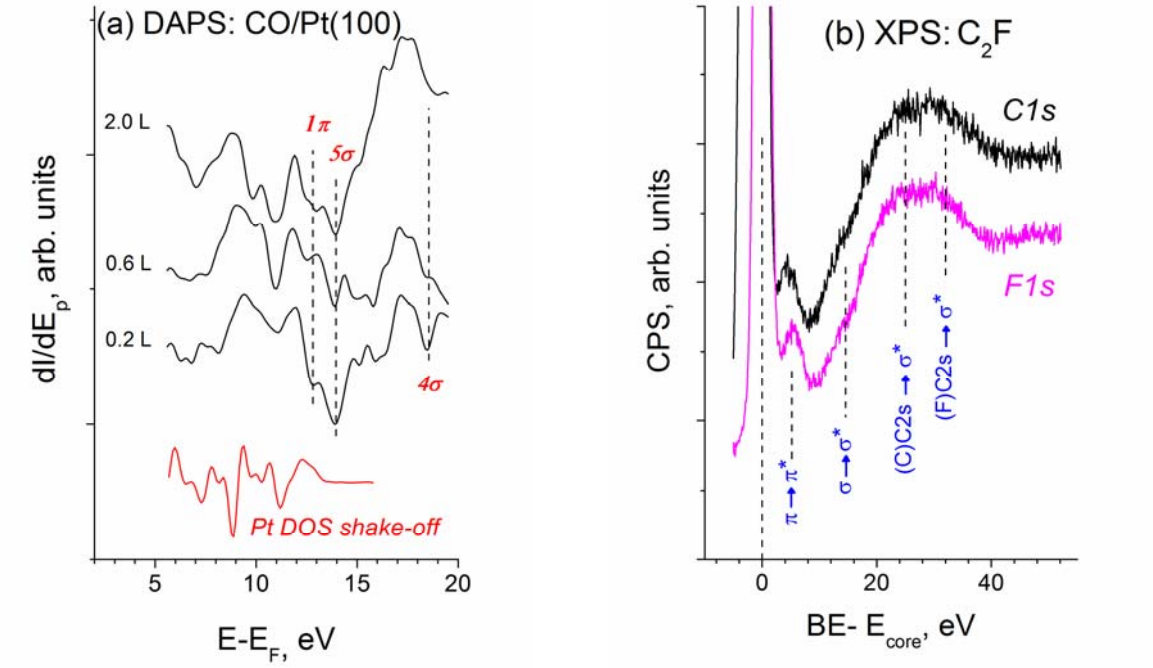

Fig. 1. (a) DAPS spectra (in black) obtained after exposure of Pt(100) surface to CO and theoretical DAPS spectrum corresponding to shake-off transition of the Pt valence band to vacuum level; (b) Interband transitions above F and C K-edge (C is bound to F) according to total DOS of C_2F.

4 Conclusions

A unified electronic structure of chemically bound atoms at surface, including adsorbed species or in the bulk originally holds a set of cells for the resonant energy absorption such as intra- and interband transitions, plasmon oscillations, ionization of valent states, etc. It becomes a common occurrence that the core level excitation is accompanied by using those cells to form an additional multichannel route for the nonradiative energy dissipation. An event comes true on condition that both, the primary and coupled electrons belong to the same configuration.

Surface Defects: Evaluation the Gap between Structure and Catalytic Activity

Cholach A.R.*, Matveev A.V., Bulgakov N.N.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* cholach@catalysis.ru

Keywords: surface defect, structure, catalytic activity

1 Introduction

Surface imperfections often make a strong influence on heterogeneous catalytic reaction. The surface defect may serve as an active center accelerating the rate limiting step; and on the contrary, it can accumulate impurities thus inhibiting the reaction [1]. The wave nucleation observed by Field Emission Microscopy during $NO+H_2$ reaction on a Rh twin tip [2] and in $CO+O_2$ reaction at Pt(110) and Pt(210) surfaces [3] are truly governed by structural defects, while stabilization effect ~ 50-80 kJ/mole of low-coordinated sites at edges and corners of Pt nanoparticles against Pt(111) plane was reported for CH_n species [4]. Anyway, surface defects take there a direct part in the reaction process. The specific behaviour of surface imperfections is usually interpreted at qualitative level and the lack of quantitative considerations encouraged the present study highlighting a simple model bridging up the structure and activity of surface defects as specific centres for adsorption and catalytic reactions.

2 Theoretical

Thermodynamic investigation of the adsorbed species was performed by semi-empirical Method of Interacting Bonds (MIB). MIB does not predict coordination, bond angles and other particular features, but empowers a perfect comparative accuracy. An equality of operating parameters, i.e. an identity of chemical bond nature in reference molecules and in a substance being examined is the only condition for high quantitative reliability of calculations [5].

3 Results and discussion

The sum of Lost Bonds by adjacent atoms (*LB*) forming a given adsorption site as compared with bulk atoms is taken for evaluation the local surface imperfection, while the heat of hydrogenation in the adsorbed layer $N + H \rightarrow NH$ at that site is considered as a measure of activity, in regard to a particular case [2]. Model calculations within the *LB* range of 1-20 have shown that *N* atom expectedly prefers defective adsorption sites of larger *LB* at basic planes of the transition and noble metals, whereas *NH* formation exhibits an opposite behaviour; Fig. 1 shows typical data on Fe as an example. As it turned out, surface defects are responsible for the formation of weakly bound, but inclined to hydrogenation atomic nitrogen as well as the larger by 5-8 orders equilibrium *NH* coverage against perfect terraces. Just these peculiarities force *N* atoms to recombine and desorb at a particular spot between (111) terraces and (100) steps at the Rh(533) single crystal [6] and make an extended defect of the grain boundary to be the center for surface wave nucleation in the $NO+H_2$ reaction on a Rh tip [2].

The model was further tried in examination the optimal catalytic center for NH_3 synthesis assuming the maximum activity corresponds to maximal *NH* coverage θ_{NH} under equilibrium θ_H, θ_N and θ_{NH}. So far as θ_{NH} is a function of *LB*-dependent equilibrium constants K_N, K_{NH} at invariable K_H, then the required sum of *LB* on a volcano curve $\theta_{NH}(K_N, K_{NH})$ is provided by $\partial\theta_{NH} / \partial(LB) = 0$. The latter equation comes true on condition that $K_N = \alpha/(\beta - 1)$, where α

and β are the slopes in opposite linear dependences for heats of *N* adsorption and *N+H* reaction vs. *LB* in Fig. 1, respectively. In these terms an optimal site for *Ru* at typical conditions of NH_3 synthesis ($P_{N_2} \sim 10^2$ atm.; $T \sim 800$ K) was found to consist of 2 atoms at (110)-(2x1) FCC plane, while *Rh* is an unpromising catalyst due to unrealistic *LB* values. Analogous consideration has revealed the coincidence between an optimal sum of *LB* predicted for catalytic center of *Fe* atoms in Fig. 1 and that related to *"C_7"* center in Fig. 2 as responsible for largest activity of the Fe(111) single crystal among others in NH_3 synthesis [7].

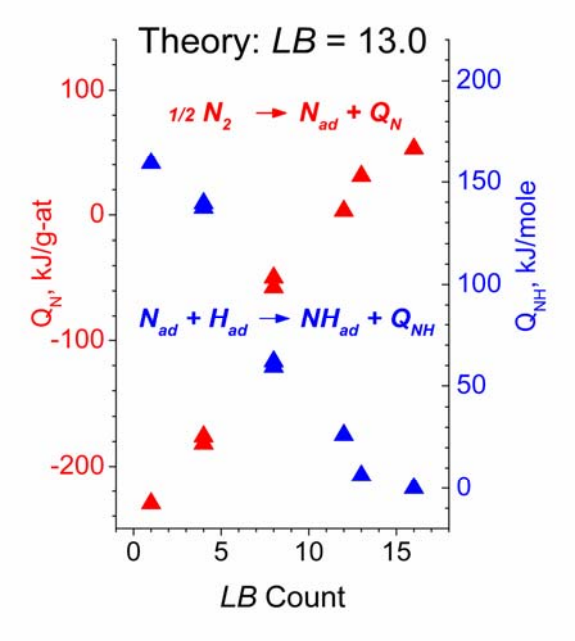

Fig. 1. Heats of indicated reactions at various adsorption sites of basic Fe BCC planes and 0.5 monolayer coverage.

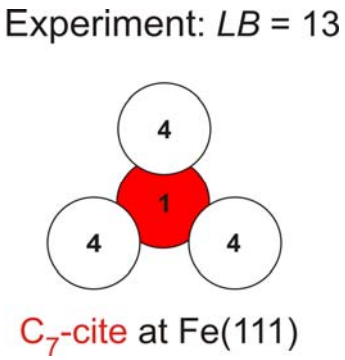

Fig. 2. LB numbers for atoms composing the "C_7"-cite, where "7" originally means the number of nearest neighbors around the middle atom [7].

4 Conclusions

The sum of bonds lost by atoms forming an adsorption site as compared to bulk atoms is a handy and useful measure of local surface imperfection close to physical meaning of the matter. This statement has been specifically confirmed by the following points: the reason of advanced activity of the grain boundary in chemical surface wave nucleation becomes clearly understood; the sum of lost bonds predicted for optimal catalytic center in NH_3 synthesis and formed by various atoms is close to experimental data, and this especially concerns C_7-cites as responsible for largest activity of the Fe(111) single crystal among others. The same approach can be applied to any other adsorption or catalytic process exhibiting high surface sensitivity.

Keywords: Cu-Al ceramometals, microstructure, water-gas shift reaction

1 Introduction

Water-gas shift reaction (WGS) is one of the primary industrial reactions of hydrogen production. One of the main problem of low temperature shift is the low activity of conventional catalyst per volume of the catalyst bed [1]. The possible way to increase the volume activity is the use of ceramometal catalysts with enhanced real and loading density [2]. The aim of the presented work is development of new CuAl-based catalyst prepared through the stage of mechanical alloying of Cu-Al powders and its detailed characterization.

2 Experimental

Aluminum powder with platelet-shaped particles and electrolytic copper powder of dendritic shape were used as starting materials. The powders were mixed in the weight ratio Al:Cu = 13:87 and mechanically milled (MA) in an APF mill (65 g acceleration) under air for 3, 6, 9 and 12 min (denoted as CuAl(3)- CuAl(12)). The details of MA procedure are presented in [3]. The procedure of porous cermets preparation from the MA product included next steps:

a) loading of the MA product into a stainless steel die specially designed to ensure a free access of water and hydrogen release;

b) hydrothermal treatment (HTT) of the loaded die in boiling water for few hours.

This stage provides formation of strong monoliths due to conjugation of the red-ox reaction of aluminum oxidation and formation of contacts between the particles due to crystallization of aluminum hydroxides. Similar to the stage of MA, oxidation of Al at HTT stage diminishes the extent of the exothermic reaction of Me-Al interaction at the stage of calcination.

c) Removing the monolithic product of HTT from the die followed by drying for 1 hour at 120°C and thermal treatment under air at 550°C.

The cermets before and after WGS testing were studied by XRD, NMR, SEM with an energy-dispersive spectroscopy unit EDX INCA, XPS. Compressing (crushing) strength, textural properties as well as thermal conductivity and coefficient of the thermal expansion (CTE) were determined as well. Catalytic activity of samples in the water gas shift reaction was estimated using a flow system in the temperature range of 160-270°C at atmospheric pressure. The tests were performed in the reaction mixture CO : H_2O : H_2 = 8 : 42 : 50 on a catalyst fraction of 0.14– 0.25 mm mixed with quartz fraction of the same particle size in 1:1 ratio. Before the tests, the catalyst was activated in 5% H_2 in He for 2 h at 270°C.

3 Results and discussion

According to XRD the initial cermets consist of CuO, Al_4Cu_9 intermetallide and solid solution of aluminium in copper Cu(Al). Alumina was not detected but by ^{27}Al NMR. After catalytic tests Cu, Cu(Al), Al_4Cu_9 were found. With the time of preliminary milling the

structural properties of cermets are changing non-monotonously. The amount of Al_4Cu_9 passes through the maximum, while that of amorphous alumina – through the minimum.

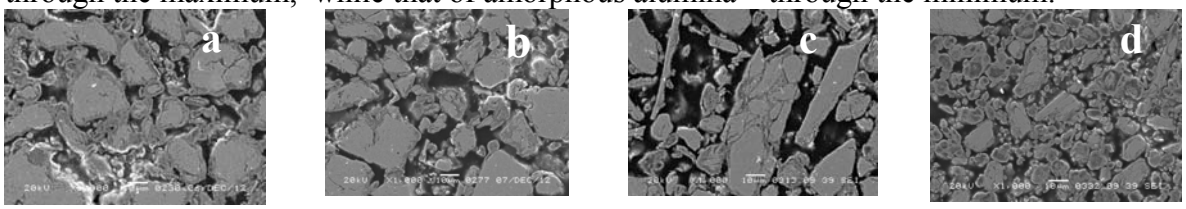

Fig. Microstructure of Cu-Al cermets: (a) – 3 min; (b) – 6 min; (c) – 9 min; (d) – 12 min.

SSA and mesopore volume pass through the minimum, while macropore volume (pore size – up to few microns, see Fig.) - through the maximum (Table). Large amount of open macropores provide improved permeability of cermet monoliths.

Table . Properties of Cu-Al cermets.

Sample	Time MA, min	SSA, m^2/g	V_{meso}, cm^3/g	V_{macro}, cm^3/g	Compress. Strength, MPa	$\rho_{catal.bed}$, g/cm^3	k', s^{-1}	Cu (Cu+Al)	TOF, s^{-1} (240°C)
CuAl(3)	3	14.4	0.02	0.05	10.5	~2.3	2.8	0.59	0.3
CuAl(6)	6	9.9	0.01	0.06	9.9	~2.2	3.3	0.51	0.4
CuAl(9)	9	9.0	0.02	0.07	7.7	~2.1	4.8	0.52	0.6
CuAl(12)	12	15.7	0.04	0.04	9.7	~2.0	7.8	0.59	0.5
$Cu_{50}Zn_{20}Al_{30}O$	-	121	-	-	-	~1.0	9.1	0.39	0.3

The microstructure of initial cermets has an egg-shell character with metallic phases in cores randomly distributed in the oxide matrix (Fig). A large amount of metallic phases provides cermets enhanced loading density (Table), thermal conductivity (1.8-2.4 W/(m·K)), and CTE ($9 \div 15 \cdot 10^{-6}$ K^{-1}) compared to conventional porous ceramics used in WGS catalysis. This makes possible to connect ceramometals with metallic elements to provide regular structure of the catalyst bed and to increase its loading density.

The cermets catalyst possesses a higher concentration of copper on the surface. But the first order WGS rate constants estimated with taking into account the difference or real density of cermet catalysts were found to be lower than for conventional oxide catalyst prepared by precipitation method due to much higher SSA of the latter (Table). The TOF values of some cermet catalyst were found to be higher than for mixed oxide catalyst, having the same order of magnitude like other active CuZnAl oxide catalyst [4]. The specific nature of Cu active sites on the surface of cermets probably related with the surface structure of intermetallic Al_4Cu_9 phase is discussed.

4 Conclusions

The detailed study of the structural, textural, surface and other physical properties in comparison with catalytic properties of cermet CuAlO/CuAl catalysts has been carried out. It was found that TOF values of some cermet catalyst are higher than for CuZnAl oxide catalyst. The structure sensitivity of cermets has been discussed.

Parahydrogen-Induced Polarization (PHIP): a Superior Tool for Mechanistic Studies of Heterogeneous Catalytic Reactions

Salnikov O.G.[1,2*], Kovtunov K.V.[1], Barskiy D.A.[1,2], Burueva D.B.[1,2], Koptyug I.V.[1,2]

Keywords: hydrogenation, parahydrogen-induced polarization, mechanisms of catalytic reactions

1 Introduction

Parahydrogen-Induced Polarization (PHIP) is a very informative method for mechanistic and kinetic investigations of catalytic reactions involving hydrogen. Parahydrogen is a nuclear spin isomer of hydrogen with a total zero nuclear spin. PHIP technique is based on the use of parahydrogen-enriched gas mixtures in hydrogenation reactions. If the reaction mechanism allows addition of two atoms from the same hydrogen molecule to the same substrate molecule (i.e., pairwise hydrogen addition) than the usage of parahydrogen-enriched gas results in hyperpolarized (non-equilibrium) nuclear spin states of reaction product molecules. Consequently, the corresponding NMR signals of product molecules are significantly enhanced, allowing detection of short-lived reaction intermediates and minor products. Moreover, the characteristic anti-phase line shape of hyperpolarized NMR signals clearly indicates the existence of pairwise hydrogen addition route. Thus, the PHIP technique can provide unique information about reaction mechanisms which cannot be obtained with other methods.

So far, mostly investigations of homogeneous hydrogenations catalyzed by transition metal complexes benefited from the use of PHIP technique. However, in 2007-2008 it was found that PHIP effects can be observed in heterogeneous hydrogenations catalyzed by both immobilized metal complexes and supported metal nanoparticles. Thereafter PHIP was used for mechanistic studies of heterogeneous hydrogenations of hydrocarbons (propene, propyne, 1,3-butadiene, 1-butyne) over supported metal catalysts [1].

2 Experimental/methodology

Parahydrogen-Induced Polarization (PHIP) technique was used for mechanistic and kinetic studies of catalytic hydrogenations. H_2 gas was enriched with parahydrogen up to 50 % by passing it through the spiral tube with FeO(OH) powder maintained at liquid N_2 temperature or up to 92 % with the use of Bruker Parahydrogen Generator BPHG 90. The mixtures of parahydrogen-enriched H_2 and various substrates were used in hydrogenation experiments carried out in the gas phase at atmospheric pressure both inside and outside the NMR probe. The reaction products were analyzed by ^{1}H NMR spectroscopy.

3 Results and discussion

In this work PHIP technique was used for investigation of heterogeneous hydrogenation of α,β-unsaturated carbonyl compounds [2] and vinyl acetate. The existence of route of pairwise hydrogen addition to C=C bonds of acrolein, crotonaldehyde and vinyl acetate over several supported Pt, Pd and Rh catalysts was demonstrated. In hydrogenation of acrolein over Pd-Sn/Al_2O_3, Pd-Sn/TiO_2, Pd-Zn/TiO_2 and Pd/TiO_2 catalysts with parahydrogen the proton of CHO group of propanal was also polarized. This can be explained by C(O)-H bond dissociation which represents a side process on the catalysts surface. In hydrogenation of acrolein and vinyl acetate over Rh catalysts the formation of hyperpolarized 2-butene was observed. We assume that this

by-product is formed as a result of dimerization and hydrogen addition to adsorbed vinyl species which are formed by decarbonylation of acrolein or hydrogenolysis of vinyl acetate C-O bond. In hydrogenation of acetone and propanal the hyperpolarized NMR signals of propane resulting from C=O bond hydrogenolysis were observed. All these observations of side reactions products became possible only due to the high NMR signal enhancement provided by PHIP. This again demonstrates the unique possibilities of PHIP technique. It is notable that in our experiments with carbonyl compounds we never observed PHIP effects in C=O bond hydrogenation. This suggests that C=O bond is probably hydrogenated exclusively in non-pairwise manner.

Also for the first time deuterated precursor (propene-d6) was used in heterogeneous hydrogenation with parahydrogen [3]. In case of Rh/TiO_2 catalyst PHIP effects were observed not only for the hydrogenation product propane-d6 but also for the reactant. It means the occurrence of H/D-exchange via hydrogen addition with subsequent dehydrogenation.

In this work it was demonstrated for the first time that PHIP effects can be successfully observed in heterogeneous hydrogenations catalyzed by bulk metals (Pt, Rh) and metal oxides (CaO, Cr_2O_3, CeO_2, PtO_2, PdO, Rh_2O_3). This result indicates the existence of pairwise hydrogen addition route on both types of catalysts [4].

For the first time PHIP technique was used for kinetic studies of heterogeneous hydrogenations. It was found that in propene hydrogenation over Pt/Al_2O_3 catalyst the reaction orders with respect to H_2 are different for the non-pairwise and the pairwise hydrogen addition [5]. Therefore, different types of active sites on catalyst surface are responsible for these two routes of hydrogenation reaction. Also the evaluation of activation energies for both pairwise and non-pairwise routes of H_2 addition to propyne hydrogenation over Pd/aluminosilicate fiberglass catalyst was carried out [6]. It was found that at 175-275 °C the activation energies have similar values (about 60-70 kJ/mol) for both reaction routes. However, at 275-350 °C the rate constant for pairwise hydrogen addition is practically temperature-independent, while the rate constant for non-pairwise hydrogenation continues to grow with increasing temperature.

4 Conclusions

Our results clearly demonstrate that PHIP is a superior method providing unique information about mechanisms of not only homogeneous but also heterogeneous catalytic hydrogenations.

Keywords: template, sawdust, CTAB, ceria-zirconia, copper oxide, CO oxidation

1 Introduction

Ceria-zirconia catalysts modified with CuO are promising systems for low-temperature CO oxidation. Developing of the mesoporous system of such catalyst increases the amount of adsorption sites and provides good transportation of reagents and products. In this work both organic surfactant (cetyltrimethylammoniumbromide, CTAB) and pine sawdust were compared as templates to create mesoporous structure for $CeO_2\text{-}ZrO_2$ and $CuO\text{-}CeO_2\text{-}ZrO_2$ catalysts. Catalytic tests were performed in CO oxidation in the range of from 100 to 450°C.

2 Experimental/methodology

The catalysts were prepared by impregnation of pine sawdust (0,25 – 0,5 mm) with the solution of $ZrO(NO_3)_2{\cdot}H_2O$ and $(NH_4)_2[Ce(NO_3)_6]$ together with $Cu(CH_3COO)_2{\cdot}H_2O$ ($CuO/Ce_xZr_{1-x}O_2$) or without it ($Ce_xZr_{1-x}O_2$) with further drying at 120°C and calcination at 600 - 630°C. On the base of literature data [1] the amount of modifier CuO was chosen to be about 20-25 mol.%.

Comparative systems were prepared using CTAB by slow addition of the solution of the same salts (0.01 mol/100 ml) and 0.05 M citric acid in water to 0,005 M ethanol solution of CTAB with subsequent aging during 3 h, drying at 120°C and calcination at 600 - 630°C.

The catalysts were characterised by SEM (JSM 6490 LV, JEOL), XRD (Bruker D8 Advance ($Cu\ K_\alpha$, using database ICDD JCPDS PDF1, low-temperature N_2 adsorption-desorption (Micometrics ASAP 2000), XPS (Kratos Axis Ultra DLD), TPR and DSC-TG (449PC Jupiter Netzsch, Netzsch GmbH).

Catalytic tests were performed by pulse microcatalytic method using the mixture of 2 vol.% CO and 1 vol.% O_2, balance He, pulse value 1 ml, with GC analysis of products.

3 Results and discussion

Ce:Zr mole ratio in the prepared samples varied from 1:1 to 4:1, the content of CuO was about 20-25 mol.%. The samples based on sawdust denoted as (SD), the others as (CTAB).

SEM investigation demonstrated biomorphic structure for the samples prepared using sawdust as a template (Fig.1a). Both morphology and S_{BET} depends on temperature ramp-up during calcination. Slow temperature increase in the range 150-250°C promotes the saving of biomorphic structure in final complex oxide, fast process promotes material sintering. The samples prepared using CTAB were also characterized by porous structure (Fig. 1b).

XRD diffractograms of $CeZrO_2$ and $CuO/CeZrO_2$ prepared using CTAB or SD contain ceria-circonia phase reflexes (28.8, 33.3, 47.9) broadened slightly for $CeZrO_2$ (SD) and strongly for $0.25CuO/CeZrO_2$ (SD). Separate CuO phase is present in all Cu-containing samples. The weak reflex at 2theta = 60° is characteristic for the presence of Cu_2O phase.

The presence of both CuO and Cu_2O was confirmed by XPS, where the shoulder at 932.5 eV characteristic for Cu^+ was present in Cu 2p spectra near the peak of Cu^{2+} at 934 eV for $0.25CuO/CeZrO_2$ (SD) and $0.25CuO/CeZrO_2$ (CTAB) samples. Local EDS analysis gives $0{,}23CuO/Ce_{0{,}44}Zr_{0{,}56}O_2$ formula for the

surface of 0.25CuO/$CeZrO_2$ (SD). TPR demonstrated the presence of two hydrogen absorbtion peaks: small one with maximum at 240°C and broad one with maximum at 360°C assigned to Cu reduction from oxides.

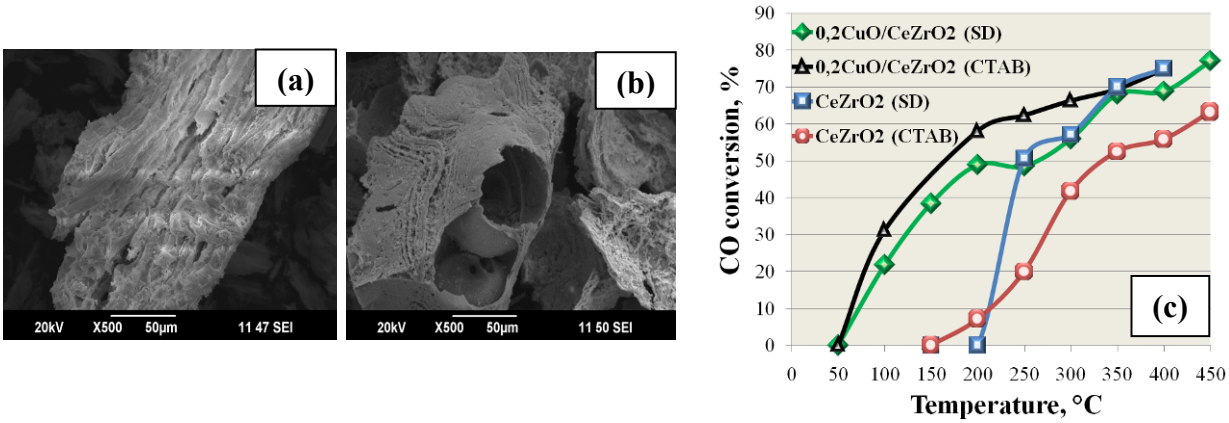

Fig. 1. SEM images of 0.2CuO/$CeZrO_2$ (SD) (a) and 0.2CuO/$CeZrO_2$ (CTAB) (b); CO conversion vs temperature for different samples (c)

All prepared catalysts are active in CO oxidation (Fig. 1c). The addition of CuO to $CeZrO_2$ (SD) leads to the significant decrease of the reaction temperature: the CO conversion at 200°C was 0 on $CeZrO_2$ (SD) and 62% on 0.2CuO/$CeZrO_2$ (SD); at 100 and 150°C it was 25 and 50% respectively. 0.2CuO/$CeZrO_2$ (CTAB) has even better catalytic performance, at 100 and 200°C CO conversion was 30 and 58% respectively. According to [1], it could be explained by better crystallinity of 0.2CuO/$CeZrO_2$ (CTAB) seen from XRD data, that facilitate the transfer of lattice oxygen from the bulk to the surface. However the difference could be connected also with the difference in Cu:Ce:Zr ratio in the samples prepared using CTAB or SD.

4 Conclusions

1. The sawdust which is the waste in timber industry could be effectively used as the template for active ceria-zirconia catalysts instead of organic templates. The application of bio-template and careful tuning of calcination conditions helps to form the biomorphic structure in $CeZrO_2$ and CuO/$CeZrO_2$.

2. The phase composition of $CeZrO_2$ and CuO/$CeZrO_2$ produced using sawdust and CTAB as template is similar, both contain mixed ceria-zirconia oxide and separate phase of CuO with the traces of Cu_2O. However the extent of crystallinity of ceria-zirconia oxide is higher for the CuO/$CeZrO_2$ (CTAB) and lower for CuO/$CeZrO_2$ (SD).

3. Modification of $CeZrO_2$ with Cu oxide leads to the significant decrease of the temperature of CO oxidation, from 250 to 100°C and less. CuO/$CeZrO_2$ prepared using CTAB or SD provide comparable conversion of CO to CO_2, however the first was slightly more active than 0.2CuO/$CeZrO_2$ (SD) possible due to higher crystallinity facilitating the transfer of lattice oxygen from the bulk to the surface.

Keywords: nanoshaped ceria, ethanol steam reforming, operando XRD, ceria-supported, noble metals

1 Introduction

One of the challenges of ethanol steam reforming (ESR) to produce hydrogen (H_2) is how to employ lower temperatures and improve the efficiency of ESR [1], in order to scale down the ESR for diverse forthcoming applications. In the last two decades, a myriad of supported metals have been investigated as potential catalysts for ESR [2]. Among them, the bimetallic Rh-Pd system supported over CeO_2 pioneered by the Idriss' group in 2008 [3] has shown an outstanding catalytic performance for ESR. The synergic effect of Rh that provides C-C bond cleavage with Pd that promotes H_2 recombination and the simultaneous dissociation of H_2O and oxygen mobility provided by CeO_2 leads to a highly active, selective and stable catalyst for the ESR. Recent advances on RhPd/CeO_2 catalysts demonstrated their functionality in several applications, for instance, catalytic membrane reactors to yield high purity H_2 [4], steam reformer for direct PEM fuel cell feeding [5] or microreactors to generate H_2 by bio-ethanol reforming [6]. Earlier last year, Llorca's group illustrated for the first time strong restructuring of the ceria-supported RhPd nanoparticles that takes place under ESR conditions, inducing strong changes to the behavior of the catalyst [7].

Here we report a systematic study of the ESR reaction over RhPd nanoparticles supported on ceria with different morphologies (nanocubes, nanorods and nanopolyhedra), analyzing their catalytic performance and using several characterization tools (operando X-ray diffraction, electron microscopy, etc.) in order to investigate the role of the oxide morphology and the importance of the size and synthetic routes to load RhPd nanoparticles onto ceria supports.

2 Experimental/methodology

Nanoceria supports with different morphologies were fabricated by a hydrothermal method in the range of 373-453K as reported elsewhere in detail [8,9]. Briefly, ceria nanocubes (CeO_2-C) were prepared mixing $Ce(NO_3)_3 \cdot 6H_2O$ and NaOH under vigorous stirring. After precipitation, the suspension was heated for 24h at 453K in an autoclave. Ceria nanorods (CeO_2-R) were synthesized similarly, but heating for 24h at 373K. Conventional nanopolyhedral ceria (CeO_2-P) was prepared by precipitation of an acidic solution of $Ce(NO_3)_3 \cdot 6H_2O$ with a base. Noble metals (3% w/w total with respect to the ceria support, Rh:Pd=1:1 molar) were loaded onto the nanoceria using two different procedures: (i) wetness impregnation, using $PdCl_2$ and $RhCl_3$ solutions and (ii) deposition of core-shell RhPd@dodecanethiol preformed nanoparticles. The ESR reaction tests were performed at 600-1050K.

3 Results and discussion

The H_2 production by catalytic ESR at low temperature (<700 K) over RhPd/CeO_2-C is higher than RhPd/CeO_2-R catalyst and both perform better than a conventional RhPd/CeO_2-P

catalyst, as illustrated in Fig. 1.

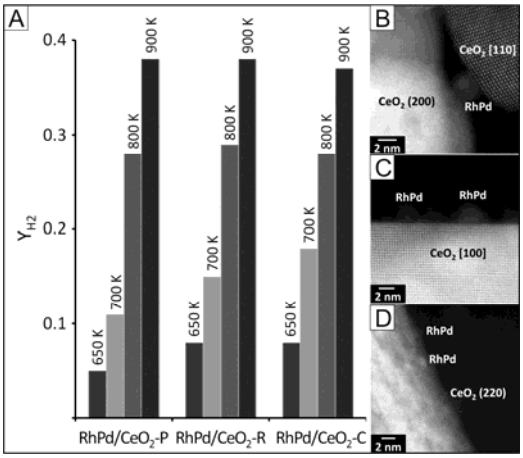

Fig. 1. (A) Hydrogen yield (Y_{H2}, between 0 and 1) obtained at different temperatures over RhPd/CeO_2 catalysts prepared by impregnation from chloride salts. STEM images of RhPd/CeO_2-P (B), RhPd/CeO_2-R (C) and RhPd/CeO_2-C (D). Adapted from [10].

According to operando XRD results, we further show that the reorganization of RhPd nanoparticles is much easier on CeO_2-C and CeO_2-R than CeO_2-P, where the XRD profiles do not show significant variations. Ongoing experiments with preformed RhPd nanoparticles will show the influence of the morphology of the nanoceria support on the performance of the ESR.

4 Conclusions

We have demonstrated the effect of the morphology of the nanoceria support to enhance H_2 production by ESR reaction. The use of RhPd/CeO_2-nanocubes catalyst at low temperature (<700 K) showed a better performance than other morphologies, such as nanorods or nanopolyhedral ceria. The behaviour observed in these catalytic systems can be understood by considering the metal reorganization over {100} and {110} crystallographic planes of ceria compared with over the low surface energy {111} planes of ceria.

Keywords: catalyst, design, vanadium, lanthanum, silicate, co-precipitation, formation, mechanism

1 Introduction

Lower alkenes as well as styrene are important materials for chemical industry. Thereby, production of these hydrocarbons is of increasing interest. Oxidative dehydrogenation (ODH) of alkanes is believed to be promising reaction for their production [1,2].

Catalyst based on supported vanadia showed promising results for the ODH reaction [1,2]. However, the outlook of ODH of propane and other hydrocarbon shows that new concepts for catalyst design are required [2]. Previous investigations have shown that various parameters, including oxidation state, coordination number, aggregation state, reducibility of vanadium species, vanadium content, support nature etc., are required to be considered to account for the catalytic behavior observed for the selective ODH, with the factors that govern the catalytic performances of the surface VO_x species still being debated [1,2].

The presence of isolated tetrahedral vanadium oxide species is commonly supposed to be essential for maintaining high conversion and selectivity in the ODH of lower alkenes, whereas polymeric vanadium species could favor undesired combustion reaction pathways [1-4]. The vanadium incorporation into the support structure was shown to allow stabilizing isolated VO_4 species [3,4]. Using of complex oxides containing isolated VO_4 units in their structure could be an alternative way to development of new active and selective catalysts for ODH.

Lanthanum orthosilicates with an apatite structure can be a possible matrix for isolated tetrahedral vanadium oxide species [5,6]. However, a tailor-made design of materials with desired properties requires developing of controlled synthesis method based upon understanding general physicochemical regularities at each stage of the selected preparation technique. In the present work, the peculiarities of genesis of the structure and texture of lanthanum orthosilicates in the course of synthesis by co-precipitation as well as preparation of vanadium catalysts on the basis of lanthanum silicates are considered.

2 Experimental

Undoped and doped lanthanum silicates were produced by co-precipitation method. To clarify the features of the structure and texture genesis of lanthanum silicates in the course of synthesis, the local structure, phase composition and textural characteristics of undoped and Al- and Fe-doped samples were studied at different stages of their synthesis by XRD, thermal analysis, low-temperature adsorption of N_2, IR spectroscopy, ^{27}Al and ^{29}Si MAS NMR spectroscopy, UV-Vis DR spectroscopy and TEM with EDXA.

3 Results and discussion

Some features of genesis of the structure and texture of apatite-type lanthanum silicates in the course of synthesis via co-precipitation were elucidated, which can be interpreted in terms of formation of amorphous precipitates of slightly soluble hydroxides and their crystallization via

the mechanism of "oriented accretion" [7]. Thus, according to IR, UV-Vis DR, ^{27}Al and ^{29}Si MAS NMR spectroscopy as well as TEM with EDXA data, an amorphous lanthanum silicate with the local structure typical for the orthosilicate, containing Al or Fe atoms in the polymeric structure in the case of doped samples, is formed already at the stages of co-precipitation, ageing and drying of the residue. This indicates that the interaction between constituents under precipitation occurs at the level of hydroxocomplexes or at the molecular level in the step of polycondensation. The polycondensation of La polyhydroxocomplexes in the presence of Si and Al ones during co-precipitation was assumed to result in the formation of primary particles with the polymeric structure similar to that of $La(OH)_3$ hydroxide with columns to be partially filled by Si and Al. It is also interesting from a catalytic point of view that, according to ^{27}Al MAS NMR and UV-Vis DR spectroscopy data, only a part of dopant atoms is present as four-coordinated AlO_4 or FeO_4 units located in the volume of primary particles, while another part is present as six-coordinated AlO_6 or FeO_6 units, being situated at the surface of primary particles forming the amorphous precursor.

Besides, according to low-temperature N_2 adsorption and TEM data, the growth of size of primary particles forming precipitate as well as crystallization of the amorphous lanthanum silicate does not occur in the course of precipitate aging in mother solution at ambient conditions as well as drying up to 120 ºC, but only in the course of the subsequent temperature treatment of the xerogel up to 800 ºC, with intermediate and final products of ageing preserving a "memory" about the initial sample structure. According to the TEM data, irregular-shaped crystalline and partially crystallized lanthanum silicate particles as well as amorphous ones of the precursor are simultaneously present in the sample during its crystallization. Thus, one can assume that the formation of the crystalline structure of the lanthanum orthosilicate occurs inside primary particles formed via the rearrangement of their polymer structure during subsequent thermal treatment in accordance with the mechanism of "oriented accretion" [7]. The irregular shape of formed crystalline particles, in turn, indicates that the formation rate of secondary crystal during crystallization is higher than the ones of crystallization centers and nuclei. In general, textural characteristics of produced crystalline lanthanum silicates were shown to be determined by those of amorphous precursor, which structure formation begins at the early synthesis stages and is mainly completed during thermal treatment in the range of 120-500 ºC.

4 Conclusions

Peculiarities of genesis of the structure and texture of lanthanum silicates in the course of synthesis by co-precipitation were examined. The possible mechanism of the apatite-type lanthanum silicate formation is considered. Given the peculiarities of their formation via co-precipitation, the vanadium catalysts based on amorphous and crystalline lanthanum orthosilicates will be prepared by co-precipitation as well as wetness impregnation methods. Their structure peculiarities and catalytic properties in ODH of propane will be examined.

The Interaction of Model NSR Catalysts BaO/MO_2 and $Pt\text{-}BaO/MO_2$ (MO_2 = TiO_2, ZrO_2, TiO_2-ZrO_2) with NO_2

Smirnov M.Yu.*, Kalinkin A.V., Toktarev A.V., Bukhtiyarov V.I.

Keywords: NOx storage, nitrate, nitrite, Pt, oxidation

1 Introduction

NSR (NO_X storage-reduction) catalysts are used for nitrogen oxides neutralization in automobile exhaust gases by NO_x storage in the form of nitrites and nitrates followed by their reduction to nitrogen. A disadvantage of the NSR-catalysts containing Ba-substances supported on γ-Al_2O_3 as a NO_x absorbing component is their high susceptibility to poisoning by sulfur oxides. The stability of the NSR catalysts to poisoning can be improved by replacing the traditional support material (γ-Al_2O_3) on TiO_2 or ZrO_2. In this paper we studied the interaction of model NSR-systems BaO/MO_2 and $Pt\text{-}BaO/MO_2$ (M = TiO_2, ZrO_2, TiO_2-ZrO_2) with NO_2 using XPS.

2 Experimental

The most of stages of the preparation of the model NSR-catalysts, their reactions with NO_2, and XPS spectra acquisition were carried out in SPECS spectrometer ($P < 5 \times 10^{-9}$ mbar, Mg Kα radiation). Samples of the catalysts were prepared in the form of thin films on substrates made of FeCrAlloy plates coated with an alumina layer. The support films of ~10-15 nm in thickness were deposited by evaporation in vacuum (TiO_2, ZrO_2) or by hydrolysis of titanium or/and zirconium complexes (TiO_2, ZrO_2, TiO_2-ZrO_2). BaO (~3.5-5.5 monolayers) was deposited by evaporation of barium from $BaAl_4$ alloy, followed by annealing in oxygen at 500°C. Platinum was deposited by evaporation of metallic Pt. Treatment in NO_2 was performed in a preparation chamber of the spectrometer at pressure of 3×10^{-6} mbar and a sample kept at room temperature. NO_2 was produced by lead nitrate decomposition.

3 Results and discussion

BaO/MO_2. At the initial NO_2 exposures, the line with the binding energy of ~ 403.5-404 eV appears in the N 1*s* region that is attributable to barium nitrite species (Fig. 1). With increasing exposure, the intensity of this line is reduced, and simultaneously the line with the binding energy of 407-407.5 eV belonging to barium nitrate species starts to grow. At the initial stage, the reduction of NO_2 molecules into the nitrite species is accompanied by the oxidation of surface carbon that is confirmed by spectra recorded in the C 1*s* region. The formation of barium nitrate occurs more efficiently when the support contains ZrO_2 (Table 1). Apparently, barium titanates are present in the sample BaO/TiO_2 that are less reactive than BaO with respect to NO_2.

$Pt\text{-}BaO/MO_2$. After platinum deposition, an asymmetric shape of the Pt $4f_{7/2}$ and Pt $4f_{5/2}$ lines in the Pt 4*f* region and the binding energy BE($Pt4f_{7/2}$) ~72 eV indicate that the samples contain small platinum particles in the metallic state. The interaction of these samples with NO_2 also leads to the successive formation of barium nitrite and barium nitrate. The total amount of NO_2 absorbed is greater than in the case of BaO/MO_2 samples, mainly due to a more efficient formation of nitrite (Table 1). Two new states of platinum are formed in the reaction with NO_2 (Fig. 2a). The first state, which is characterized by a doublet of asymmetric lines (drawn in

green) and BE(Pt4$f_{7/2}$) increasing monotonically with NO_2 exposure, belongs to metallic platinum particles with dissolved oxygen [1]. With the further exposure increase, the second doublet appears and grows, which lines (drawn in red) have a symmetric shape, and BE(Pt4$f_{7/2}$) ~72 eV corresponds to PtO_2.

Pt 4*f* spectra of the samples annealed in vacuum at 500ºC reveal that the annealing makes Pt particles larger. Again, the reaction with NO_2 leads to the successive formation of barium nitrite and barium nitrate, but with the preferential formation of nitrate (Table 1). In this case, spectra in the Pt 4*f* region (Fig. 2b) show that PtO_2 is formed in very small quantities and only after the largest NO_2 exposures. The result is not surprising, since larger Pt particles are oxidized more difficult [2].

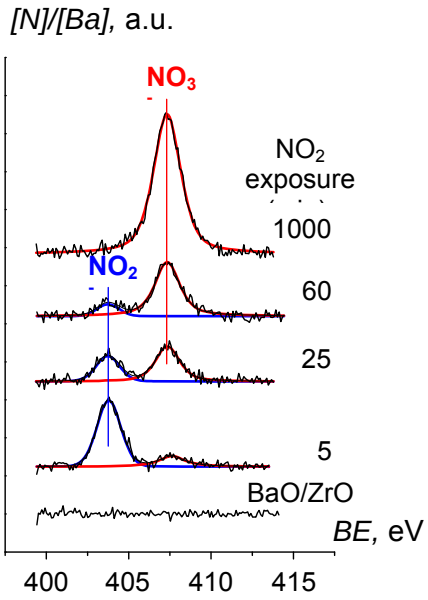

Fig. 1. N 1*s* spectra for BaO/ZrO_2 sample under its reaction with NO_2.

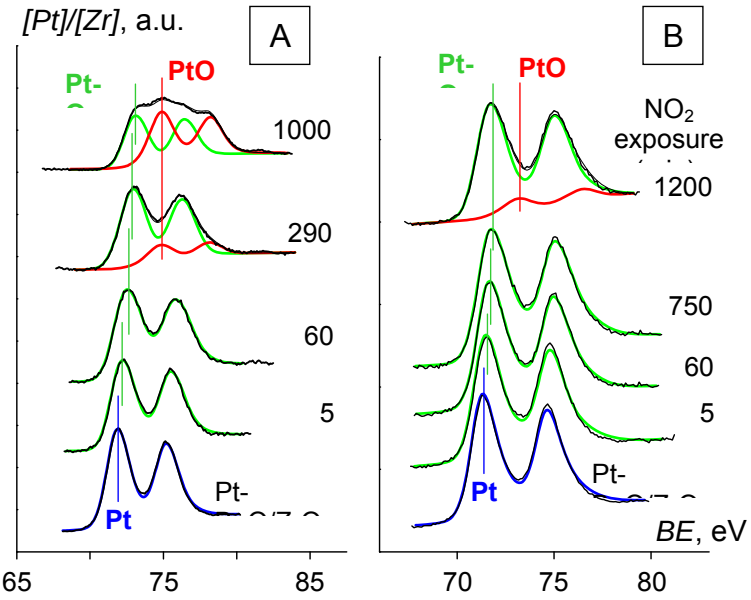

Fig. 2. Pt 4*f* spectra for fresh (A) and annealed (B) Pt-BaO/ZrO_2 samples under its reaction with NO_2.

Table 1. The nitrate ($[NO_3^-]/[Ba]$) and total NO_x^- ($[NO_x^-]/[Ba] = [NO_2^-]/[Ba]+[NO_3^-]/[Ba]$) concentrations achieved in the reactions of the model NSR catalysts with NO_2.

Model catalyst	BaO/TiO_2	BaO/ZrO_2	BaO/TiO_2-ZrO_2	Pt-BaO/TiO_2-ZrO_2, fresh	Pt-BaO/TiO_2-ZrO_2, annealed
$[NO_3^-]/[Ba]$	0.18	0.38	0.41	0.43	0.58

Location, Toxicity and Growth Mechanism of Coke on Hierarchical MOR Zeolites

Chouati M.[1,2], Soualah A.[2], Pouilloux Y.[1], Pinard L.[1*], Astafan A.[1]

Keywords: Mordenite, desilication, coke, deactivation, regeneration

1 Introduction

The presence of regular pores of molecular dimensions in zeolite can have multiple effects on the catalyst lifetime. In favourable cases, the microporous shape selectivity can prevent formation of bulkier molecules that block pores and thus dramatically slow down catalyst deactivation. In many cases however, depending on pore shapes and dimensionality of zeolite system, bulky molecules, usually called "coke", can accumulate inside the porous network and impede diffusion of reactants/products to/from active sites by pore blocking or poisoning, leading to a rapid deactivation [1].

The size and shape of micropores, channel intersections, external surface apertures determine the shape and the maximum size of trapped coke molecules [1-2]. Moreover, the zeolite dimensional channel system affects catalytic consequences of deactivation. On a three-dimensional system like MFI, deactivation occurs mainly by acid site poisoning; i.e. one coke molecule poisons one active site. Contrariwise, deactivation occurs only through pore blockage on one-dimensional zeolite system; i.e. on MOR more than 20 Brønsted acid sites can be deactivated by only one coke molecule [1].

The creation of mesopores on MOR zeolite crystal, through demetallation treatments, leads to a three-directional porous system that could reduce considerably the coke toxicity. The degree of the three dimensionality of the hierarchical MOR zeolite is related to the interconnection between mesopores with micropores.

The aim of this work is to establish a relation between the textural properties of different hierarchical HMOR zeolites and the toxicity, location composition of coke formed during the propylene oligomerisation.

2 Experimental/methodology

A commercial Mordenite was used as a starting material (MOR structure type and Si/Al = 10) in protonic form (**MOR**). Three hierarchical zeolites were prepared by alkaline treatment using aqueous sodium hydroxide (0.2M, 70 °C, 2h); **MOR D** was prepared by desilication with NaOH, **MOR DL** by desilication followed by acid leaching with aqueous of HCl (0.5 M, 10 min, 30 °C) in order to remove all fragments formed during alkaline treatment, susceptible to block the micropore access, and **MOR LDL** by acid leaching before and after desilication. The table 1 reports some selected properties of the catalysts.

Table 1: Selected properties of commercial and hierarchical mordenite zeolites

Catalyst	MOR	MOR D	MOR DL	MOR LDL
V_{micro}[a] ($cm^3.g^{-1}$)	0.20	0.19	0.23	0.20
V_{meso}[b] ($cm^3.g^{-1}$)	0.15	0.25	0.20	0.34
$[PyH^+]$[c] ($\mu mol.g^{-1}$)	1056	621	680	784
[PyL][d] ($\mu mol.g^{-1}$)	31	162	133	130

[a]micropore volume calculated by using *t*-plot method; [b] Mesopore volume $=V_{total}-V_{micro}$ (V_{total}: volume adsorbed at $p/p_0=0.99$) ; [c,d] Measured by pyridine adsorbed on Brønsted (PyH^+) and Lewis (PyL) acid sites, respectively, after evacuation at 150 °C.

3 Results and discussion

The evolution of carbonaceous deposits was monitored by gravimetric measurements during conversion of propene at 623 K under pressure of 1 bar, by conventional microbalance instrumentation. The coking rate is very fast on MOR, after 4 min all the access of micropores were blocked to nitrogen. Initially, all coke molecules are soluble in methylene chloride after dissolution of the zeolite matrix, but insoluble coke appeared during the coking time. Soluble coke molecules can be lumped in four families according to their number of aromatic rings: naphthalene, anthracene, benzoflorene and chrysene. It should be underscored that the degree of alkylation of coke molecule is low, it does not exceed 4. On Hierarchical MOR zeolite, an additional porosity leads to a supplementary coke uptake. This additional coke leads to insoluble coke as the expense of the soluble coke. Detailed coke features, in term of molecular structure, have been obtained by combining a large range of techniques: matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) directly on the spent catalyst. From these data a schematic build-up of carbonaceous residues will be proposed.

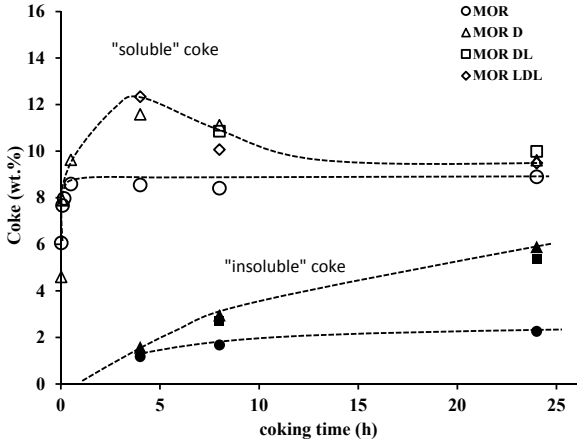

Fig. 1. (a): Content of soluble and insoluble coke deposited on mordenites samples during propylene oligomerisation.

Computational Investigation of Palladium Supported Boron Nitride Nanotube Catalysts

Schimmenti R.*, Prestianni A., Ferrante F., Duca D.

Università degli Studi di Palermo, Dipartimento di Fisica e Chimica, Palermo, Italy

* roberto@cccp.unipa.it

Keywords: metal supported, catalysts, oxygenate, adsorption, DFT, calculations, ONIOM

1 Introduction

Boron nitride based nanotube (BNNT) derivatives showed really interesting properties such as high chemical and thermal stability as well as great mechanical strength and high thermal conductivity. [1] These features make them especially suitable for high temperature technologies and catalysis: as an example, the lack of acidic sites and their peculiar thermal properties, should reduce the sintering of disperded metals. Metal supported on BNNTs have been studied as catalysts for the selective oxidation of lactose, showing high activity and selectivity. [2] For this and other related reactions, namely carbohydrates oxidation, it has been showed that the chemical nature of the support could affect the degree of dispersion and dimension of the dispersed nanoparticle, ruling the reaction activity and selectivity. [3] A computational study could elucidate effectively how the interactions between metals and BNNTs affect the growth of metal clusters. Since it has been showed that the presence of edge and corners on the metal nanoparticle could exert a detrimental effect on the global activity of the above mentioned reactions, the modelling of high dimension metal clusters showing different surfaces should be addressed.

In this study the interactions of small palladium clusters (Pd_2, Pd_3 and Pd_4) with a single walled BNNT were modelled. Since it has been previously demonstrated to be a representative model for a range of relevant sites, [4] a Pd_{30} cluster was chosen in order to investigate the interaction of a larger cluster with the BNNT support. Finally, the oxygenate D-glucopyranose adsorption on the Pd_{30}/BNNT system was analysed to model medium-complex biomass derived molecules.

2 Computational details

Calculations were performed by the Gaussian 09 code package. A QM/MM approach, exploiting the 2-layer ONIOM method was employed. The UFF molecular mechanics was selected as the low level (real system) while the high level (model system) was defined in the framework of the DFT, employing the Coulomb-attenuated CAM-B3LYP hybrid exchange-correlation functional. The Los Alamos LANL2 effective core potential and the corresponding double ζ basis set were used for the Pd atoms, while for the lighter atoms (H, B, N, C, O) the D95V basis set was adopted.

3 Results and discussion

The interaction energy and the geometry of the calculated most stable structures are reported in Figure 1. On the whole, the adsorption processes seem to be favoured, increasing the size of the cluster. This can be outlined taking into account the most stable spin state of the clusters, which in almost every case is the triplet one. The geometrical features of the optimized structure can be rationalized considering a balance between both the Pd–Pd and the metal–support interactions.

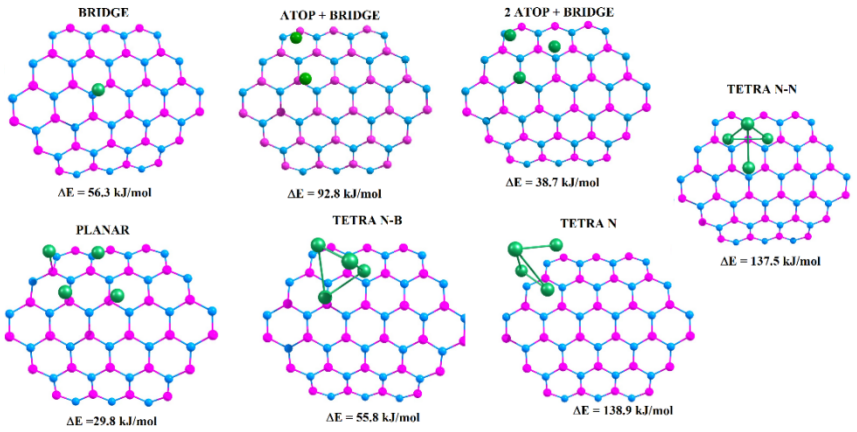

Fig. 1. Optimized structures and interaction energies, characterizing Pd_n/BNNT systems

These peculiar interactions are particularly significant in the Pd_4 planar structure in which a mixed endo/exocyclic coordination of the cluster with the BNNT surface is observed. Simulation of a massive Pd_{30} cluster suggests that the BNNT could decisively affect the geometry of the supported particles: indeed, the global effect of the adsorption onto the BNNT can be described as a screw displacement of the [100] plane toward the [111]. Moreover, the BNNT support exerts an electron donating effect on the cluster. The effects above would seem to be important in the description of the catalytic properties of the BNNT systems. As an example, the adsorption process of one D-glucopyranose molecule on the cluster is less favoured if the Pd_{30} is supported on the BNNT. With respect of this, it is thus reasonable to infer that the negative charge, which might be confined on the Pd_{30} cluster is pretty limited hence the BNNT support could consistently affect the adsorption of electron donating species on the same cluster.

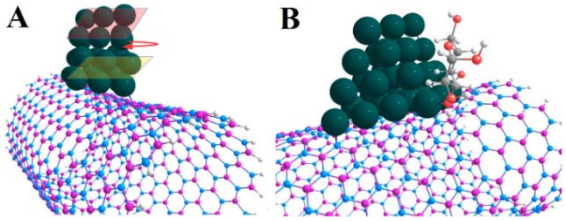

Fig. 2. **A**) "Screw" displacement of the 100 plane of the cluster toward the 100; **B**) Optimized structure of a D-glucopyranose molecule on the supported Pd_{30}

4 Conclusions

The interaction of Pd_2, Pd_3, Pd_4 and Pd_{30} clusters with BNNT surface was studied by means of a computational approach. It has been showed that the adsorption process is moderately exoergic; the geometry of the clusters is largely depending on the considered spin state. Furthermore, the BNNT clearly affects the supported metallic cluster structures, which results quite different with respect of those unsupported, *i.e.* optimized *in vacuum*. This effect is much more relevant for the larger clusters. On the latter, indeed, i) a rearrangement of the [100] and [111] planes and ii) a negative charge enrichment occur. These phenomena could promote a detrimental effect on the adsorption of the D-glucopyranose molecule on the Pd_{30} cluster.

Keywords: Cu catalysts, methanol synthesis

1 Introduction

Catalytic methanol synthesis from carbon oxides and hydrogen is a key step of natural gas conversion to valuable organic compounds and polymers. Nowadays the world production of methanol is over 60 million tons per year. The composition and the method of preparation of the Cu-Zn-Al methanol synthesis catalysts are almost unchanged during last 50 years and close to the initially proposed by ICI. However, the structure of the catalyst and its active state, as well as the mechanism of methanol synthesis are still the challenges further investigation. This paper reports the experimental data about the nature of the active component, the structural features of precursors and the active state of Cu-Zn-containing methanol synthesis catalysts.

2 Experimental/methodology

CuZnAl(Cr) catalysts precursors of different composition have been obtained by coprecipitation method, that provides complete chemical interaction of the components in the form of hydroxocompounds (HOCs) and high reproducibility of their properties. HOCs and the products of their thermal treatment and reductive activation were thoroughly studied with a large set of modern physico-chemical methods: XRD, including *in situ* XRD, DTA, EM, IR. Catalytic behaviour was tested in the laboratory flow reactor at 1 atm.

3 Results and discussion

The results presented in Table 1 evidence that both in Al- and Cr-containing samples HOCs of different structure are formed. The conditions of coprecipitation and quantitative ratio of the components determine the composition and structure of HOC. The chosen composition and conditions provided obtaining of homogeneous model samples of hydrozincite, aurichalcite and hydrotalcite structure. Their thermal decomposition results in the oxide compounds formation, which are solid solutions on the base of anion-modified oxides - ZnO* (wurtzite-type) and spinel*. The reductive activation of solid solutions leads to the formation of Cu^0 nanoparticles on the surface of hard-to-reduce oxides. As it is seen from Table 1, the catalytic activity of these Cu^0 nanoparticles differ significantly. The most active are the catalysts on the base of aurichalcite-type precursor. The same catalysts are the most stable.

The detailed study of the products of thermal decomposition and reductive activation of CuZnAl(Cr) HOCs of aurichalcite structure has been performed. Figure 1 presents the micrograph of reduced at 220^0C in hydrogen CuZnO sample. Nanoparticles Cu^0, epitaxially bonded to the ZnO surface, are clearly visible. Their stability in reductive atmosphere depends on the Al(Cr) presence and restricted to 380-400^0C.

Table 1. Cu^0 species and hydroxo- and oxo- precursors compounds, methanol synthesis rates at 220^0C, 1 atm, reaction gas CO : CO_2 : H_2 = 20 :5 : 75 ($C_{MeOH} = 1 \cdot 10^{-3}$ vol.%).

Hydroxo- and oxo precursor (at.fraction)	Cu-mode	W, mmol MeOH/g/h

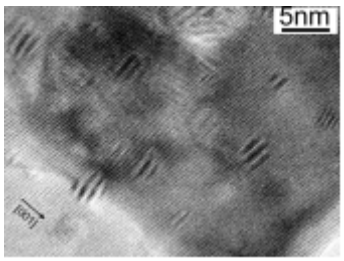

Fig.1 HR-TEM micrograph of metallic Cu nanoparticles epitaxially bonded to ZnO (note the characteristic Moire fringes due to mismatch of interatomic distances in the epitaxial phases) in the Cu-Zn oxide after its reduction in hydrogen at 220^0C.

4 Conclusions

The obtained results and recently published data suggest that the active state of Cu-Zn-containing methanol synthesis catalysts is an extremely complicated system, which includes defective metallic particles that strongly interact with the supporting defective ZnO phase in the form of epitaxial bonding and are at least partially decorated by amorphous oxide overlayer [1, 2]. Both the metallic nanoparticles and the oxide support have mixed (Cu-Zn) composition and are defective. $Al^{3+}(Cr^{3+})$ cations are not merely structural promoter, however, directly affect the specific activity of the active sites.

The intimate interaction of Cu-Zn species may only be possible as the result of their genesis from mixed Cu-Zn oxide phases. Solubility Cu^{2+} in ZnO* can be dramatically increased by anionic modification of the mixed oxide structure. Promotion of the oxide structures by small quantities of $Al^{3+}(Cr^{3+})$ cations can further expand solubility ranges and thermal stability of the catalyst. Evolution of anionic admixtures due to overheating the mixed oxide beyond the threshold of their thermal stability (*ca.* 380-400^0C) leads to decomposition and recrystallization of mixed oxides, causing the decrement of the catalytic activity in methanol synthesis. The most natural way for production of anion-modified mixed oxide is decomposition of mixed hydroxycarbonates at moderate temperatures.

Keywords: hydrogenation, diatomite, trans-isomers, Pricat-9910, palladium, catalyst, canola oil

1 Introduction

The hydrogenation of vegetable oils is an important practice in the modifications of fats and oils. Catalytic hydrogenation of vegetable oil has seen a lot of advances recent years, especially regarding efforts to reduce the *trans*-fatty acids (TFA). High intake of TFA has been associated with increased risk of coronary heart disease, diabetes mellitus and decrease HDL-cholesterol and promote inflammation [1-2]. Nowadays, Ni-catalysts are most commonly used for vegetable oils hydrogenation in industrial hydrogenation. It is carry out high temperature (180-230°C), this conditions of hydrogenation using Ni catalysts promote the formation of *trans*-isomers and products of thermal decomposition of fatty acids. Nickel tend to be dissolved in the oil to form corresponding salts, its salts may lead to the cause product toxicity. For hydrogenation vegetable oils reaction many researches shows that nickel catalysts are not very active below 130°C. Palladium catalysts are active at low temperature of 70°C and decreased *trans*- fatty acids in hydrogenation of vegetable oils. Therefore, the main challenge in developing new technologies obtain pure product is to the replacing the nickel catalyst with palladium catalyst can be more efficient and real prospects [3-6].

In this research work new low content palladium catalysts supported on diatomite were synthesized, investigated for good support qualities, and tested for their hydrogenation activity on vegetable oil in laboratory and experimental-industry testing. The results are compared to those obtained over a commercial nickel catalyst (Pricat-9910).

2 Experimental/methodology

In this study, we choose a catalyst support using diatomite. The raw diatomites obtained from Aktobe/Kazakhstan and chemical treatment was performed with hydrochloric acid. Then, 0.2% palladium supported on diatomite was prepared by the adsorption method, investigated for good support qualities, and tested for their hydrogenation activity on canola oil. Pilot testing hydrogenation process carried out in 10t of capacity batch reactor at 90°C and pressure of hydrogen 0.5MPa by using 0.2% Pd/D catalyst and compared to commercial nickel catalyst (Pricat-9910) at 150°C and 0.5MPa. The fatty acid composition of the hydrogenated canola oil was determined by gas chromatography (GC). Iodine values and melting point were determined. Solid fat content (SFC) determined using nuclear magnetic resonance (NMR) spectrometry, taking readings from samples in at temperature 10, 20, 30 and 40°C.

3 Results and discussion

The commercially refined and bleached canola oil used in this work. The calculated iodine value (IV) was 133. Acid value - 0.26±0.01 mg KOH/g, peroxide value - 8.7±0.2 meq. of

oxygen/kg, and content of phosphorus - 5±1 mg/kg of oil.

It was canola oil used in industrial pilot hydrogenation. Pilot testing of palladium catalyst for hydrogenation of canola oil was carried out on LTD "Maslo-Del" (Almaty city) oil and fat factory. The fatty acid composition at hydrogenation process is listed in table 1 and solid fat content figure 1.

Table 1. The composition of fatty acids partial hydrogenated canola oil over low percentage palladium catalyst and commercial Ni catalyst

Catalysts	T, °C	IV*	Melting point, °C	Fatty acid composition, %					*Trans*-isomers, %
				$C_{16:0}$	$C_{18:0}$	$C_{18:1}$	$C_{18:2}$	$C_{18:3}$	
Feedstocks	-	128.9	-	6.6	3.0	38.5	33.2	14.1	1.4
Pricat-9910	150	78.5	33.0	9.5	8.8	65.6	11.3	-	20.5
0.2% Pd/D	90	72.4	32.6	8.7	9.9	67.5	5.6	-	13.4

On table 1, pilot tests and analysis of products shows that low percentage palladium catalyst is able to carry out the process at lower temperature than the commercial nickel catalyst. Hydrogenation at lower temperature and pressure can minimizes the isomerization of a *cis*- to *trans*-isomer double bond conformation. The results of the chromatographic analysis of products show that *trans*-isomers content was reduced at 1.5 times as palladium catalyst is compared with nickel catalyst.

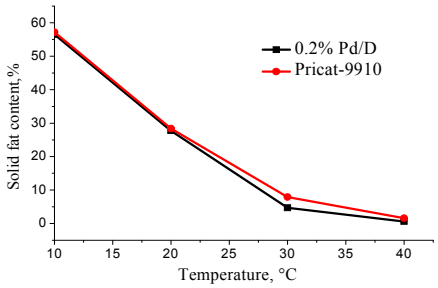

Fig.1. Hydrogenated canola oil SFC curve depending on the temperature

Figure 1 shows physical parameters of products such as solid fat content obtained from both catalysts are the same. Also, other parameters like melting point and iodine values are the same too.

4 Conclusions

A low percentage of palladium catalyst is more effective and highly selective in hydrogenation of canola oil. Palladium catalysts are active at low temperature of 90°C and decreased *trans*-fatty acids in hydrogenation of vegetable oils than nickel catalyst.

Metal-Free N-Doped Carbon Networks as Hydrogenation Catalysts: a Computational Study

Cortese R.*, Ferrante F., Duca D.

Università degli Studi di Palermo, Dipartimento di Fisica e Chimica, Palermo, Italy

* remedios.cortese@unipa.it

Keywords: metal-free, hydrogenation catalysts, N-doped carbon, frameworks, DFT

1 Introduction

The development and assessment of a future industry more environmentally-friend will include the use of metal-free catalysts. Most of the reported metal-free catalysts are homogeneous and, as a consequence, their recycle is often difficult. Therefore, the development and investigation of heterogeneous metal-free catalysts is of great interest both theoretically and experimentally. N-doped nanotubes and graphene sheets were recently synthesized. [1,2] With respect of these, it was demonstrated that the incorporation, within the carbon structures, of nitrogen atoms causes a larger electron mobility and introduces more active sites for catalytic reactions. The nitro- and cyano-moieties were experimentally compared toward hydrogenation catalyzed by these new-generation doped materials, founding that although the former is in any case hydrogenated the latter does not show any reactivity [3]. The present investigation is aimed at elucidating the main features of the hydrogen fragmentation over these carbon frameworks and subsequently the hydrogenation mechanism potentially involved when nitro- and cyano-moieties over N-doped carbon networks are considered.

2 Experimental/methodology

Several models and different theoretical approaches were employed in this study, to characterize the structural and energetic properties of nitrogen pyridinic moieties framed within a carbon network, commonly classified as pyridinic defects. Two different kinds of pyridinic defect configurations within a carbonaceous environment, here referred as 4N and 3N sets of defects were studied. The species belonging to the 4N set were obtained by removing two carbon atoms from the carbonaceous framework and substituting the four unsaturated carbon atoms formed by an equivalent number of nitrogen atoms. To form a 3N defect, conversely, one carbon atom was removed and the resulting three unsaturated carbon atoms were replaced by three nitrogen atoms. Three different model classes were employed in the here investigation. The classes above may be identifiable as molecular, truncated nanotubes, and periodic nanotubes.

The calculations on the first and second class of models were carried out by employing the Gaussian 09 code package whereas the third one was managed using the SIESTA method as implemented in the homonymous code. Molecular models were analyzed within the density functional theory (DFT) framework, using as exchange-correlation functionals both the hybrid B3LYP and the new-generation hybrid M06-2X joined with the correlation-consistent polarized double zeta basis set cc-pVDZ. Truncated nanotube models were finally treated employing a hybrid QM/MM approach using the ONIOM energy extrapolation scheme. DFT was employed as higher level, by using the same computational specifications employed for the molecular models, and UFF as lower level.

3 Results and discussion

The title study can be here summarized into three main issues: i) the analysis of hydrogen fragmentation on N-doped carbon network models, bearing 3N and 4N defects, [4] ii) the

adsorption of nitro- and cyano-moieties on hydrogenated N-doped carbon networks models containing 3N defects and, finally, iii) the search of the catalytic hydrogenation pathways involving the C_6H_5-NO_2 and C_6H_5 -CN molecules (see Fig. 1).

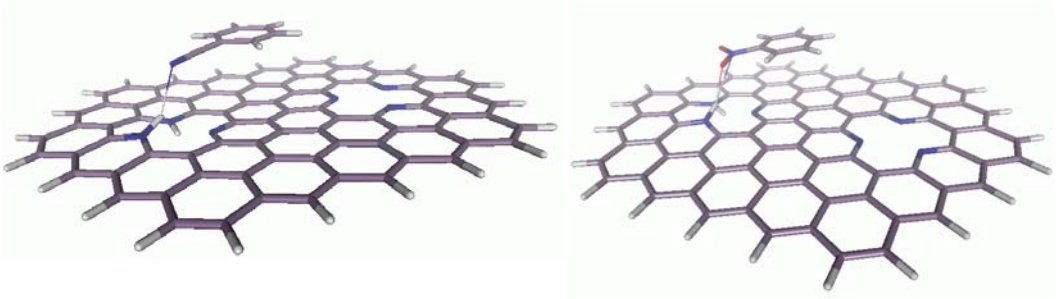

Fig. 1. Adsorption of C_6H_5 -CN and C_6H_5-NO_2 on hydrogenated 3N carbon framework models.

The H_2 fragmentation ergonicity was studied on all the carbon networks models containing 4N as well as 3N defects. This analysis was performed studying the ergonicity as a function of both i) the size of the π-system, surrounding the N-defect and ii) the curvature of the carbon network. On the ground of the performed analyses, it was found that all the N-defect arrangements considered give rise to largely exergonic H_2 fragmentation while the characteristics of the π-systems, surrounding the N-defects, affect the H_2 activation and chemisorption processes, increasing the transformation exergonicity with increasing the size and regularity of the aromatic environment. Moreover, the different N-defect topologies influence the H_2 fragmentation and activation processes while the carbon framework curvature seems to have only limited influence on the energetics. Concerning the reactivity of C_6H_5-NO_2 and C_6H_5 -CN molecules, it was found that the adsorption process of the two molecules is largely different: a more pronounced adsorption energy on the hydrogenated N-doped carbon network was indeed found for the C_6H_5-NO_2 with respect to the C_6H_5-CN molecule. These adsorption properties very probably are related to the occurrence of their pretty different reported reactivity.

4 Conclusions

The H_2 fragmentation was analyzed on different carbon networks containing pyridinic defects. The influence of the π-system characteristics as well as of the nanotube curvature on the ergonicity associated to the H-H cleavage on these metal-free catalysts was investigated and important insights within the hydrogenation reactions of the C_6H_5-CN and C_6H_5-NO_2 were gained.

Enhanced Catalytic Performance of Ni-Fe Alloy in Methane Dry Reforming: Role of Fe

Theofanidis S.A.*, Galvita V.V., Poelman H., Marin G.B.

Ghent University, Laboratory for Chemical Technology (LCT), Ghent, Greece

* StavrosAlexandros.Theofanidis@UGent.be

Keywords: Ni-Fe alloy, effect of Fe, methane dry reforming, *in-situ* XRD, carbon formation

1 Introduction

Methane reforming processes are currently used to produce syngas or hydrogen. Due to increasing demands for H_2 and syngas applications, the role of these processes has recently become more important. Methane dry reforming ($CH_4 + CO_2 \leftrightarrow 2CO + 2H_2$) converts two greenhouse gases into valuable chemicals and offers the attractive advantage of a H_2/CO molar product ratio close to one, suitable for widespread use in many industrial processes (Fischer-Tropsch synthesis, etc) [1].

Conventional catalysts for methane dry reforming are Ni supported over oxides such as Al_2O_3, SiO_2, MgO. Despite the large variety of catalysts currently in use, the rapid deactivation caused by sintering of the active metal and by carbon formation remains the major challenge of this reaction. Carbon deposition results from methane decomposition ($CH_4 \rightarrow C + 2H_2$) and/or Boudouard reaction ($2\ CO \rightarrow C + CO_2$). Alloying Ni with other metals can improve the catalytic performance and one suitable modifier is Fe [2]. Iron species have good redox properties, like CeO_2 [3]. Previously an improved performance was reported in the steam reforming activity of Ni–Fe/Al_2O_3 catalysts, due to Ni–Fe alloy formation [4].

In order to investigate the effect of Fe on Ni/$MgAl_2O_4$, a series of Fe-Ni /$MgAl_2O_4$ catalysts are tested. One aspect that awaits clarification is whether and how the Ni-Fe alloy contributes to the elimination of carbon deposition during methane reforming. Further, the mechanism for dry reforming over a Ni-Fe catalyst is not clear. These questions are addressed in this study by performing in-situ X-ray diffraction (XRD) characterization of Ni-Fe/$MgAl_2O_4$ catalysts during H_2 temperature-programmed reduction (H_2-TPR), CO_2 temperature-programmed oxidation (CO_2-TPO) and dry reforming. Alternate pulses are also applied by switching the flow between CO_2, inert He and CH_4 over a Ni/$MgAl_2O_4$, Fe/$MgAl_2O_4$ and Fe-Ni/$MgAl_2O_4$ catalysts.

2 Experimental

Catalyst preparation. Four Ni-Fe catalysts were prepared by incipient wetness impregnation on the support ($MgAl_2O_4$) using an aqueous solution of corresponding nitrates. The catalysts were dried at 393 K for 12h and subsequently calcined in air at 1023 K for 4 h. The Ni loading was maintained at 8wt%, while the Fe loading was varied from 0 to 5, 8 and 11wt% as it is shown at Table 1.

In-situ time resolved XRD. In-situ XRD measurements were performed in a home-built reaction chamber housed inside a Bruker-AXS D8 Discover apparatus (Cu Kα radiation of 0.154 nm). The reactor chamber had a Kapton foil window for X-ray transmission. The setup was equipped with a linear detector covering a range of 20^o in 2θ with an angular resolution of 0.1^o. The pattern acquisition time was approximately 10 s.

3 Results

During H_2-TPR, Fe_2O_3 and NiO were reduced above 973K to form a Ni-Fe alloy (Figure 1A), which constitutes the active phase for the methane dry reforming reaction. This

alloy remained stable in a flowing gas stream of CO_2 during re-oxidation (Figure 1B), until 900 K, but was decomposed to metallic Ni and Fe_3O_4 above this temperature.

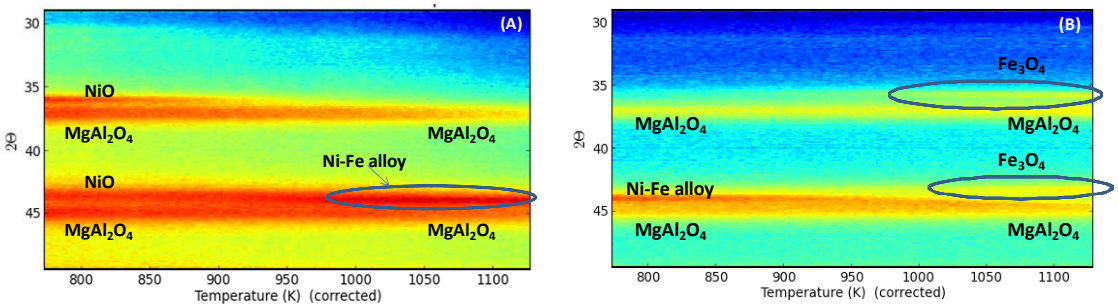

Figure 1. 2D XRD pattern for Ni/Fe=0.7 (A) Alloy formation during H_2-TPR. Conditions: maximum temperature= 1123 K, heating rate: 30 K/min, flow rate: 60 ml/min, 10%H_2/He. (B) Alloy decomposition during CO_2-TPO. Conditions: maximum temperature=1123 K, heating rate: 30 K/min, flow rate: 60 ml/min

The effect of Fe addition to the activity of a Ni/$MgAl_2O_4$ catalyst, under methane dry reforming reaction conditions was found to depend on the employed Ni/Fe ratio. Activity measurements indicated that Fe/Ni=0.7 mol/mol presented a high selectivity towards CO and a CO/H_2 ratio close to unity. Even though lower Ni/Fe ratios led to lower CO/H_2 values, the latter were still higher than those resulting from Ni/$MgAl_2O_4$. Furthermore, the implementation of regeneration cycles showed that the catalyst activity can be restored. Lower amounts of accumulated carbon were observed after reaction on Fe-promoted samples compared to the Ni/$MgAl_2O_4$ sample.

Alternate CH_4 and CO_2 pulses in combination with in-situ XRD allowed to determine the mechanism of methane dry reforming over Ni-Fe catalyst. Mars-Van Krevelen mechanism can describe this reaction where CO_2 oxidizes Fe to FeO_x (Eq. 1), and CH_4 is activated on Ni sites to form H_2 and surface carbon (Eq. 2). The latter was reoxidized by lattice oxygen from FeO_x, producing CO (Eq. 3).

$$Fe + CO_2 \rightleftharpoons FeO_x + CO \quad (1)$$

$$CH_4 \xrightarrow{Ni} C + 2H_2 \quad (2)$$

$$FeOx + C \rightleftharpoons xCO + Fe \quad (3)$$

Keywords: SILP, catalysts, carbon materials, Rh, complex, hydrogenation, hybrid catalysts

1 Introduction

SILP ("Supported Ionic Liquid Phase") catalysts constitute a way to prepare hybrid catalysts in which the active phase (frequently a metal complex) is dissolved in a supported IL phase, avoiding thus important chemical or geometrical modifications. The hybrid condition arises from the combination of significant properties of homogeneous and heterogeneous catalysis. In brief, the advantages of SILP catalysts are [1]: (i) concomitant use of ILs, (ii) high catalytic activity owing to a uniform distribution of catalytic active species within the SILP, and (iii) easy separation from the reaction products for further reusability. Carbon materials have proved to be suitable catalysts supports [2] and they can also be appropriate for SILP systems [3]. This is because they can be prepared with large surface areas, tuned porosity and surface chemistry, and variable morphology. This allows, thus, a broad variety of arrangements and interactions of the IL within the support surface. The present work deals with the preparation of SILP catalysts with a Rh complex as active species, using several carbon materials as support and different IL loadings. The purpose is to study the effect of the support properties and of the amount of IL in the catalysts activity and stability, tested in the hydrogenation of cyclohexene.

2 Experimental/methodology

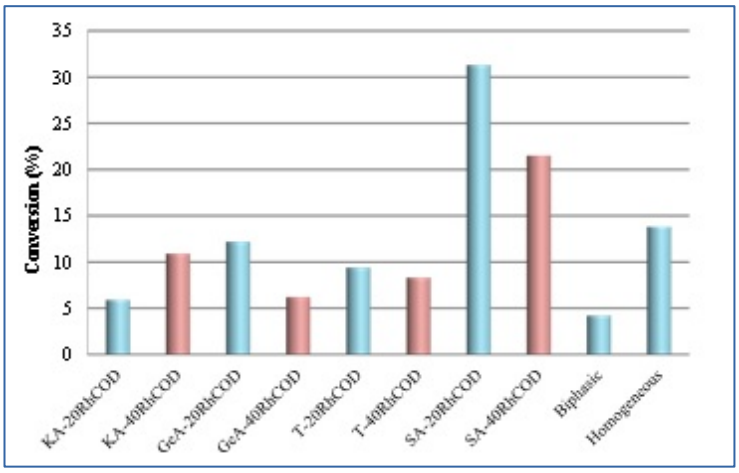
The carbon materials used in this work are: i) GeA: Spherical shaped activated carbon (Gun-ei Chemical Industry (Japan)), with average diameter of 150 μm. ii) KA: Spherical shaped activated carbon (Kureha Corporation (Japan)), with average diameter of 780 μm. iii) T: Carbon black T-10157 from Columbian Chemical Company (USA) and iv) SA: Powder activated carbon SA-30 from MeadWestvaco (USA).The ionic liquid used in this work is 1-butyl-3-methyl-imidazolium hexafluorophosphate ([bmim][PF_6]) supplied by Solvionic and the Rh complex was chloro(1,5-cyclooctadiene)rhodium(I) (RhCOD).

The catalysts were prepared inside a Schlenk system as follows: about 0.5 g of the carbon material were degassed in vacuum at 150 °C for 5 h; after cooling, variable amounts of ionic liquid and the required amount of Rh complex to obtain 1 wt% Rh, mixed with 2 mL acetone, was added to the outgassed solid and the system was kept under Ar atmosphere and stirring until the sample took on a dry aspect.

Conditions of the activity experiments are: 10 mL of 5 vol% cyclohexene in toluene, 30 mg catalyst, 10 bar $H_2$and 333 K. Reusability tests were performed under the same conditions with the catalysts recovered by filtration. Homogeneous and biphasic tests were carried out dissolving the required amount of the RhCOD complex in toluene or in the amount of IL equivalent to that loaded in the hybrid catalysts, respectively. Analysis was carried out by gas chromatography.

3 Results and discussion (font style: Times New Roman bold 12pt)

Figure 1 shows conversion data obtained with some of the catalysts prepared and with homogeneous and biphasic systems having a similar amount of Rh complex.



It can be observed that the biphasic system is less active than the homogeneous one, meaning that the ionic liquid hinders the access to the active phase. However, the SILP catalysts are more active than the biphasic system. It is interesting that there is a very important effect of the support and it must be pointed out that the two SA based catalysts (with 20 a 40% IL)are more active than the complex in homogeneous phase. Regarding the IL loading, it seems that 20% gives better results than 40%, and this is agreement with the mentioned effect of the IL to hinder the access to the active phase.

Upon use, the catalysts lose a certain amount of IL, higher in the catalysts with 40% IL and also dependent on the support. Rh leaching is negligible and thus it can be concluded that the reaction takes place with the heterogenized complex. Table 1 includes data about IL leaching. The catalysts were tested in two consecutive catalytic runs and they showed to be recyclable.

	leaching(%)		**leaching(%)**
Catalyst	**IL**	**Catalyst**	**IL**
KA20-RhCOD	48	KA40-RhCOD	65
GeA20-RhCOD	25	GeA40-RhCOD	72
SA20-RhCOD	17	SA40-RhCOD	24
T20-RhCOD	5	T40-RhCOD	45

Table 1. IL leaching after use in cyclohexene hydrogenation.

4 Conclusions

Hybrid SILP catalysts prepared with carbon materials as support have shown to be active and reusable in the hydrogenation of cyclohexene, being with a given support much more active than the homogeneous one. There is a notable effect of the support properties on the catalytic activity.

Keywords: supported palladium, liquid-phase hydrogenation, maleic, acid, cyclohexene, support effect

1 Introduction

The phenomenon of metal-support interaction and its influence on the performance of supported metal catalysts is commonly associated with an electron transfer between the metal and the support. However, for the case of liquid-phase reactions, their specific activity (i.e. turnover frequency – TOF) seems to be also affected by the liquid-solid interface structure which is dependent on both the nature of the catalyst constituents and the solution composition [1]. In our first paper [2], we succeeded in preparing a set of highly dispersed palladium catalysts supported on different inorganic powders (oxides, carbons, salts) with low specific surface areas (less than 20 m^2/g) to avoid diffusion limitations in their pores during catalytic testing. We revealed the TOF values for palladium nanoparticles in hydrogenation of C=C bond of maleic acid (**MA**) in water at 50°C to decrease with increasing effective charge of the cations forming oxide supports. Though this fact could be attributed (from the classical point of view) to modification of metal electronic state under action of the cation's electric field, an influence of the catalyst-solution interface structure on the catalytic activity remained unclear.

This work aims at investigating the catalytic effects caused by the existence of the electric double layer (EDL) at the catalyst surface, which is formed due to the difference between aqueous solution pH and pH_{IEP} of the supports. This layer might hamper the diffusion of ionized MA molecules to the active sites of the catalyst. For comparison, catalytic hydrogenation of non-polar unsaturated molecules (cyclohexene – CH) in solvents with relatively low dielectric constants (aliphatic alcohols) was also investigated. This reaction is known to be structure insensitive [3] and no EDL formation can be expected under its conditions.

2 Experimental/methodology

Supports' texture properties (pore volume, S_{BET}) were investigated by low-temperature N_2-adsorption. Zetasizer Nano ZSP was used to measure ζ-potential values for the support particles in water. Procedure of the supported palladium catalysts (0.5 wt% Pd) preparation by hydrolysis of H_2PdCl_4 in basic media was described in ref. [2]. Dispersion of Pd particles was determined by XRD, TEM and CO-chemisorption methods. The electronic state of the supported metal was characterized by XPS using SPECS and ESCA HP spectrometers.

Catalytic tests were carried out in 100 ml jacketed glass reactor under static conditions at 2°C (CH)/50°C (MA) and P_{H2} = 1 atm (1200 rpm, 7-40 mg of the charged catalyst, 6 ml of the substrate solution). Concentration of CH in anhydrous methanol or 96% ethanol was 0.32 M and MA in water 0.2-1.5 M. The catalysts were pre-reduced in the reactor with 2 ml of the solvent at 50°C before testing. The reaction rate values were calculated from the time-dependences of H_2 uptake.

3 Results and discussion

1. No explicit interrelations between electronic state of Pd particles (according to XPS), pH_{IEP} of the supports and TOFs of the catalysts in CH and MA hydrogenation were found.

2. TOF values of the palladium catalysts in CH hydrogenation depend on the support nature but not the solvent (Table 1).The latter fact agrees with conclusions previously mentioned in ref. [3]. Otherwise the support-dependence has been revealed for the first time and now it cannot be strictly attributed to Pd particle size or support material type. Also within alumina-supported catalysts decrease of TOFs with increasing S_{BET} of the supports (Table 1, samples nos. 7-9) for both CH and MA hydrogenation reactions is observed. Note that the apparent activation energy of the reaction falls down to zero for the porous aluminas. Addition of up to 10 wt% water in alcohol solvent in CH hydrogenation doesn't result in changing of TOFs.

3. Unlike to regularities of MA hydrogenation in water, TOF values of the Pd catalysts in CH hydrogenation in alcohols don't regularly vary with effective charges of oxide supports'cations, emphasizing that their electric field is not the only TOF-determining factor.

4. For both catalytic processes, TOF values of the related catalysts don't depend on Pd dispersion if the catalysts are subjected to low-temperature reduction (<150°C) with H_2, however, sintering of Pd in H_2 at 400°C leads to structure sensitivity of CH hydrogenation, probably due to the manifestation of the strong metal-support interaction.

Table 1. Catalytic activity of 0.5% Pd/Support catalysts in hydrogenation reactions in different solvents.

No.	Support	S_{BET}, m^2/g	d_s (Pd), nm	TOF values (s^{-1})		
				CH hydrogenation		MA hydrogenation
				ethanol	methanol	water [2]
1	In_2O_3	3.9	6.0	11.8	10.3	0.6
2	TiO_2	1.9	8.3	9.0	9.0	2.9
3	Kieselguhr (SiO_2)	1.7	5.1	7.4	7.4	3.1
4	Carbon Black T-900	8.0	5.1	3.5	3.3	7.3
5	Sibunit 159	11.6	3.3	6.2	7.4	8.6
6	ZrO_2	14.3	1.5	2.9	2.0	0.9
7	α-Al_2O_3	10.6	2.0	6.6	3.7	3.0
8	γ-Al_2O_3Reachim	105	1.2	2.3	2.1	1.4
9	γ-Al_2O_3Puralox	200	1.4	1.3	0.9	1.2

4 Conclusions

Palladium catalysed liquid-phase hydrogenation of C=C bonds of CH and MA is governed by the nature of the catalyst support. Electronic state of Pd apparently isn't a parameter directly influencing the catalyst activity. As hydrogenation of non-polar molecule (CH) occurs without EDL formation the cause of its support-dependence could be found in different wettability of support material surface by solvent molecules. The structure sensitivity of the reactions occurs only after high-temperature reduction of Pd with H_2 at 400°C.

Keywords: electrochemical synthesis, alternating current, electrocatalyst, disel, oxidation, catalyst, photocatalyst

1 Introduction

At present composition materials containing nanoparticles of metals or metal oxides are widely used in catalysis. Pt/C or Pd/C catalysts are used as electrocatalysts for anode and cathode for low temperature fuel cells, for electrolysis of water. Pt/Al_2O_3 diesel oxidation catalysts apply for removing of diesel engines pollutants. Powder oxides of tin, nickel, titan or copper are well known as effective nanomaterials for different hetero- and photocatalytic processes. The electronic structure, bonding, surface energy, and chemical activities of the materials are directly related to their morphology, and the shapes are directly related to their properties and stabilities. The development of micro- or nano- composite materials with special size and well-defined shape may open new opportunities for exploring materials catalytically properties. The proposed "one-pot" electrochemical method of nanocatalysts synthesis is based on phenomena of oxidation and dispergation of metals under alternating current.

2 Experimental

The method of preparation of composite materials (Pt/C, Pt/SnO_x-C, Pt/NiO-C, Pt/Al_2O_3, Cu_2O-ZnO) based on metal oxidation and dispergation under alternating current was used. This method has been utilized in our previous works, in which highly efficient Pt/C [1] and Pt/SnO_x-C [2] catalyst for low temperature fuel cells and NiO/C composite for supercapacitors [3] have been successfully prepared.

The electrochemical cell has two metal foil electrodes with surface area 3 cm^2 and 0.25 mm thick immerged into the aqueous solution containing alkaline cations. The electrodes are connected to pulse ac source operating at 50 Hz. Finally, the prepared catalysts was carefully washed with bidistilled water to a neutral pH and dried at 80 ^oC for 1 hour.

The crystal structure of the products was characterized by X-ray powder diffraction (XRD, X-ray diffractometer ARL X'TRA («Thermo Scientific», Switzerland) with Cu Ka radiation (l = 1.540562Å) . The morphology, particles sizes and microstructure were performed using scanning electron microscope (SEM, Quanta 200), transmission electron microscope (TEM, JEOL JEM-EX-1200). The specific surface areas of oxide materials were measured by the Brunauer-Emmett-Teller (BET) method on a ChemiSorb 2750. Electrocatalytic properties of the as-prepared Pt/C, Pd/C and Pt/MO_x-C catalysts were evaluated by means of polarization measurements in modeling conditions and membrane-electrode assembles using a potentiostat ELINS P-30S. UV-vis adsorption spectrophotometer (Shimadzu 1800) was used to detect the absorbance of the dye solution during the photocatalytic processes in the wavelength of 300 – 600 nm.

3 Results and discussion

A method of electrochemical synthesis of materials for hetero- and electrocatalysis was

developed. The method is based on a phenomena of metal oxidation and dispergation in non-stationary conditions of electrolysis. The process of metals oxidation/partial reduction of oxides is periodic and accompanied by intensive gas evolution (oxygen appears during anodic impulse, hydrogen appears during cathodic impulse). This fact and a high current frequency in the whole allow obtaining the highly dispersed structures.

The effect of the essential technological parameters (current asymmetry and density, composite and temperature of electrolyte) on the process rate was investigated. The main technological parameters, which define a structure of composite materials on a base of platinum and palladium nanoparticles or copper, tin and nickel oxides, are a composite of electrolyte and current density. The highly dispersed metals or metal oxides are formed in the electrolytes containing chlorides (for Cu and Sn) and hydroxides (for Pt, Pd and Ni) alkaline metals. Increasing the current density in the range of 0.1 to1.0 A/cm^2 was found to result in formation of more defective disordered structures with high values for dispersion. The temperature varying from 30 to 80 °C does not have any influence on the structure of materials. Asymmetry of alternating current defines a process rate but not a type of oxide structure.

Electrocatalytic properties of composite materials on the base of produced oxides and Pt nanoparticles Pt/MO_x-C (M=Sn, Ni) with catalytic activity towards the oxidation of aliphatic alcohols (methanol and ethanol), which are prospective fuels for low-temperature fuel cells, were investigated. Oxide component of MO_x-C composite promotes adsorption of oxygen-containing particles on catalyst and contributes to the reaction of adsorbed alcohol molecules oxidation via the Langmuir-Hinshelwood mechanism providing the reaction rate increase by 20% compared to the one on Pt/C catalyst and anode potentials decrease that result in reduction of anode overpotential in low-temperature fuel cells.

Pt/γ-Al_2O_3 diesel oxidation catalysts prepared by electrochemical dispergation technique demonstrate high catalytic activity and reasonable hydrothermal stability.

Prepared Cu_2O nanocrystallites and nanocomposite Cu_2O/ZnO exhibited superior photoactivities in a very small irradiation time.

4 Conclusions

The possibility of application of electrochemical metal oxidation and dispergation as an operation technique for the production of composite catalysts materials was evaluated. The method is easy-to-use and inexpensive. As-prepared materials can be effectively used as electrocatalysts in fuel cells, diesel oxidation catalysts and photocatalysts in technologies of purification of water as well as in the processes of organic compounds oxidation.

On Combined Reactivity and Thermogravimetric Study of CO and CO_2 Hydrogenation to Methanol over Cu Based Catalyst

Tarasov A.V.*, Frei E., Schumann J.

Fritz-Haber Institut der Max-Planck Gesellschaft, Dapartment of Inorganic Chemistry, Berlin, Germany

* tarasov@fhi-berlin.mpg.de

Keywords: methanol synthesis, thermogravimetry, adsorbates, CO and CO_2 hydrogenation

1 Introduction

Catalysts for conversion of CO_2 into chemicals and fuels are an important building block for sustainable usage of energy resources and feedstock in chemical industries. This work aims to illustrate the potential of the thermogravimetric technique combined with activity measurements in studying reaction intermediates and mechanistic aspects. One of the promising reactions of industrial relevance used for CO_2 conversion is methanol synthesis over Cu – based catalyst.

$$CO_2+3H_2 \rightleftarrows CH_3OH+H_2O$$

The instant study elucidates the working principle of two realistic high performance catalysts with respect to the adsorbates accumulated during the steady state under reaction conditions (30bar, 250°C) in CO or CO_2 gas feeds.

2 Experimental/methodology

A number of combined experimental techniques were applied for obtaining data for the catalysts under realistic working conditions. The continuous weight measurement of a catalyst while exposing it to a reactive atmosphere under controlled ambient or high-pressure conditions provides important information about chemical reactions and structural changes of the solid sample material. *In-situ* high pressure thermogravimetry coupled with mass-spectrometry was used to examine the catalyst surface coverage with adsorbed species in different feeds. The reactivity measurements in steady and transient state in combination with surface titration experiments were performed for the analysis of stable surface intermediates and exploring the nature of the active catalytic site with respect to the specific catalyst.

3 Results and discussion

Two limiting cases for Cu-based catalyst are considered: copper nanoparticles supported on irreducible MgO (Cu/MgO) and Cu particles of comparable size and shape supported on ZnO (Cu/ZnO). For both systems the reactivity measurements indicate the presence of a sticky adsorbate layer in CO and CO_2 feed which might be removed as methanol by continues purging in H_2 (see Figure 1). For the Cu/ZnO catalyst the total amount of methanol formed under transient state during purging in H_2 after CO exposure under steady state is 6 times less than the one estimated after CO_2 exposure. This data are in good agreement with catalysts performance under steady state. On the opposite Cu/MgO system showed in transient state the same amount of accumulated mobile adsorbates in CO as well as in CO_2 feed. However the activity in CO_2 hydrogenation is 100 times less than in CO hydrogenation. This behavior supports the presenceof significant amounts of adsorbed carbon formed on the catalyst under steady state, e.g. in a formate-derived adsorbate layer which in the absence of carbon in the feed can still be hydrogenated to methanol, but not converted in a catalytic cycle under reaction conditions.

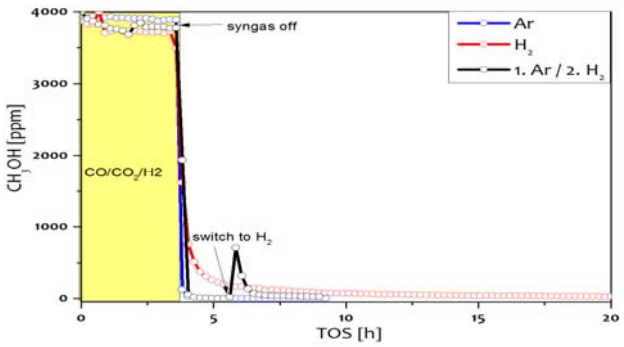

Fig. 1. Variation of methanol concentration over Cu/ZnO catalyst (GC data) by switch from syngas $CO_2/CO/H_2/He$ (6/8/59/27) to argon, pure hydrogen and argon with subsequent purging with hydrogen.

A gravimetric *in situ*-measurement under methanol synthesis reaction conditions showed that Cu - based catalysts gain mass in CO_2-containing feed and reversibly lose that weight when the feed is switched to CO only indicating the same type of adsorbates for the different Cu catalysts. The total amount of adsorbed species under steady state varies for the different catalytic systems. The Cu/ZnO system possesses a weight gain of 1.9wt% and 1.2wt% in CO_2 and CO respectively, while Cu/MgO catalyst showed a total weight increase due to adsorbates of 0.39wt% and 0.27wt% (see Figure 2) in the corresponding feeds.

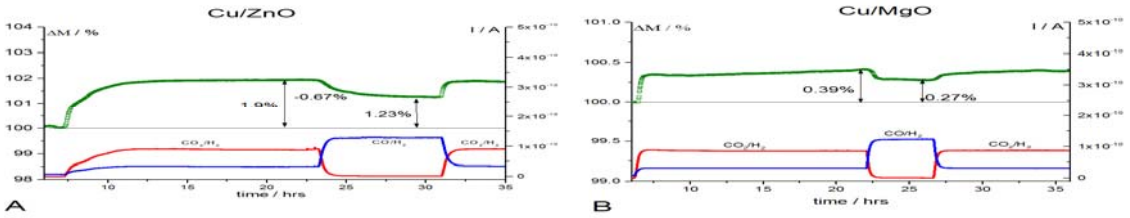

Fig. 2. In situ-thermogravimetry at 30 bar, 250°C in different gases (A) Cu/ZnO and (B) Cu/MgO

4 Conclusions

Analysis of the catalyst performance and the surface titration data provide evidence that CO hydrogenation requires isolated Cu-sites whereas the prerequisite for the successful CO_2 hydrogenation is the presence of ZnO decorated Cu surface [1]. This Cu/ZnO interface can be realized for instance as a graphitic ZnO overlayer [2], which hinders at the same time a successful CO hydrogenation.

Keywords: alumina, desiccant, preparation

1 Introduction

Due to stability in humid atmospheres and high capacity alumina exsiccates are widely used for natural gas exsiccation [1, 2]. Their properties depend on a phase composition, acid and base properties of alumina and granules porosity, that depend on exsiccates preparation details. For example, the exsiccates based on eta alumina prepared via energy and resources reserving CTA (centrifugal thermal activation) technology are characterized with higher capacity as compared with that based on gamma alumina [3-5]. At that these exsiccates differ in porosity and acid and base properties. One of the ways to influence the acid and base properties of alumina is modification with different electrolytes. The modification may be done by impregnation of calcined exsiccates or f.e. during plastic paste preparation stage.

The main goal of the paper is investigation of eta and gamma based alumina exsiccates (phase composition, acid and base properties, porosity and durability of granules, static and dynamic capacities) prepared via CTA technology depending on row hydroxides (bayerite or pseudo boehmite structured) and nature of electrolytes (acid or base) used for pastes preparation.

2 Experimental

As the raw material the product prepared by centrifugal thermal activation of gibbsite in the pilot flash-reactor TSEFLAR^{TM} (CTA-product) was used [5]. The hydration of CTA- product was carried out in alkaline or acid solutions to prepare bayerite (Ba) or pseudo boehmite (Pbe) containing hydroxides [3]. As prepared hydroxides as powders were placed in a mixer for peptization at alkaline (NaOH, KOH) or acid (HNO_3, H_2SO_4) modulus of 0.07-0.1. The prepared plastic pastes were forced through the draw die of a ram extruder with a hole diameter of 4 mm to obtain extrudates. Finally the extrudates were calcined in a tubular furnace in flowing dry air at 420^{o}C (obtained from bayerite) and 500^{o}C (obtained from pseudo boehmite) for 4 hours.

The dynamic capacity of as prepared adsorbents was determined as the mass of water absorbed by a 100 cm^3 of adsorbent (at dew point of dry gas -40^{o}C). Static water capacity of the adsorbents was determined as the mass of water adsorbed by a 100 g of adsorbent (25^{o}C, relative humidity of 10% and 60%). The type and concentration of acidic and basic sites on sample surfaces were studied by FTIR spectroscopy of adsorbed CO and $CDCl_3$, correspondingly. [6]. X-ray diffraction (XRD) was performed on an HZG-4 diffractometer. Because of the complexity of the quantitative determination of individual phases in a multiphase system (due to the similarity of their parameters), the phase composition of the products was characterized in terms of (γ+η)-Al_2O_3, χ-Al_2O_3 and χ-like Al_2O_3 + X-ray amorphous phase. Textural data were obtained via nitrogen adsorption.

3 Results and discussion

In the Table 1 there are data on alumina exsiccates prepared via CTA technology with using of different row hydroxides (bayerite or pseudo boehmite) and electrolytes (HNO_3, H_2SO_4, NaOH, KOH). Using of H_2SO_4 and especially NaOH and KOH as compared with HNO_3 during

preparation lead to decrease of specific surface areas of exsiccates of both series (based on eta or gamma alumina) and changing their porosity. Such textures changing are more expressed for exsiccates based on gamma alumina. So using of H_2SO_4 leads to decrease of mezopores volume without change in micropores volume, that result in decrease of mean pore size, while using of base electrolytes lead to increase the mezopores volume and micropores disappearance, that result in increase of mean pore size. Such changing in texture does not strongly influence the static capacity but influence the dynamic capacity of exsiccates.

Preparation	Static capacity, %		Dynamic capacity, g/100 cm^3	S_{sp}, m^2/g	V_{micro*}, cm^3/g	V_{mezo}^{**}, cm^3/g	$\sum V$, cm^3/g	D^{***}, nm
	10%	60%						
Ba-HNO_3	-	21.59	5.29	379	0.15	0.13	0.28	2.9
Ba- H_2SO_4	-	21.19	5.59	313	0.13	0.13	0.26	3
Ba-NaOH	7.6	17.9	4.8	272	0.11	0.17	0.28	3.5
Ba-KOH	7.9	17.5	4.1	269	0.05	0.18	0.23	3.7
Pbe- HNO_3	-	21.13	2.9	346	0.20	0.25	0.45	4.1
Pbe- H_2SO_4	-	23.10	5.25	327	0.16	0.10	0.26	2.7
Pbe-NaOH	7.8	21.5	4.8	263	0.005	0.41	0.415	6.4
Pbe-KOH	7.6	20.3	4.4	314	-	0.39	0.39	5.5

Table 1. Properties of exsiccates

It is interesting that increase in dynamic capacity of exsiccate based on gamma alumina due to using of H_2SO_4 occurs simultaneously with decrease of mean pore size while due to using of NaOH(KOH) – simultaneously with increase of mean pore size.

Investigation of acid and base properties of exsiccates with probe molecules (CO and $CDCl_3$) has shown that using of H_2SO_4 leads to increase of Lewis acidity while using of NaOH(KOH) leads to appearance of strong basic sites without change of Lewis sites concentration. Hence the increase in dynamic capacity of based on gamma alumina exsiccates due to modification with alkaline is mainly due to appearance of basic sites while increase in pore size may decrease the effect.

4 Conclusions

Using of acid (H_2SO_4) and base (NaOH, KOH) electrolytes instead of HNO_3 during preparation lead to strong increase the dynamic capacity of gamma alumina based exsiccates up to level of eta alumina base exsiccates mainly due to decrease of mean pore size (H_2SO_4) or appearance of basic sites (NaOH, KOH).

Keywords: Xe-NMR, γ-alumina, porosity, connectivity, diffusion

1 Introduction

During last decades, the environmental legislation became more severe, a sulfur level lower than 10 ppm is required on the produced diesel fuel. Those levels can only be reached by hardening the working temperature conditions or by using more active catalysts. In both cases the activity and selectivity of hydrotreating catalysts play an important role in petroleum industry, from an economic and a technologic point of view. Catalysts used for hydrotreating are widely composed of sulfur molybdenum promoted by nickel or cobalt phase supported on high surface alumina (200–250 m^2/g).

The characterization of textural and transport properties of catalytic materials is decisive to better understand the impregnation processes of metal salt solutions or chelating agents into the pores and improve active phase. ^{129}Xe NMR is a spectroscopic technique able to characterize pore size and tortuosity for zeolites, mesoporous solids and MOF.

The xenon atom has significant highly-polarizable electron cloud, very sensitive to its environment and ^{129}Xe NMR has proved to be very useful to study the porosity of micro and mesoporous solids [1]. In this study we show that ^{129}Xe NMR is an alternative technique to porosimetry or electron microscopy 3D transmission experiments.

2 Experimental/methodology

Different types of ^{129}Xe NMR experiments have been performed on a Bruker DSX 300 spectrometer: i) measurements of the chemical shift of adsorbed xenon under chosen conditions in order to correlate the chemical shift to the pore size of catalysts, ii) 2D exchange NMR (EXSY) to study the connectivity between pores of different sizes in catalysts presenting multi modal porosity.

To minimize the effect of strong adsorption sites existing at the alumina surface on the chemical shift of adsorbed Xe, the samples have been pretreated at 573 K overnight and the chemical shift has been measured at P ≈ 600 Torrs. In these conditions, the chemical shift is expected to depend on the pore size only. The porosity of all alumina samples (≈ 20) has also been characterized by N_2 adsorption at 77 K.

In 2D EXSY spectra, off diagonal peaks arise from the exchange of Xe atoms between two environments, characterized by the diagonal peaks, during the so-called mixing time (t_{mix}). The variation of the intensity of the off-diagonal peaks as a function of the mixing time allows determining an exchange rate which characterizes the pore connectivity.

3 Results and discussion

As it has been already obtained with zeolites [2] and silicas [3-5], we have established a correlation between the measured chemical shift, corresponding to the interactions of the Xe atoms with the pore surface solely, and the pore size (Figure 1). Considering that the measured chemical shift, δ_S, arises from the chemical exchange between adsorbed and bulk phase, it can be expressed as [3]:

$$\delta_s = \frac{\delta_a}{1 + \frac{V}{K_{ads} \cdot S \cdot R \cdot T}}$$

where δ_a is the chemical shift of a Xe atom interacting with the surface, V and S are the pore volume and the pore surface area, respectively. K_{ads} is the Henry adsorption constant. The V/S ratio is equal to D/η, D being the pore size and η a parameter depending on the pore geometry. Fitting the experimental results with equation gives δ_a = 117 ppm and K_{ads} = 2.2×10^{14} $Torr^{-1}m^{-2}$. These values are very similar to those obtained for silicas [3] and allow us to use the variation of the chemical shift for silicas as a reference to determine the value of the geometric factor, η, describing the complex pore geometry in aluminas.

In the example given Figure 2, the 2D EXSY spectrum shows an exchange between the two types of pores and between the larger pores and the gas phase outside of the pellet.

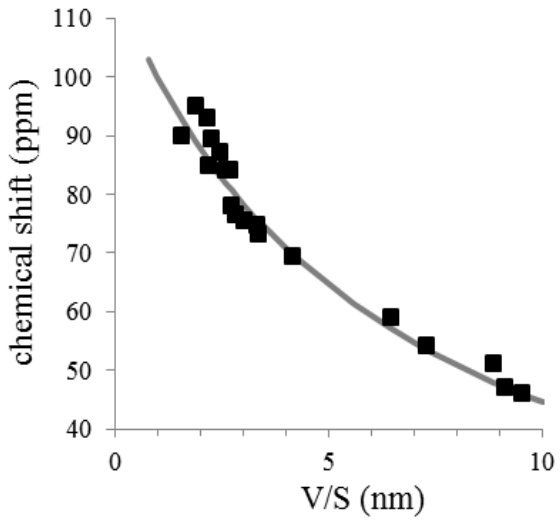

Figure 1 : Chemical shift variation versus the volume-to-surface ratio of pores for different aluminas.

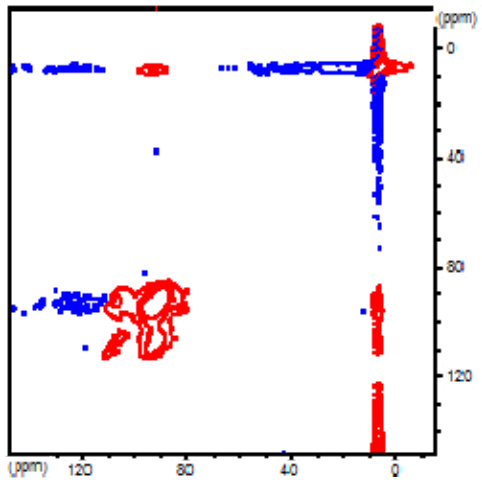

Figure 2: 2D EXSY **spectrum** of an **alumina** with **bimodal porosity**, $\mathbf{P_{Xe}}$ **= 10 bars**, T = **293 K**, $\mathbf{t_{mix}}$**=30 ms**

4 Conclusion

Xe NMR technique has allowed us to establish a correlation between the chemical shift and the pore size for aluminas, to obtain information on the connectivity between different porosities (EXSY) in order to characterize the tortuosity of the porous network.

Keywords: substrate effect, organoboron nanoparticles, charging, ammonia, decomposition

1 Introduction

Currently, there is not enough information to fully describe the effect of the substrate on the heterogeneous catalytic processes involving nanoparticles. In general, the substrate can prevent coalescence of the nanoparticles or contribute in opposite process, modify the shape, structure and charge of the nanoparticles, bring in the nanoparticle-padded catalytic system additional active sites (which can be for example, oxygen vacancies or nanoparticle-substrate interface in oxide substrates), stabilize the intermediate reaction products. As a result of the interaction effects described above the nanoparticle chemical properties may vary within wide limits.
Our purpose was to compare the catalytic properties of organoboron nanoparticles (OBN) deposited on substrates of various nature (conductors and semiconductors), on the example of the ammonia decomposition.

2 Experimental/methodology

Experiments were performed in ultrahigh vacuum setup equipped with a scanning tunneling microscope (STM), Auger and mass spectrometers, additional accessories. The residual gas pressure in the setup chamber didn't exceed $P = 2 \times 10^{-8}$ Torr.

Organoboron nanoparticles (OBN) with an average size of 14.6 nm and composition $(C_2B_{10}H_4)_n$ synthesized by high-temperature pyrolysis of the vapor carborane $C_2B_{10}H_{12}$ in the flow type setup with an initial vapor pressure $P = 6.35 \times 10^{-3}$ MPa and temperature T = 1273 K [1]. Samples were prepared by depositing lyosol (1 mg of OBN per 2 ml of CCl_4) on several substrates: high-oriented pyrolythic graphite (HOPG) plate, oxidized silicon wafer, and oxidized aluminum plate and dried at room temperature. Taking into account the self-substrate and setup catalysis the measurements on the cells with substrates without OBN were also made.

The measurements were carried out at a temperature of 750 K.

Determining the structure and electronic structure of the OBN coating was carried out by atomic force and scanning tunneling microscopy.

3 Results and discussion

OBN formed individual clusters of on the substrates surfaces. Clusters size varied from 4-5 micron laterally with 140 nm altitude which is about 10 nanoparticles layers down to single nanoparticles.

Mass spectra of the gaseous medium components in the vacuum chamber exhibit a number of lines corresponding to the starting substances and their decomposition products. Lines with M/e = 2 and 28 correspond to H_2^+ and N_2^+, ions formed from NH3 decomposition products, M/e =17 – mainly correspond to NH_3^+ ions, formed from NH_3 reactant. The degree of ammonia decomposition achieved by OBN coverage was determined by comparing NH_3 conversion in the OBN-on-substrate experiment with the control experiment on substrate without OBN. Thus obtained ammonia conversions due OBN are 2.8%, 2.3% and 1.2% for HOPG, Al_2O_3 and SiO_2 substrates respectively.

State of the OBN coverage before and after reaction was determined by scanning tunneling microscopy and spectroscopy. To do this, we measured the current-voltage characteristics (CVC) of STM tunneling nanocontact, including OBN deposited on the substrate, or a substrate area containing no OBN. These data showed that the OBN physical characteristics do not undergo changes during the interaction with NH_3. At the same time, shape of the CVC curves for OBN on substrates of various natures varies considerably. OBN/HOPG sample CVC matches CVC formed by conductors (S-shaped relationship), while CVC for OBN/Al_2O_3 and OBN/ SiO_2 samples are both diode-like as they demonstrate sharp asymmetry of positive and negative voltage branches. Wherein the CVC measured on OBN coverage are shifted relative to CVC measured on pure substrates in 0.2 V and 0.6 V for Al_2O_3 and SiO_2. Such a shift indicates potential difference between OBN and the substrate due to the transition of electrons in OBN.

Thus, it can be argued that there is a correlation between the catalytic ability of OBN and their potential against the substrate. This result can be explained as follows. The NH_3 decomposition is a straight-chain process with radicals generated by the ammonia decay $NH_3 \rightarrow NH_2\bullet + H\bullet$, which occurs under pretty high activation energy (750 K). Carborane easily transforms into a diradical $C_2B_{10}H_{12}\bullet\bullet$. The two-stage formation of radicals in the $NH_3/C_2B_{10}H_{12}$ system $C_2B_{10}H_{12}\bullet\bullet + NH_3 \rightarrow C_2B_{10}H_{12}H\bullet + NH_2\bullet$, $C_2B_{10}H_{12}H\bullet \rightarrow C_2B_{10}H_{12} + H\bullet$ should occur at a higher rate than single-stage $NH_3 \rightarrow NH_2\bullet + H\bullet$. OBN consist of interconnected partially dehydrated $C_2B_{10}H_{12}$ molecules, so diradicals can be easily generated on the surface of OBN, accelerating the $NH_2\bullet$ and $H\bullet$ radicals emergence, which explains the catalytic properties of OBN in the decay of ammonia. The presence of relative to the substrate negative potential on the OBN causes OBN negative charging. Surplus electrons fill upper energy orbitals of OBN and prevent the formation of diradicals as their presence implies an OBN valence electron transition to higher free energy level. Thus, the higher the OBN potential, the smaller will be the OBN surface diradicals concentration and, accordingly, less catalytic effect, as is observed experimentally.

4 Conclusions

The substrate effect on catalytic properties of organoboron nanoparticles was investigated on the example of ammonia decomposition reaction. OBN deposited on HOPG achieve the highest rate of the ammonia decomposition. Catalytic activity ratio for OBN on HOPG, Al_2O_3, SiO_2 substrates is 1.00 : 0.82 : 0.43 relatively. Correlations between substrate nature and its influence on the catalytic properties were discovered. The difference in the substrates influence was explained by OBN charging. Reaction mechanism elucidating the OBN catalytic effect on different substrates was presented.

Keywords: chromia containing catalysts, mixed supports, hydrocarbons, dehydrogenation, isobutane

1 Introduction

Dehydrogenation of saturated (C_3-C_5) hydrocarbons is a large-scale process to produce olefins (propylene, n-butenes, isobutylene, etc.) in the world petrochemical industry. These products are widely used for production of synthetic rubbers, plastics and other valuable chemical products. Catalytic dehydrogenation is the widely used method of olefin production.

Currently, Cr-containing catalysts are the main type of materials for dehydrogenation of C_3-C_5 hydrocarbons. Support properties and preparation conditions define the state of supported chromium and its catalytic properties. The state of active component may be controlled by changing of support nature or by introduction of modifying additives. Alumina (especially γ-Al_2O_3) is the most widely used support due to low cost, stability at high temperatures, high porosity and surface area, ability to stabilize active component in highly dispersed active state. The main problems of alumina application are formation of inactive chromium aluminate and side reactions leading to reduction of catalyst activity. Besides, there are chromium oxide catalysts supported on ZrO_2, SiO_2, TiO_2 [1, 2]. Typical silica supports have high specific surface area and pore volume as well as insignificant proper catalytic activity. The pore size of silica can be varied in a wide range. However, the use of silica instead of Al_2O_3 is limited by inability to stabilize active component in desirable state, and thus, low activity. The highest activity in dehydrogenation reactions shows chromia catalysts supported on ZrO_2 [3] because of chromia stabilization in highly dispersed state. However, high cost, low surface area and low stability of zirconia at high temperatures limit its use.

Thereby, the purpose of the present work is to develop systems on mixed supports and study the effect of support properties on the state and activity of the active component (CrO_x) in isobutane dehydrogenation.

2 Experimental/methodology

Cr-containing catalysts with loading of Cr corresponding to one monolayer (5 at_{Cr}/nm^2) were prepared by incipient wetness impregnation method using water solution of H_2CrO_4 and KNO_3 (K/Cr molar ratio was 1:5). The catalysts were dried at room temperature for 12 h and calcined at 600 °C for 4 h. ZrO_2, SiO_2, $nZrO_2/SiO_2$, Al_2O_3 and $nZrO_2/Al_2O_3$ (n = 0.5, 1.0, 2.0 monolayer of zirconia, 5 at_{Zr}/nm^2) were used as supports. $nZrO_2/Al_2O_3$ and $nZrO_2/SiO_2$ supports were prepared by incipient wetness impregnation method using water solution of $ZrO(NO_3)_2 \cdot H_2O$ stabilized by citric acid (molar ratio Zr:citric acid = 1:2). Catalysts were studied by low temperature N_2 sorption, XRD, TPR, UV-vis spectroscopy, XPS, TEM and tested in reaction of isobutane dehydrogenation in a fixed bed reactor.

3 Results and discussion

The results of investigation of support structure by N_2 sorption show that ZrO_2 is characterized by low value of surface area (34 m^2/g). Modification of the Al_2O_3 and SiO_2 supports (surface area 176 and 102 m^2/g, respectively) by means of zirconia leads to reduction of the volume of large mesopores. In spite of this the obtained supports have high values of surface area (110-157 m^2/g) with developed system of wide transport mesopores, which make them promising to be used as supports for Cr-containing catalysts.

The absence of reflexes of Cr-containing phases for Cr/ZrO_2 and Cr/Al_2O_3 catalysts in XRD patterns indicates on small particle sizes (less than 3 nm) or covering distribution of chromia on the surface of these supports. Cr(VI) species were determined by TPR and UV-vis spectroscopy for Cr/ZrO_2 and Cr/Al_2O_3 catalysts. The formation of highly dispersed Cr_2O_3 clusters (UV-vis and XRD results) due to reduction of Cr(VI) species was observed. The formation of large Cr_2O_3 particles (29 nm according XRD results) was shown for Cr/SiO_2 catalyst. Figure 1 shows possible models of formation of Cr-containing phase depending on interaction with different supports. Increasing amount of Cr(VI) species was observed for $Cr/nZrO_2/SiO_2$ and $Cr/nZrO_2/Al_2O_3$ catalysts.

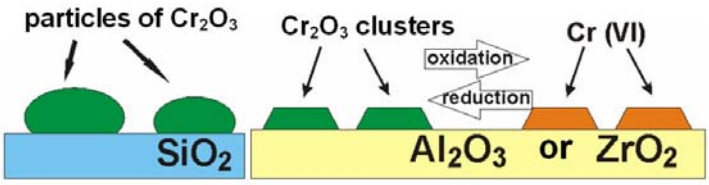

Fig. 1. The model of CrO_x phase formation on the surface of different supports

The testing of catalysts in the isobutane dehydrogenation shows that Cr/ZrO_2 catalyst has the highest specific catalytic activity. The reducing of Cr(VI) in Cr/ZrO_2 during catalytic process leads to formation of dispersed Cr_2O_3 clusters, having high activity in the dehydrogenation reaction. The highest activity of Cr/ZrO_2 catalysts also may be explained by specific interaction of Cr with ZrO_2. The formation of large α-Cr_2O_3 particles observed for Cr/SiO_2 catalyst causes low activity of this catalyst. The activity of Cr/Al_2O_3 catalyst was lower than the one of Cr/ZrO_2 but higher than the one of Cr/SiO_2. Modification of silica support with zirconium oxides leads to significant increase in activity of Cr-containing catalyst compared to initial Cr/SiO_2 catalyst. It is connected with increasing of the share of Cr(VI), which is stabilized by ZrO_2 in highly dispersed state.

4 Conclusions

It was shown that states of chromium depend on the nature of support. The combination of properties in mixed supports allowed us to control the state and activity of supported chromium, which can be considered as the foundation for the preparation of efficient Cr-containing catalysts for dehydrogenation of hydrocarbons.

Keywords: hydroxonium, heteropolyacid, acid, protons, mobility, 2H NMR, proton, conduction, ion

1 Introduction

Heteropolyacids (HPAs) represent a promising class of solid acids with a particularly high catalytic activity in acid-type reactions such as hydration, dehydration, alkylation, isomerization, and sulfhydration and good proton conduction properties for PEM fuel cells. For each case, the functionality of the system based on HPA is governed by the structure and the mobility of its protonic species [1-2]. In the anhydrous state the latter are represented by surface protons with superacidic properties. When hydrated by interaction with water new active species the $[H_3O]^+$ and the $[H_5O_2]^+$ ions are formed. The location and mobility of these protonic species play a crucial role in any dynamical process running in the system, being it an acid-type catalytic reaction or a charge transfer in PEM fuel cells. Among the family of HPAs, 12-tungstophosphoric acid with Keggin-type heteropolyanion structure ($H_3PW_{12}O_{40}$ or the TPA) exhibits the strongest acidity and overall stability, thus being of major interest for industrial applications. Despite good knowledge of the TPA primary and secondary structures both in the hydrated and dehydrated states, even the location of the acidic protons on the surface of the Keggin anion in anhydrous TPA until recently was actively debated. The possible migration of the acid sites in the anhydrous TPA received only qualitative estimations. Location and dynamics of protonic species in hydrated TPAs was studied in details for only high water concentrations (> 10 water molecules per Keggin unit) leaving the mechanism of interaction of TPA with water somewhat uncertain.

Considering the practical and fundamental importance of the problem, in the present work, we have performed the analysis of both ^{2}H NMR line shape and the evolution of T_1, T_2 relaxation with temperature for the deuterated analogue of the solid 12-tungstophosphoric acid (TPA × nH_2O) at different hydration levels ($0 < n < 6$) in wide temperature range of 103−503 K. This allowed us to characterize in detail the mobility of different protonic species, including acidic OH groups, water molecules, and hydroxonium ions.

2 Experimental

Details of preparation of HPA hydrate with a certain amount of water are given in refs. [3]. ^{2}H NMR experiments were performed at 61.424 MHz on a Bruker Avance-400 spectrometer using a high power probe with a 5 mm horizontal solenoid coil. All ^{2}H NMR spectra were obtained by Fourier transformation of the quadrature-detected phase-cycled quadrupole echo arising in the pulse sequence. The duration of the π/2 pulse was 1.8-2.1 μs. Inversion-recovery experiments were carried out to derive spin-lattice relaxation times (T_1) and CPMG pulse sequence was used to derive spin-

spin relaxation times (T_2).

3 Results and discussion

Analysis of the ^{2}H NMR spectra line shape temperature dependence for anhydrous TPA showed, that in the absence of water, there are two types of surface protons. The ones rapidly flipping, being localized on the bridged oxygen sites, and the ones involved into relatively fast migration over the surface oxygens of the Keggin anion. While below 423 K the population of fast migrating protons is low, almost all surface protons are rapidly diffusing over the Keggin-anion surface at T > 503 K by hopping between neighboring oxygens. The temperature dependences of the two-site fliping and the isotropic reorientation by diffusion over the Keggin anion show that both motions follow the Arrhenius law. The activation barrier for the localized two-site flips is E_f = 72 kJ mol^{-1} with a pre-exponential factor of k_{f0} = 3.2 x10^{13} s^{-1}; the isotropic deuteron migration is characterized by an activation barrier of E_D = 78 kJ mol^{-1} with a pre-exponential factor of k_{D0} = 1.2 x10^{13} s^{-1}. Such observation evidences that in anhydrous TPA deuterons exhibit motional modes with rates higher than 1 kHz ($t_C < 10^{-3}$ s) already at 423 K. Moreover, at the temperatures of chemical reactions mediated by TPA (T > 373 K) the major fraction of deuterons is mobile and migrating ($t_C<10^{-4}$ s) over the Keggin-anion surface. This means that the acidic protons are not localized at certain terminal or bridging surface oxygens at the respective reaction temperatures, that is, the acidic protons can be regarded as being delocalized on the time scales of the catalytic reactions.

At low hydration levels (n < 6) the TPA surface protons interacts with water to form $[D_3O]^+$ and $[D_5O_2]^+$ ions. The analysis of the evolution of spin relaxation times with temperature for different spectral species allowed quantify the kinetic parameters of the $[D_3O]^+$ ion formation/decomposition and to characterize the mobility of the OD, D_2O, and $[D_3O]^+$ species. The water molecules and the $[D_3O]^+$ ions were concluded to exhibit fast internal rotations about their symmetry axes, and these motions are not influenced by the water concentration for the case of a low hydration level of TPA × nD_2O (n < 10, i.e., when the secondary structure remains cubic with Keggin anions directly attached to each other). The hydroxonium ion is additionally involved in a wobbling motion on the surface of the Keggin anion. This motion may be related to the mechanism of decomposition of the ion back to water hydrogen bonded to the TPA surface acid protons. The proton (deuteron) diffusion and the charge transfer mechanism in the TPA hydrates might be defined by the $[D_3O]^+$ ions formation and migration between neighboring TPA Keggin units. The rate constant of the latter process depends on the water concentration as the higher hydration levels favors the formation of the $[D_5O_2]^+$ ion which itself is not diffusing, we have found that the barrier associated with the process gradually increases from 24 kJ mol^{-1} for n = 3 to 30 kJ mol^{-1} for n = 5.2 and to ~ 35 kJ mol^{-1} for n = 14).

4 Conclusions

Location and mobility of the active protonic species in $D_3PW_{12}O_{40}$ x nD_2O (0<n<6) hydrates were successfully characterized by ^{2}H NMR solid state spectroscopy.

Differences in the Location of Guest Molecules within Zeolite Pores as Revealed by Multilaser Excitation Confocal Fluorescence Microscopy: Which Molecule is Where?

Sprung C.*, Weckhuysen B.M.

Utrecht University, Dept. of Chemistry, Inorganic Chemistry and Catalysis, Utrecht, The Netherlands

Keywords: zeolite, ZSM-5, confocal, fluorescence, microscopy, polarisation, location of guest, molecules

1 Introduction

Zeolites are an important group of heterogeneous catalysts, which are for example employed in the Fluid Catalytic Cracking (FCC) process (such as zeolite Y and ZSM-5) [1]. Their internal pore architecture makes these catalysts selective for reactants, products, and transition states. Large coffin-shaped zeolite ZSM-5 crystals are an ideal model system to investigate industrially relevant topics at the scale of a microscope [2]. In order to make this possible a Brønsted acid catalysed oligomerisation reaction was employed to form elongated molecules inside the zeolite channels. Their location (i.e. type of channel) and spectroscopic fingerprints are recorded in 3 dimensions and parent, as well as post-synthesis steamed zeolite crystals making use of multi-laser excitation confocal fluorescence microscopy.

Large coffin-shaped ZSM-5 crystals were strictly oriented with respect to the recorded polarisation plane of emission light and elongated molecules have been formed due to the acid catalysed oligomerisation of the probe molecule. In this respect, the cyclic and linear dimeric carbocation are of main interest. Steric constraints of the zeolite channels locate these dimeric carbocationic species in certain positions, which were used to determine visual and spectroscopic features of large coffin-shaped ZSM-5 crystals [3].

2 Experimental

Large coffin-shaped ZSM-5 crystals were used in its acid form and impregnated at 30°C with excess of 4-fluorostyrene (the probe molecule). Subsequent rapid heating to 180°C induced the oligomerisation reaction of the probe molecule inside the zeolite channels.

A Nikon Eclips 90*i* confocal microscope was used for fluorescence investigations. Eighteen focal planes were recorded, of which each image was a composition of 32 real colour images. For each set of focal planes, three dimensional fluorescence spectra were extracted. Three crystal batches (parent, steamed 500°C, and steamed 700°C) were positioned in roof or gable position under the microscope, and oriented to 0°, 45°, and 90° with respect to the incoming and recorded polarisation plane of excitation light (405, 457, 488, 514, 561, 642 nm) and emission light, respectively. An overview of the investigation principle is illustrated in Fig. 1 [3].

3 Results and discussion

The highest fluorescence intensity was observed for emission polarised parallel to the crystal's short axis, which coincides with the crystallographic orientation of the straight channels. This emission vanished completely when the crystal was turned 90° away from this orientation. However, fluorescence from a different location, i.e. a rim around the whole crystal was observed. In absence of the intense fluorescence light of oligomeric carbocationic species situated inside the straight zeolite channels, it was possible to observe emission from such species inside the sinusoidal channels. The increased emission from sinusoidal channels with

increasing post-synthesis steaming temperature was the onset of pore structure degradation, starting from the outer surface of the crystal.

The multilaser excitation approach was employed to specifically excite the cyclic and linear dimeric carbocation species, respectively. Their absorption bands were determined in preliminary experiments by UV/Vis microspectrsoscopy [2]. The recorded fluorescence maps revealed different polarisation dependences in accordance to the applied excitation wavelength.

In addition to the polarisation dependent observation of emission light, fluorescence spectra in a range of 320 nm with a resolution of 10 nm were extracted and translated into the third dimension (cf. Fig. 1). In addition to the location/orientation of dimeric carbocationic species inside these ZSM-5 crystals they could be distinguished by their spectroscopic features. Cyclic and linear dimeric carbocations inside sinusoidal zeolite channels revealed an additional fluorescence band shifted by 40 and 20 nm (for 561 and 488 nm excitation) to longer wavelength, respectively, compared to the same dimeric carbocation inside the straight zeolite channels.

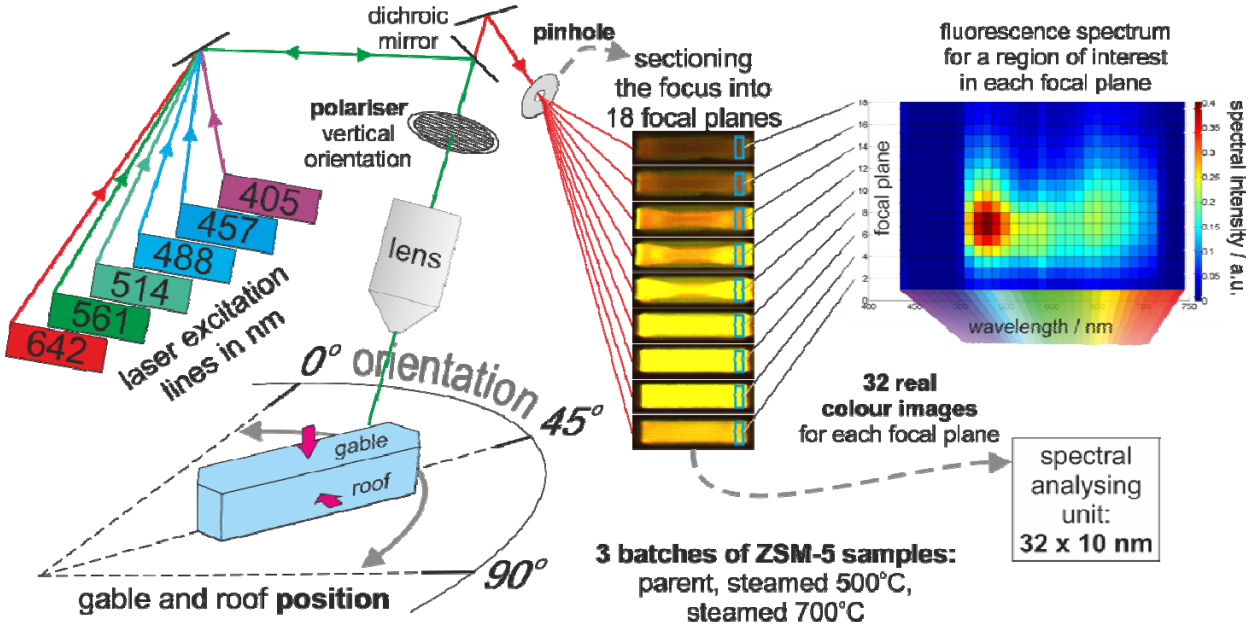

Fig. 1. Overview of the investigation and evaluation principle for the polarised fluorescence confocal microscopy on three sets of large coffin-shaped ZSM-5 crystals.

4 Conclusions

A systematic polarised fluorescence confocal microscopic investigation was presented for three batches of large coffin-shaped ZSM-5 crystals. The observation of polarised emission was linked to structural features of such crystals, and the location of dimeric carbocationic species inside straight and sinusoidal zeolite channels was distinguished. Fluorescence spectra were extracted (translated into the third dimension) from which it was possible to discriminate the same dimeric carbocationic species situated inside straight and sinusoidal zeolite channels, respectively, based on their spectroscopic features.

Keywords: Cu nanocrystals, Water-Gas-Shift reaction, active structure, reaction mechanism

1 Introduction

Water-gas-shift (WGS) reaction a very important industrial catalytic reaction involving Cu/ZnO as the catalyst, and copper is believed to the active component but the active copper structure is not clear. Here we report the successful synthesis of uniform Cu nanocrystals with various shapes preferentially exposing different crystal planes and their catalytic activity in the WGS reaction. Our results clearly demonstrate that the Cu(100) surface is the active structure for the WGS reaction. Via the combination of in-situ experimental measurements and DFT calculations, the reaction mechanism of the WGS reaction on the Cu surface was revealed.

2 Experimental/methodology

The synthesis of uniform Cu nanocrystals with different morphologies followed those reported in Ref. 1. The structures of Cu nanocrystals were characterized by SEM, TEM/HRTEM, in-situ XRD, XPS, operando-DRIFTS, TPRS, and the catalytic activity of Cu nanocrystals in the WGS reaction were evaluated by using a fixed-bed flow reactor employing an online GC-14 gas chromatograph to analyze the composition of the effluent gas.

3 Results and discussion

Figure 1 shows SEM, TEM, SEAD and HRTEM images of as-synthesized Cu nanocrystals. Cu cubes, octahedra and rhombic dodecahedra are quite uniform, but resulting from the synthesis methods, they are all with very large pores. The HRTEM and ED results demonstrate that Cu cubes, octahedra and rhombic dodecahedra are single crystals and respectively expose the {100}, {111} and {110} crystal planes. These are also verified by the CO adsorption results. The BET surface areas of Cu cubes, octahedra and rhombic dodecahedra are 1.17m^2/g, 2.35m^2/g and 3.33m^2/g, respectively.

Figure 2A shows the catalytic performances of Cu cubes, octahedra and rhombic dodecahedra in the WGS reaction and the corresponding Arrhenius plots. The catalytic activity follows the order of Cu cubes >> Cu rhombic dodecahedra >> Cu octahedra. The apparent activation energies calculated from the Arrhenius plot is 52.98±1.96 kJ/mol for Cu cubes and 71.62±4.87 kJ/mol for Cu rhombic dodecahedra. These results clearly demonstrate that the Cu{100} surface is the active Cu structure for the WGS reaction. Operando DRIFTS, TPRS experimental results and DFT calculation results demonstrate that moderate adsorption energies of all surface intermediates involved the WGS reaction on Cu(100) offer its high catalytic activity.

4 Conclusions

Uniform Cu cubes, octahedra and rhombic dodecahedra respectively exposing the {100}, {111} and {110} crystal planes were successfully synthesized and used as the catalysts for the WGS reaction. Cu cubes enclosed with the Cu{100} crystal planes were identified the active structure and the reaction mechanism was revealed. These results not only significantly deepen the fundamental understanding of Cu-involved catalysts for the WGS reaction but also provide

the guidelines to synthesize highly active for Cu-involved catalysts for the WGS reaction.

1 Introduction

Propene epoxide (PO) is an essential industrial chemical material intermediates produced by the partial oxidation of propylene. The current manufacturing processes such as chlorohydrin process and Halcon process are environmentally unfriendly and unsustainable. Gas-phase epoxidation of propylene with O_2 is a highly desirable green process for PO production but remains as a great challenge. Hayashi et al. firstly reported that gold nanoparticles highly dispersed on TiO_2 catalyzed propylene epoxidation with O_2 and H_2 to produce PO with selectivity above 90%,[1] and then this system has been extensively studied as a promising green route to produce PO. We prepared Au/TiO_2 catalysts employing TiO_2 nanocrystals with different morphologies as the supports and studied their structures catalytic performances in propylene epoxidation with O_2 and H_2. Strong morphology effects were observed, resulting in different Au-TiO_2 interaction, structures and catalytic performances of Au/TiO_2 catalysts. Au/TiO_2(001) are most active in producing PO and its PO yield is greatly enhanced over traditional Au/P25 catalyst by more than 40%. Meanwhile, the ensemble of intimately-contacting $Au^{\delta-}$ and Ti^{4+} on anatase TiO_2 {001} and {101} facets was identified as the active structure catalyzing propylene epoxidation with O_2 and H_2 to PO. There results demonstrate morphology-engineering of oxides as an effective strategy to optimize the catalytic performance and understand the fundamental catalysis of oxide-involved catalysts.

2 Experimental/methodology

Propylene epoxidation with O_2 and H_2 experiment. The catalytic performance of Au/TiO_2 nanocatalysts in propylene epoxidation with O_2 and H_2 was evaluated in a quartz tubular microreactor of 8 mm diameter and 300 mm length. The catalyst experienced no pretreatment prior to the catalytic reaction. 250 mg catalyst (particle size: 280–450 μm) was used and heated in the reaction gas mixture to 50 °C at a rate of 2 °C/min. All reaction products were analyzed using an online Shimazu GC-2014 gas chromatograph equipped with both flame ionization detectors (FID) and thermal conductivity detector (TCD). Operando DRIFTS measurements were performed on a Nicolet 6700 FTIR spectrometer equipped with an in-situ low-temperature DRIFTS reaction cell (Harrick Scientific Products, INC) and a MCT/A detector. Temperature control of the catalysts is performed via a combination of resistive heating and liquid-N_2 held in an externally attached Dewar container in the range 120-773K.

3 Results and discussion

The results are summarized in Table 1 and demonstrate a distinct TiO_2-morphology-dependent catalytic performances of Au/TiO_2 catalysts. $Au/TiO_2(001)$ is more active than Au/P25 and meanwhile keeps the similar selectivity toward PO. The C_3H_6 conversion reaches 0.69% and the PO selectivity is 97.64%, giving a PO formation rate of 25.4 $mmol_{PO}/h/g_{Au}$. However, $Au/TiO_2(100)$ is much less active than Au/P25 and its selectivity toward PO is also poorer than that of Au/P25. The C_3H_6 conversion is only 0.14%. Besides the PO production with a selectivity of 89.44%, acetone and CO_2 were observed to form with the selectivity of 5.58% and 4.98%, respectively. Thus PO formation rate over $Au/TiO_2(100)$ is as low as 4.2 $mmol_{PO}/h/g_{Au}$. Therefore, the PO formation rate of various Au/TiO_2 catalysts follows the order of $Au/TiO_2(001)$ > Au/P25 >> $Au/TiO_2(100)$, and the PO formation rate over $Au/TiO_2(001)$ is higher than that of Au/P25 by more than 40%. Fig.1 shows that the weaker adsorption ability of Ti_{5c} sites on $Au/TiO_2(001)$ and Au/P25 than that of Ti_{5c} sites on $Au/TiO_2(100)$ facilitates the desorption of PO from the surface to avoid its further oxidation. Thus $Au/TiO_2(001)$ and Au/P25 catalysts are much more active and selective in catalyzing propylene epoxidation with H_2 and O_2 than $Au/TiO_2(100)$ catalyst. The significantly-enhanced PO yield of $Au/TiO_2(001)$ over Au/P25 could be attributed to its larger number of active $Au^{\delta-}$-Ti^{4+} ensemble due to the large specific surface area of $TiO_2(001)$ and the fine size of Au particles.

Table 1. Catalytic performances of Au/TiO_2 catalysts in C_3H_6 oxidation with H_2 and O_2 (C_3H_6: O_2: H_2: Ar =1: 1: 1: 7, GHSV = 8000 $mL \cdot h^{-1} \cdot g^{-1}$ catalyst, T = 50 °C.

catalyst	Conversion (%)			C_3H_6 selectivity (%)			PO formation rate ($mmol_{PO}/h/g_{Au}$)	O_2 selectivity	H_2 efficiency
	C_3H_6	H_2	O_2	PO	Acetone	CO_2			
Au/P25	0.50	2.96	1.61	98.36	0.76	0.88	18.1	30.3%	16.5%
$Au/TiO_2(001)$	0.69	2.54	1.63	97.64	0.80	1.56	25.4	41.1%	26.5%
$Au/TiO_2(100)$	0.14	3.20	1.66	89.44	5.58	4.98	4.2	7.4%	3.8%

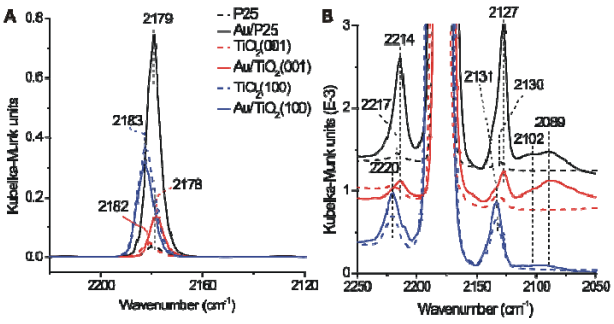

Fig. 1. Operando DRIFTS spectra of CO adsorption on TiO_2 and Au/TiO_2 samples at 120 K with P_{CO} = 2.5 mbar.

4 Conclusions

In summary, employing anatase TiO_2 nanocrystals predominantly enclosed the {001} facets, anatase TiO_2 nanocrystals predominantly enclosed the {100} facets, and P25 predominantly enclosed the {101} facets, we have successfully demonstrated the morphology/crystal plane effect of TiO_2 support on the structure and catalytic performance of Au/TiO_2 catalysts for propylene epoxidation with H_2 and O_2. $Au/TiO_2(001)$ catalyst contains the largest amount of active $Au^{\delta-}$-Ti^{4+} ensemble and thus is most active in propylene epoxidation reaction with a propylene oxide yield of more than 40% higher than traditional Au/P25 catalyst. There results demonstrate morphology-engineering of oxides as an effective strategy to optimize the catalytic performance and understand the fundamental catalysis of oxide-involved catalysts.

Keywords: hydroxyapatite, magnesium and silicon ions, surface, properties, oxidative dehydrogenation of propane

1 Introduction

Nowadays, $Ca_5(PO_4)_3OH$ hydroxyapatite (HA) is actively studied as a catalyst for many processes including dehydration and dehydrogenation of alcohols, acrylic acid production from lactic acid, levulinic acid hydrogenation to γ-valerolactone. It is known that HA has the structural flexibility due to the ability of ions in its structure to be replaced by various cations and anions. Ion substitution of Ca^{2+} ions by the cations and PO_4^{3-} ions by the anions allow changing the acid-base and catalytic properties of HA. In this study, the synthesis of HA modified by Mg^{2+} and SiO_4^{4-} ions was performed to determine the modifying effect of ions on the acid and catalytic properties for oxidative dehydrogenation of propane.

2 Experimental/methodology

Liquid-phase synthesis of HA was performed via microwave assisted approach according to the technique described elsewhere [1, 2]. Synthesis of $Ca_{9.9}Mg_{0.1}(PO_4)_6(OH)_2$ (MgHA) and $Ca_{10}(PO_4)_{5.4}(SiO_4)_{0.6}(OH)_{1.6}$ (SiHA) powders was performed via the same route adding magnesium nitrate and tetraethoxysiloxane to the stock solutions. The samples were then calcined at 600°C in air. X-ray diffraction analysis of HA, MgHA, and SiHA samples was performed on Shimadzu XRD 6000 diffractometer. FTIR spectra of the samples diluted in BaF_2 matrix were registered on Shimadzu FTIR-8300 spectrometer. The acidity of the surface was determined by FTIR spectroscopy of adsorbed CO. The catalytic activity of the samples was studied in the oxidative dehydrogenation of propane at 350-550°C in a flow unit equipped with a tubular reactor (the inner diameter of 4 mm). The reactor was charged with 0.5 g of catalyst in the form of grains of 0.2-0.5 mm. The composition of reaction mixture was 27% C_3H_8 + 5.5% O_2 + He. Before testing, the catalysts were calcined in a helium flow at 350°C.

3 Results and discussion

Table 1 summarizes the specific surface of the obtained samples as well as their catalytic properties. It can be seen that only the sample modified with magnesium revealed good selectivity in the reaction of oxidative dehydrogenation.

Table 1. Specific surface and catalytic data obtained at 550°C for studied hydroxyapatites

Sample	HA	SiHA	MgHA
S_{BET}, m^2/g	85	83	72
Propane conversion, %	9.4	9.3	17.1
Selectivity of propylene + ethylene formation, %	17	13	57

XRD method showed the presence of a single phase of $Ca_5(PO_4)_3OH$ hydroxyapatite in the samples. The impurity phases were not detected also by IR method (Fig. 1) which would allow to reveal the impurities of amorphous silica. The bands of stretching and deformation vibrations of the phosphate groups in the frequency range of 580-650 and 960-1080 cm^{-1} as well as isolated (surface) hydroxyl groups at 3560 cm^{-1} and hydrogen-bonded (bulk) hydroxyl groups at 3400 cm^{-1} were observed in the spectra.

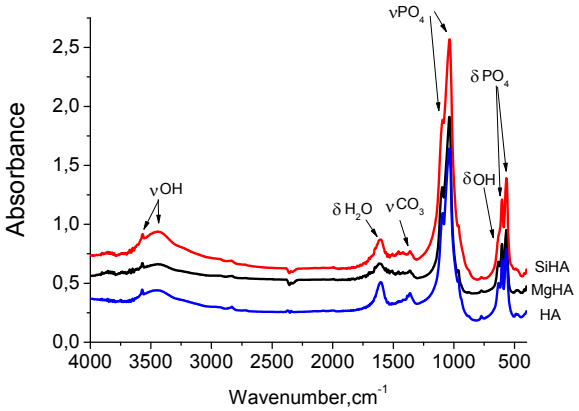

Fig. 1. FTIR spectra of HA, MgHA, and SiHA samples.

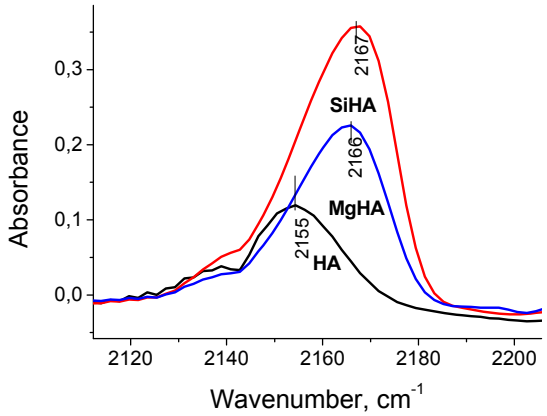

Fig. 2. FTIR spectra of CO adsorbed on the surface of HA, MgHA, and SiHA samples.

Low-temperature CO adsorption revealed the presence of Lewis acid sites (LAS) and the coordinately unsaturated Ca^{2+} and Mg^{2+} cations on the surface of HA, MgHA, and SiHA samples characterized by absorption bands in the region of 2150-2170 cm^{-1}. The strength of LAS in the samples decreases in the following order: SiHA > MgHA > HA (Fig. 2). The row of activity does not coincide with the row of site strength, which may indicate that the oxidative dehydrogenation of propane occurs with participation of acid-base pairs. The expected row of strength of basic sites is MgHA > HA > SiHA, and this row correlates well with the one of catalytic activity.

4 Conclusions

The samples of magnesium- and silicon-substituted HA were synthesized, their surface properties and catalytic activity were studied. It was found that the introduction of Mg^{2+} and SiO_4^{4-} ions into the structure of HA did not alter the hydroxyapatite structure, but it led to increased surface acid properties. The sample modified by magnesium showed the highest activity and selectivity in the oxidative dehydrogenation of propane. The achieved total selectivity in the formation of ethylene and propylene at 550°C over this catalyst was 57% at conversion of 17%.

Keywords: surface structure, thermal treatment, PtRu, bimetallic, catalyst, preferential, oxidation of CO, selective oxidation of benzyl alcohol

1 Introduction

As one of the most important and typical bimetallic catalysts, supported PtRu nanoparticles are widely used in electrooxidation and catalytic oxidation. In order to get better performance, thermal treatment under specified conditions is often conducted before being used in reactions. However, structure evolution of the supported nanoparticles during the treatment is complicated and less studied, and more research is needed to reveal its influence on the catalytic performance thus the structure-performance relationship with the purpose of designing catalysts in a more scientific way. We have recenctly studied the surface structure evolutions of PtRu bimetallic nanoparticles during thermal treatment under H_2, and obtained the influences of their surface structure on the catalytic properties via preferential CO oxidation and selective oxidation of benzyl alcohol as model reactions.[1]

2 Experimental/methodology

PtRu/C and PtRu/Al_2O_3 was prepared by a one-pot surfactant-free polyol process and then treated under H_2 at different temperatures.The samples treated at 200 ºC, 300 ºC, 400 ºC, 500 ºC, 700 ºC are labeled as PtRu-200H, PtRu-300H, PtRu-400H, PtRu-500H, PtRu-700H, respectively. The catalysts were characterized by TEM, ICP, XPS, HS-LEIS and in situ DRIFTS. Preferential oxidation of CO experiments were performed in a fixed-bed lab reactor at atmospheric pressure. The reaction mixture consisted of 1% CO, 0.5% O_2, 50%H_2 and N_2 balance. The weight hourly space velocity (WHSV) of total gaseous reactant was 40,000 $mL \cdot g^{-1} \cdot h^{-1}$. Selective oxidation of benzyl alcohol was performed in a Teflon-lined reactor. The reaction conditions are as follows: 100 mg catalysts, 20 mL benzyl alcohol, 1MPa O_2, 100 ºC, 8h.

3 Results and discussion

Figure 1 shows the TEM results of the as-prepared PtRu/C. As can be seen, the size of the bimetallic nanoparticle is about 2 nm, and the structure can also be proved as a nano-alloy.The compositions of the samples were measured by ICP and XPS, and the results are shown in table 1.The bulk Pt/Ru mole ratio, as determined by ICP, is about 1.66. The Pt/Ru mole ratio on the surface determined by XPS increased monotonously from 1.48 to 2.53 with the increase in the thermal treatment temperature. This means Pt would migrate to the surface during the thermal treatment and this can also be proved by the HS-LEIS results.

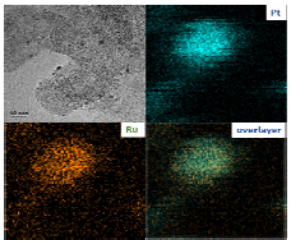

Fig. 1.TEM results of

Table 1. Summary of some characterization data

sample	size /nm	Pt/Ru Mole Ratio	
		by ICP	by XPS
PtRu-200H	1.67±0.40	1.66	1.48
PtRu-300H	1.63±0.39	1.66	1.53
PtRu-400H	1.79±0.34	1.66	1.63
PtRu-500H	1.84±0.37	1.66	1.79
PtRu-700H	3.06±1.05	1.66	2.53

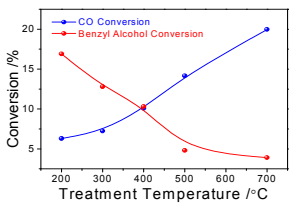

Fig. 2. Conversion of CO or benzyl alcohol at 100 ºC over different catalysts.

The influence of thermal treatment on PtRu catalytic properties was studied through the catalytic oxidation of CO and benzyl alcohol, and the results are shown in figure 2. It's clearly that the conversions of CO increase with the treatment temperature. This means a Pt rich surface is of benefit to the CO oxidation. However, the highest conversion of benzyl alcohol was obtained over PtRu-200H, which is about 17.5% and it will decrease with the increase in the treatment temperature.

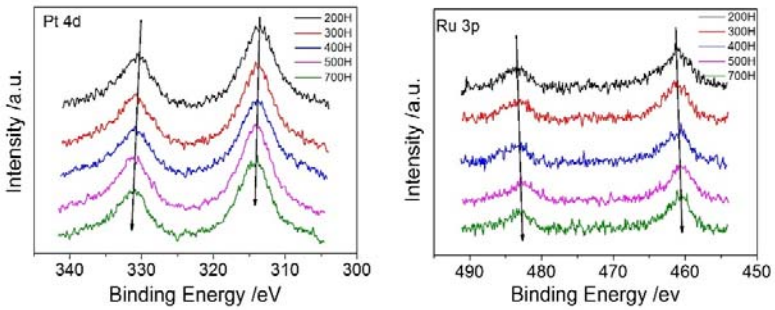

Fig. 3. XPS analysis for $PtRu/Al_2O_3$ treated at different temperatures

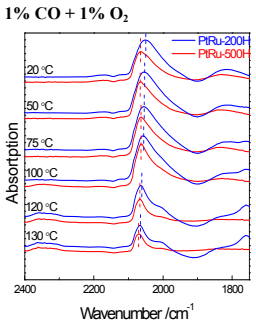

Fig. 4. In situ DRIFTSfor CO oxidation

In order to understand the opposite relationships between the activity and treatment temperature for the oxidation of CO and benzyl alcohol, we then studied the catalysts by XPS and in situ IR. Due to the black colour of carbon, it cannot be used in the IR study and thus we then supported the PtRu on Al_2O_3. The size of the bimetallic nanoparticle is also about 2 nm, and the segregation of Pt to the surface can be also proved as indicated by the XPS results. The activity towards CO oxidation also increases with the treatment temperature. This means $PtRu/Al_2O_3$ treated under different temperature resulted in similar structure to the corresponding PtRu/C. The $PtRu/Al_2O_3$ was then studied by XPS and in situ DRIFTS. As the treatment temperature increased, it can be observed from figure 3 that the binding energies of Pt 4d were shifted to higher values while that of Ru 3p were shifted to lower values.These results indicates the electronic interactions between Pt and Ru get strengthened with increased treatment temperatures, and the electrons are transferred from Pt to Ru. As shown in the figure 4, significant blue shift of the peak for linearly adsorbed CO can be observed for the sample treated at 500 degrees, as compared with that at 200 degrees. This means Pt atoms on the catalysts treated at higher temperature will be more easily oxidized during the reaction. We believe this is because the electrons of Pt are transferred to Ru as supported by the XPS results.

Based on these, the reasons for the reverse relationships between the activity and treatment temperature for the two reactions can be explained. For CO oxidation, oxidized Pt species, on which the adsorption of CO is much weaker, can work as O_2 activation sites and enhance the activity towards CO oxidation, so its activity increased with the treatment temperature. On the other hand, as for the selective oxidation of benzyl alcohol, the rate-determined step is the dehydrogenation of the alcohol. Metallic Pt species can work as hydrogen acceptors and help to accelerate the dehydrogenation step. As the metallic Pt decreased with the increase of treatment temperature, the activity for the oxidation of benzyl alcohol will also decrease.

4 Conclusions

In summary, the surface structure of PtRu nanoparticles with identical bulk composition has been successfully tuned by thermal treatment under H_2 at different temperatures. According to the XPS and LEIS characterizations, we found Pt will migrate to the surface and the electronic interactions between Pt and Ru get strengthened with the increase of treatment temperatures. Such changes lead to the Pt atoms on the catalysts treated at higher temperature more easily to be oxidized during the reaction. It was observed that oxidized Pt species is favorite to CO oxidation, while metallic Pt to oxidation of benzyl alcohol respectively.

Keywords: titanium dioxide, plasma-electrolytic oxidation, anodic oxidation, photoactive coating

1 Introduction

Improving the photoactive and photocatalytic properties of titanium dioxide (TDO) is an important task, especially in the environmental aspect, and there, in the foundations, in two directions: the formation of nanostructured film coatings TDO and its doping for regulation of the phase and chemical composition.

There governmental capabilities in these areas are methods of plasma-electrolytic oxidation (PEO) [1] and anodic oxidation (AO) .The .first lets through the implementation of the regime of microplasma discharges form the oxide not only oxidizing metal (Ti), but also include a film component of forming electrolyte. The second lets a way to form and regulate nanotubular structures TDO and use it as a photocatalyst or a template for modify its photoactive properties [2].

2 The experimental

When PEO titanium samples are formed carbonate-silicate electrolites used with different contents of sodium vanadate, sodium tungstate and europium oxide (electrolyte- suspension). The formation of the coating occurred at the selected voltage, currents and times. Anodic oxidation of titanium was conducted in fluorinated aqueous [3] and non-aqueous [4] electrolytes in the constant voltage mode (20-40 V). Morphology of surface, phase and elemental composition were investigated by SEM, XRD, energy-dispersive X-ray spectroscopy (EDX). Definition photoactivity of samples was conducted under the photocurrent generated by exposure of UV-radiation in a three-electrode quartz cell on the potentiostat "AUTOLAB PGSTAT-302N".

3 Results and discussion

Under the conditions of formation of coatings by the PEO-method volume of generated photocurrents) is a linear function of the concentration of content of dopants (given by EDX – analysis data) in coatings with correlation coefficients close to 1. Maximal quantity of dopant is disclosed under formation coating with the addition of tungsten salt – up 5.6 at%. Photocurrents generated on the undoped sample of TDO and in the presence of dopant differ by more than an order of magnitude Figure 1.

When generating a photocurrent samples of nanotubular TDO and doped Pt observed similar dependences, but the emergence of the photocurrents due here in the introduction of platinum nano-particles of titanium dioxide nanotubes with decrease recombination of photogenerated of electrons and holes, which should contribute to the efficiency of photo-catalysis. The highest photocatalytic activity in the decomposition of methyl orange showed by coating doped by maximum amount of tungsten, the degree of degradation of up to 93%.

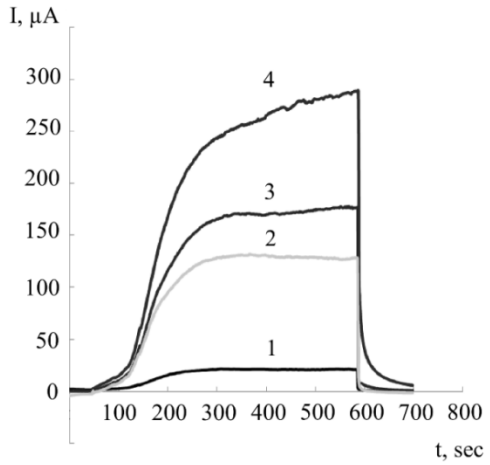

Fig. 1. The dependence of the photocurrents generated by samples of titanium dioxide coatings: undoped –1 and modified by additives of Eu_2O_3 – 2, $NaVO_3$ – 3, Na_2WO_4 – 4 from the time of UV-irradiation.

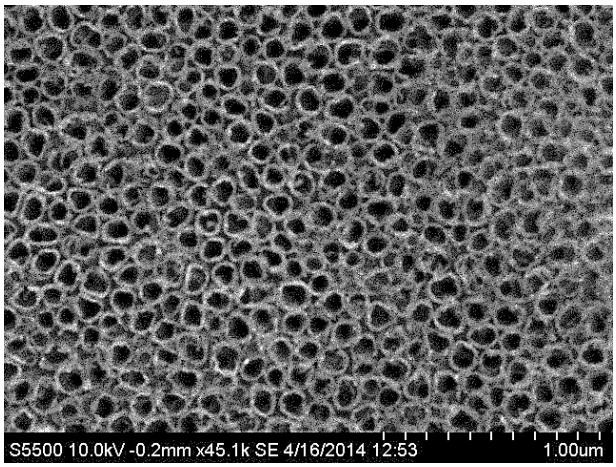

Fig. 2. SEM-image of nanotubular coating TiO_2 formed by anodic oxidation.

4 Conclusion

The photoactivity of film coatings TDO formed by PEO as well as AD, as well as the influence of dopants and nanostructures on their photocatalytic properties are showed.

Highest photoactivity for PEO-coating is disclosed for film formed in presense of tungsten salt as doping component. under bigger its concentration in electrolyte. The coatings formed by anodic oxidation in fluorine-containing electrolytes characterised by one-dimensial (nanotubular) nanostructures which-must more efficiency in photocatalysis due for specific surface area, faster electron mobility. Those factors will be investigated in future.

Keywords: platinum gauzes, ammonia oxidation, catalytic, etching

1 Introduction

Ammonia oxidation with air on platinum catalyst gauzes is widely used in chemical industry for synthesis of nitric acid [1]. It is well known that the gauzes undergo deep structural rearrangement of the surface layers (catalytic etching) during this process. It results in the formation of pits, facets and crystals, platinum loss and decrease of the catalytic activity [2-5]. Two possible mechanisms of the catalytic etching are usually discussed. They are related to increased surface mobility of metal atoms due to the influence of adsorbates [2-3] and to the formation of volatile platinum oxides (PtO_2, etc.) [4-5]. To determine regularities in the formation of pits, facets and crystals, and their role in the catalytic etching of platinum catalyst gauzes during the NH_3 oxidation, we carried out detailed investigation of the surface microstructure of platinum catalyst gauzes treated in air and in the reaction medium (NH_3+O_2).

2 Experimental/methodology

Catalytic oxidation of NH_3 in air was carried out in a laboratory flow reactor made of quartz tube with the inner diameter 11.2 mm at feed (~10% NH_3 in air) flow rate 880-890 l/h, gauze temperature 860±5 °C and total pressure ~3.6 bar. The platinum catalyst gauzes used in the study were made from a wire with d ~100 μm, which had the following chemical composition (in wt.%) 81% Pt, 15% Pd, 3.5% Rh and 0.5% Ru. The gauzes were treated in the reactor for 50 hours both in the reaction mixture and in air. The surface microstructure was studied using a scanning electron microscope (SEM) JSM-6460 LV (Jeol). The surface chemical composition of the studied samples was determined by Energy Dispersive X-ray Microanalysis (EDS).

3 Results and discussion

To determine the role of pits, facets and crystals in catalytic etching of platinum catalyst gauzes during the NH_3 oxidation, we analyzed in detail the surface morphology of regions/fragments of gauzes with different degrees of etching. Grains with 1-13 μm diameter separated by boundaries containing pores with the diameter of 200-400 nm were observed on the fragment of the surface with minimum etching (Fig. 1a). Crystallite plains with the height ~ 100 nm and many pits with the diameter of 50-150 nm were observed on the surface of the grains as dark spots. Some of the pits have pyramidal shape of the etch pits at places where screw dislocations come to the surface. The concentration of these pits is 4.5 10^8 cm^{-2}, which is close to the density of dislocations in platinum estimated in [3]. Larger pores were observed in grain boundaries and on the grain surface on the wire fragments with intermediate etching degree (Fig. 1b). The concentration of the etch pits decreased by a factor of 3-4 in comparison with the fragments having minimum etching (Fig. 1a).

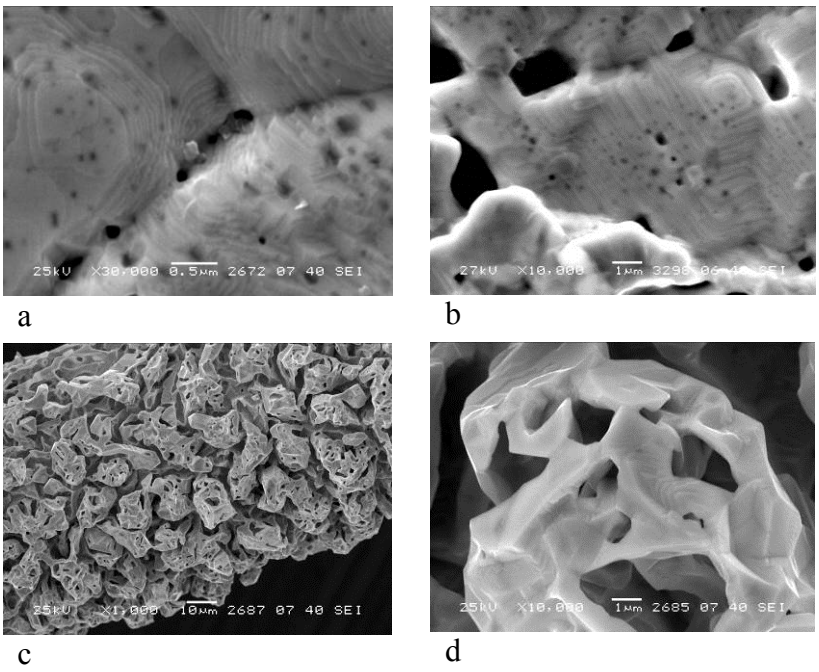

Fig.1. Scanning electron image of fragments of the platinum catalyst wire treated in reaction mixture (~ 10% NH_3 in air) at 860 °C for 50 h.: a, b – fragments with minimum and intermediate catalytic etching; c, d – fragments with maximum catalytic etching.

The fragments of the wire with maximum etching have developed surface morphology (Fig. 1c, 1d). Figure 1c shows a continuous layer of crystallites with the size of 3-16 μm separated by voids with the width of 1-10 μm. An image of such crystallite in higher magnification is shown in Fig. 1d. Voids between grains and penetrating pores in the crystallites were observed. They can be formed by merging of growing etch pits in grain boundaries and on the surface of grains. Treatment of platinum catalyst gauzes in air at 860 °C results only in the formation grain boundaries. No formation of pits, facets, crystals or other surface structures, i.e. surface etching, was observed.

4 Conclusions

Detailed investigation of the surface microstructure of platinum catalyst gauzes after 50 hours of treatment in the NH_3+O_2 reaction mixture revealed fragments of wires with different etching degrees demonstrating the formation, growth and merging of etch pits resulting in catalytic etching. We believe that the NH_3 oxidation on metal atoms located on surface defects (grain boundaries, dislocations) results in weakening of bonds between these atoms. As a result, the mobility of the atoms increases, they migrate and are gradually incorporated into crystal plains on the grain surfaces. Due to these processes, the etch pits formed at the surface defects gradually grow and merge forming voids between and inside the formed crystallites. These processes may result in catalytic etching of the surface of platinum catalyst gauzes.

Keywords: solid phase, synthesis, intercalation, molybdenum disulfide, hydrodesulfurization

1 Introduction

Earlier in the process of constructing of massive 1-, 2-, 3-, 4-component sulfidehydrotreating catalysts we have developed methods [1] that were based on the solid-phase direct combination of catalytic components.The catalysts were prepared from molybdenite (MoS2 as dimensional inorganic precursor of the active component), 3d-metal powders (as promoters), electroexplosivepseudobohemite, nanodiamonds, carbon nanotubes and nanofibers (as structurants and binders).Thus was shown the possibility of obtaining a hydroprocessing catalysts which have a high level of activity, easily and simple - in a single step and without using of aqueous solutions or organic solvents [2]. It is known that the activity of the two-component Co-MoS_2/Al_2O_3 systems is largely increasing subject to pre-intercalation of active phase - nanocrystallites of potassium [3].Significant activity in model hydrogenolysis reactions were shown by catalysts which were obtained by monolayer dispersion (exfoliation).Previouslyintercalationandexfoliationwasn'tobservedinsolid-phaseconditions.

The subject of this work was researching of possibility of intercalation during mechanical activation of molybdenum disulfide in the presence of polar liquids, as well as the determination of the activity of catalysts in the model reaction of hydrogenolysis of DBT.

2 Experimental

Catalysts were prepared from the purified coarse molebdenite in the presence of trace amounts of polar liquids (water, methanol; 100 and 200 μL) under conditions of mechanical activation (4, 8 and 12 hours) in a vertical vibration mill in vacuo.Experiments to test the activity of the catalysts were made in an autoclave type «AUTOCLAVEENGINEERS» reactor with a volume of 100 ml at a pressure of 3.4 MPa and temperature of 340 ° C ($S_{initial}$ = 500 ppm).Composition of the hydrodesulfurization products was identified by results of gas chromatography-mass spectrometry analyzes using magnetic chromatography-mass spectrometr DFS "ThermoScientific"(Germany).The rate constants of DBT hydrogenolysis were defined assuming pseudo-first order of that reaction :$C_{DBT} = C^0_{DBT} \cdot e^{-kt}$. From tangent of angle of slope of the dependenceln (C^0_{DBT}/C_{DBT}) from t were obtained the corresponding values of the rate constants.Samplesfromthereactorwerecollectedat 0.5, 1, 2, 3, 4, 6 and 7 hours.

Activity of the catalysts was assessed by the level of residual sulfur (sulfur analyzer OXFORD InstrumentsLab - X 3500 SCL) in the final hydrogenation products taking into account the values of the rate constants for the conversion of DBT (initial sulfur content of 500 ppm).Catalyst samples MoS_2 + CH_3OH "before" and "after" the model reaction was analyzed by synchronous thermal analysis and mass spectrometry (TGA/DSC + MS) on the instrument STA-449C ("Netzsch") combined with a quadrupole mass spectrometer QMS 403C.

Heating was carried out in air (flow rate 20 ml / min) to 650^0C at a heating rate of 10 ° C /

min.For processing the results of thermogravimetry (TGA) and differential scanning calorimetry (DSC) was used in the program "ProteusAnalysis".

3 Results and discussion

The greatest activity in the hydrogenolysis model reaction has been demonstrated with catalyst MoS2 + 100 μL of CH_3OH; residual sulfur content decreased from 500 ppm to 2 ppm.As can be seen from the TEM images shown in Figures 1 and 2, after mechanoactivating (8 hours), both samples were heavily milled and crystallites were aggregated.At the same time, in nanocrystallite packs of molybdenum disulfide (Figure 1) the distance between the layers remain close to 0,615 nm.Figure 2 shows a sample of MoS2 wich was mechanoactivated in the presence of 100 μLCH3OH and that picture reflecting crystallographic shifts and rotations of the layers, the additional formation of defects, nanocrystallitessplitted to separate layers.
In other words, intercalation occurs with partial exfoliation in the experimental conditions and in a presence of trace amounts of methanol.

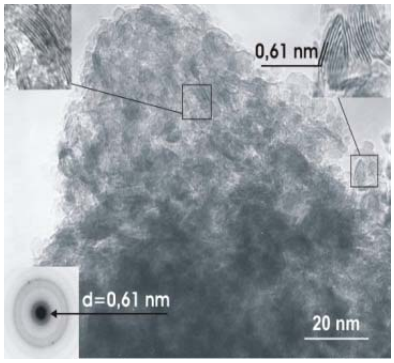

Fig. 1. TEM picture of MoS2 after mechanoactivation (8 h.)

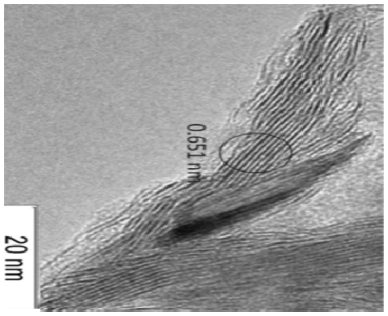

Fig. 2. TEM picture of system MoS_2+ 100 μL of CH_3OH after mechanoactivation (8 h.)

The paper discusses the results of XPS, XRD, synchronous thermal analysis with mass spectrometry for catalysts "before" and "after" their participation in the model reaction.

4 Conclusions

For the first time, was carried out method of direct solid-phase combination of coarse MoS2 with microscopic quantities CH3OH received catalyst with high activity for hydrodesulfurization structures for dibenzothiophene's series. Intensive increasing of activity can be attributed to the formation of new active sites during intercalation and partial exfoliation.

Keywords: low-temperature ammonia synthesis, sibunit, ruthenium, rubidium, EXAFS-spectroscopy

1 Introduction

It is known that ruthenium-alkali metals-carbon support system is highly active in ammonia synthesis [1, 2]. In our case the carbon-carbon composite Sibunit was used as effective carrier for Ru-Rb components. Sibunit is the mesoporous support which combines electrical conductivity with high mechanical strength.

The preparation of modified Ru/Sibunit catalysts is a complex multi-stage process, so catalytic activity depends on processes occurring on each preparation step. The aim of this work is the investigation of structural changes in the Ru-Rb-Sibunit system, which take place on different stages of catalyst preparation. The main advantage of using the Ru-Rb/Sibunit catalysts for investigation by the EXAFS and XANES spectroscopy is the possibility to study local environment not only for ruthenium but for rubidium, which acts as catalyst promoter.

2 Experimental

Supported ruthenium catalyst was prepared by impregnation of Sibunit (S_{BET} = 320 m^2/g, particle size was 0.4 – 0.8 mm) with aqueous solution of $[Ru(NH_3)_nCl_m](OH)_p$ (n =5-6, m=0-1, p=1-2) complex, followed by drying at 120 °C for 3 h (air) and reduction in hydrogen flow at 450 °C for 4 h (H_2 flow was 60 ml/min, heating rate 10 °C/min up to 450 °C). Obtained 4%Ru/Sibunit catalyst was impregnated by aqueous $RbNO_2$ solution, followed by drying at 120 °C for 3 h and activation in argon flow (60 ml/min, 350 °C, 2 h, heating rate 5 °C/min). The sample after activation was reduced in H_2 at 350 °C, 2 h, heating rate was 5 °C/min. Derived 4%Ru-8.5%Rb/Sibunit (mas. %) catalyst was flowed by Ar. The part of the catalyst was taken for EXAFS-spectroscopy after each step of synthesis.

Determination of catalytic activity in reaction of ammonia synthesis was carried in flow reactor under pressure of gaseous mixture H_2:N_2 (molar ratio 3:1) 0.7 MPa and 350 °C. The amount of outlet ammonia was determined by absorption of NH_3 with sulfuric acid solution followed by titration of the H_2SO_4 excess with NaOH solution.

Ruthenium and rubidium K-edge EXAFS spectra were measured on an EXAFS spectrometer at the Siberian Synchrotron Radiation Center. The spectra were obtained using synchrotron radiation at electron energy of EXAFS 2 GeV in the VEPP-3 storage ring, and a current of 70 mA employing a cut-off Si (111) crystal as a monochromator. All spectra were recorded in the transmission mode with a step of 2.5 eV. The resulting spectra were processed using the Viper software following the standard procedure in [3]. The spectra were processed as $k^2\chi(k)$ in a wave number range of 2.50–12.00 $Å^{-1}$. The data on the structure of the compounds were taken from the Inorganic crystal structure database (ICSD).

3 Results and discussion

List of examined samples is presented in table 1.

Table 1. List of samples

№	Sample	Preparation
1	4%Ru/Sibunit	Sibunit impregnation by $[Ru(NH_3)_nCl_m](OH)_p$ complex, dried 120°C 3 h
2	4%Ru/Sibunit	Sample № 1 reduced H_2 450°C 4 h
3	4%Ru-8.5%Rb/Sibunit	Sample №2 impregnated by $RbNO_2$, dried 120°C 3 h
4	4%Ru-8.5%Rb/Sibunit	Sample № 3 activated in Ar 350°C 2 h
5	4%Ru-8.5%Rb/Sibunit	Sample №4 reduced in H_2 350°C 2 h, final
6	4%Ru-8.5%Rb/Sibunit	Sample №5 after NH_3 synthesis

According to EXAFS data, ruthenium in Ru/Sibunit catalyst after drying (sample №1) presents as initial complex. The spectrum of the sample after hydrogen treatment (№2) has only one distance Ru-C of 2.08 Å, which refers to the distance from ruthenium to support carbon. Absence of distances corresponding Ru-Ru, Ru-O-Ru or Ru-C-Ru, means that after reduction ruthenium presents in monatomic state. After impregnation by $RbNO_2$ solution and drying the peak attributed to distance Ru-C (2.08 Å) is remaining. The other peaks in the spectra of sample 3 have low intensities that indicate the absence of an ordered structure.

EXAFS spectra for samples 4% Ru-8.5% Rb/Sibunit after activation in argon (sample №4) and subsequent reduction in hydrogen (№5) are almost identical. The RDF curve in each case exhibits three peaks corresponding to the first (2.69 Å), second (3.79 Å) and third (4.69 Å) coordination spheres of metallic ruthenium.

In all cases the presence of peak at 1.8 Å (in the R-δ scale) in the RbK spectra is related with processes of two-electron excitation in alkali metals [4] and does not refer to actual interatomic distance. The next peak corresponds the Rb-C or Rb-O distance with ~2.9 Å.

4 Conclusions

It is shown that ruthenium in Ru-Rb/Sibunit catalyst after reduction presents in metallic state. Absence of Ru-Rb distance indicated that ruthenium and rubidium are located mainly separate from each other.

Keywords: carbon nanotubes, CO hydrogenation, oxidation process

1 Introduction

Carbon nanotubes (CNT) possess unique set of properties such as high thermal conductivity and stability, large surface area and chemical inactivity, which allow to use this material as effective support for various catalytic processes [1]. However, pristine CNT are usually unsuitable for metal coating due to the absence of surface stabilization sites. Therefore, different methods are used to stabilize and disperse metal particles on the surface of CNT. The most common methods are surface functionalization, partial substitution of carbon atoms by heteroatoms and controlled formation of surface defects. In this study we considered the influence of CNT oxidation on the morphology and catalytic activity of Co/CNT catalysts.

2 Experimental

Multiwall CNT were synthesized using catalytic chemical vapor deposition method (CCVD). Hexane was used as carbon source, the temperature was 650°C. Complex oxide Co-Mo/MgO was used as growth catalyst. Synthesized material was annealed at 400°C in air flow, washed by HCl and distilled water to remove amorphous carbon and metal impurities.

Washed CNT were boiled in nitric acid during 1, 3, 6, 9, 12 and 15 h. BET Surface area and pore radius were determined by nitrogen adsorption; oxygen content was measured by XPS (surface content) and TGA-MS (volume content); the intensity ratio of the D to the G band (I_D/I_G) from Raman spectra was used to estimate the amount of disorder or defects present in the structure of the CNTs. Samples were denoted as CNT-n, where n means hours of oxidation.

Catalysts were obtained using impregnation of Co nitrate ethanol solution for the Co loading of 15 wt. %. CO hydrogenation was performed in a fix-bed reactor. *In situ* reduction of catalysts (H_2, 400°C, 4 h) was carried out before catalytic tests. Reduced samples were tested in CO hydrogenation conditions (220°C, 1 bar, H_2:CO=2.1:1, 70 h). Reduced and treated catalysts were studied by TEM.

3 Results and discussion

CNT-n characteristic are given in table 1. Maxima of the defectiveness, BET surface area, surface oxygen content (degree of functionalization) are obtained at 9 h oxidation, while total oxygen content has a maximum at 15 h.

Table 1. CNT supports features depending on the oxidation time.

CNT oxidation time (h)	BET surface area (m^2/g)	Average pore radius (nm)	Content of O bounded with C (at.%, XPS)	Total content of O (wt.%, TGA-MS)	I_D/I_G
0	192	18.8	0.3	-	1.13
1	229	12.7	6.5	4.3	1.03
3	233	12.9	8.0	5.0	1.07
6	237	9.8	8.6	4.8	1.38

9	249	1.8	8.9	5.2	1.36
12	246	1.8	8.7	5.5	1.29
15	232	1.8	8.8	6.2	1.17

TEM images of the reduced catalysts reveal CNT destruction in case of long-time oxidation (fig. 1a). It was found that Co particle size decreases and metal dispersion increases with increase of oxygen content. Particles with average diameter 4 nm mixed with huge agglomerates of Co were detected in the sample which contains 6.5 at. % of O (fig. 1b). Otherwise, no large particles were found in the sample with 8.8 at. % of O (fig. 1c).

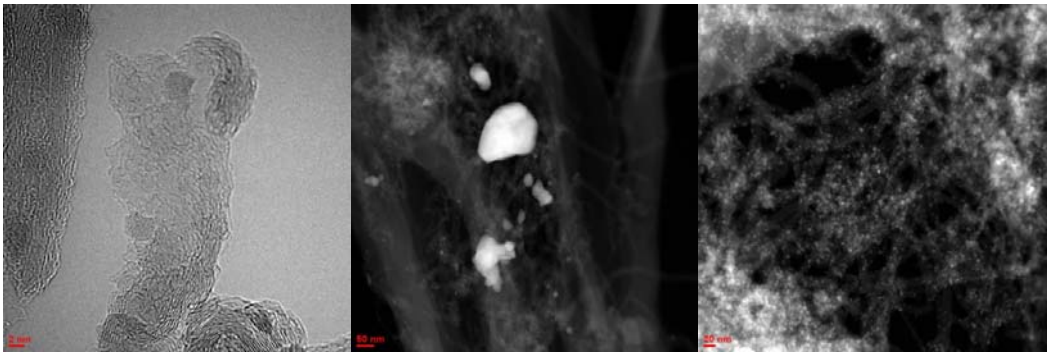

Fig. 1. TEM images of cobalt catalysts supported on CNT: a, c – Co/CNT-15; b – Co/CNT-1.

The dependences of catalytic activity and selectivity from Co/CNT-n structure were obtained in present work. Fig. 2 shows increase of CO conversion with surface oxygen content in CNT growth. The correlation between C_{5+} selectivity and defectiveness was also discovered.

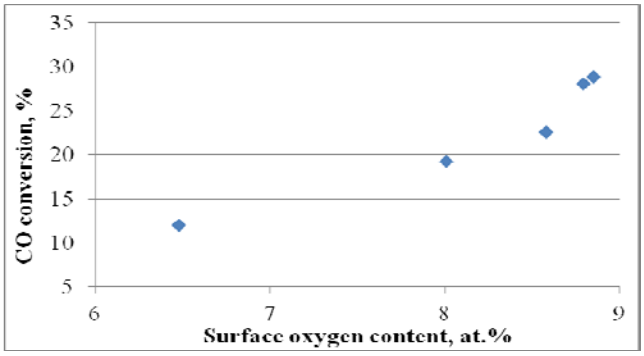

Fig. 2. Change of CO conversion with CNT-surface oxygen content.

Hydrothermal Treatment of Gamma Alumina: Mechanisms and Effects on Catalytic Properties

Mukhambetov I.N.*, Lamberov A.A.

Kazan (Volga region) Federal University, Kazan, Russia

* hello_@bk.ru

Keywords: hydrothermal treatment, gamma alumina, skeletal, isomerization of n-butenes, boehmite, lewis, acidity, solid, phase, transition

1 Introduction

Gamma alumina is one of the most commonly used materials as catalysts and their supports. For some catalytic processes it is necessary to increase the acidity of γ-alumina for the synthesis of catalysts with perfect activity. It is known that hydrothermal treatment is an alternative method for the modification of alumina acidity. This process accompanied by a formation of boehmite, however, the cause of the additional active sites have not been identified.

The purpose of this work were: study of structure transformations alumina during hydrothermal treatment, mechanism of the acidity increasing and its influence on catalytic properties in skeletal isomerization of n-butenes and 1-phenylethanol dehydration.

2 Experimental/methodology

The hydrothermal treatment of aluminum oxide was performed in an autoclave at 150°C and heating/cooling rate of 7 deg min^{-1}. On being kept for a certain time, the autoclave was cooled to room temperature and the sample was extracted, dried at 120°C for 2 h.

Hydroxyl groups of alumina and boehmite were studied by IR spectroscopy (Vertex 70) after the evacuation (residual pressure 10^{-3} mbar). The acid centers of the samples were studied by the method of temperature-programmed desorption (TPD) of ammonia on a Quantachrome ChemBET Pulsar TPR/TPD instrument and also via IR spectroscopy (Vertex 70) of adsorbed pyridine.

The catalytic activity of the samples in the course of skeletal isomerization of n-butenes was tested in an isothermal flow-through laboratory reactor in the continuous mode at a temperature of 540°C, raw material : steam molar ratio of 1 : 4. For 1-phenylethanol dehydration – 280°C and raw material : steam molar ratio of 1 : 10.

The porous structure of the samples was studied by the method of low-temperature adsorption of nitrogen with a Quantachrome Autosorb IQ instrument.

The differential-thermal analysis (DTA) was made with an MOM Q-1500 D derivatograph (Hungary) in the temperature range 24–1000°C at a heating rate of 10 deg min^{-1} in argon.

Micrographs of the samples were obtained with a Zeiss EVO-50XVP scanning electron microscope (SEM).

3 Results and discussion

Shown that the transition alumina→boehmite occures in solid phase. In the process of hydrothermal treatment takes a linear accumulation of boehmite, thus sizes of boehmite microcrystals change nonlinearly (Figure 1).

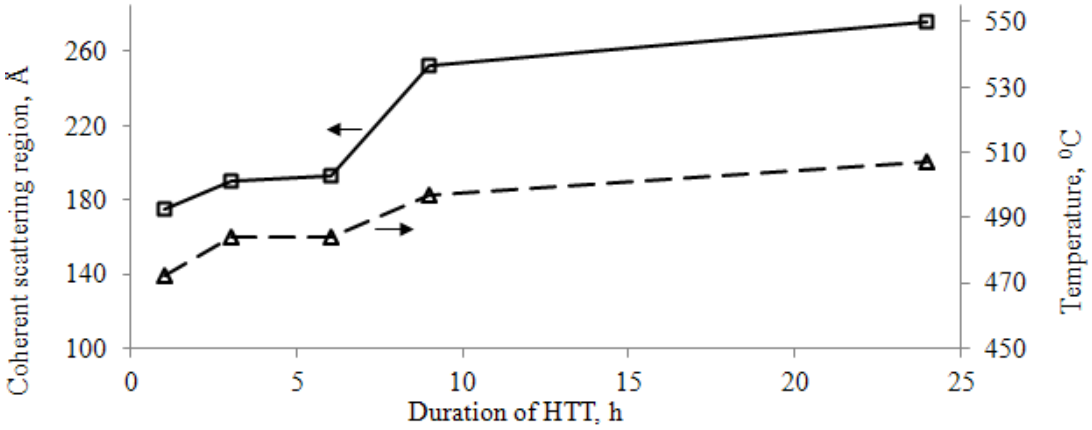

Fig.1. Resizing CSR of boehmite along the [120] and a maximum of thermal decomposition to alumina during the HTT.

After 1–3 h of hydrothermal treatment, secondary aggregates of the starting aluminum oxide are dispersed, which leads to an increase in the specific surface area. In the process, the content of acid centers and the activity of the samples in the skeletal isomerization of *n*-butenes on strong Lewis acid centers also grow. At a long treatment duration (>6 h) the specific surface area and acidity of aluminum oxide decrease.

We analyzed the change of the hydroxyl cover and it is assumed that boehmite forms layer by layer from surface of alumina primary particles (Figure 2). From this viewpoint, the pore structure and acidity distribution changes attributed.

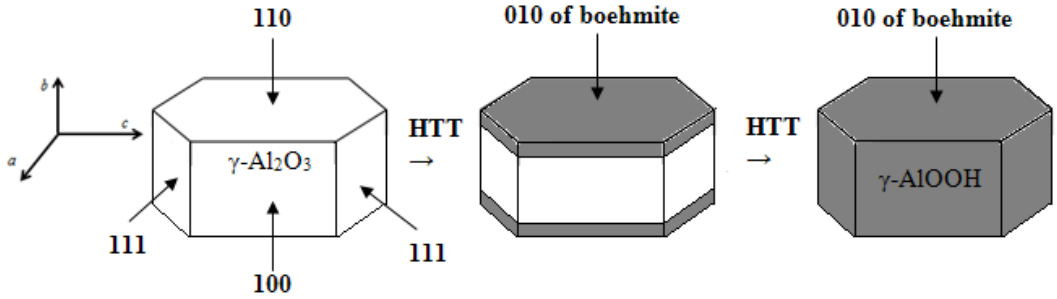

Fig.2. The scheme of conversion of primary particles during the HTT.

4 Conclusions

- Shown mechanism of the transition alumina→boehmite during hydrothermal treatment.
- Interpretated the increase in acidity.
- Catalytic activity of alumina in skeletal isomerization of n-butenes can be improved by hydrothermal treatment from 30 to 33 % at the same selectivity.

Keywords: transition metal catalysts, ordered mesoporous, alumina, methane dry reforming, syngas, iron, nickel

1 Introduction

Biogas, a mixture of CH_4 and CO_2 is formed in large quantities as a result of anaerobic digestion of organic material, wastes and energy crops. Its production in Europe is growing exponentially in the last decades [1]. CH_4/CO_2 gas mixtures can be directly catalytically converted to syngas via methane dry reforming reaction. If CH_4-CO_2 reforming reaction is to become a complimentary pathway for syngas production, transition metal catalysts which exhibit good activity and especially high resistance to coke accumulation are essential. The latter requirement is difficult to achieve due to high thermodynamic driving force for coke formation and catalyst fouling by its accumulation.

The following rationale was utilized in this work: active transition metal clusters were deposited within the pores of ordered mesoporous alumina to prevent their sintering and growth. The function of neighboring CeO_2-ZrO_2 clusters was to supply oxygen species and gasify the coke, prevent its accumulation and ensure continuous catalyst self-regeneration. This study demonstrates stable and selective reforming of CH_4 with CO_2 over extended time with bimetallic transition metal catalysts containing Ni, Co, W and Fe.

2 Experimental

Ordered mesoporous Al_2O_3 was prepared by evaporation-induced self-assembly method [2] using Pluronic P123, anhydrous ethanol and aluminum isopropoxide. CeO_2 and ZrO_2 (4 mol. % relative to Al_2O_3, Ce:Zr = 4:1) were deposited over the Al_2O_3 using wet-impregnation technique, dried and calcined for 4 h at 350 ^oC (sample denoted as AlCZ). A total of 3 wt. % metals (NiFe, NiW, CoFe and CoW) was wet-impregnated over the AlCZ support. The weight ratio of Ni or Co to Fe or W was equal to 1 to 4 in all cases. The samples were calcined for 4 h at 650 ^oC and are denoted by: NiFe/AlCZ, NiW/AlCZ, CoFe/AlCZ and CoW/AlCZ. Prior to catalysis, samples were activated *in-situ* (20 % H_2/N_2) at 750 °C. Catalytic tests were performed in a tubular quartz reactor at 750 ^oC. Equimolar reactant feed of CH_4 and CO_2 (50 NmL/min each) was fed into the reactor at WHSV = 30 L/(g_{cat}·h). Prepared catalysts were characterized by XRD, N_2 sorption, HR TEM-EDX, H_2-TPR, Raman and UV-Vis techniques.

3 Results and discussion

N_2 sorption showed that AlCZ supports exhibit type-IV isotherm with H1-type hysteresis loop and pore size distribution between 5 and 10 nm. TEM characterization confirmed ordered mesoporous structure of AlCZ support (Fig. 1a). Fig. 1b shows TEM image of the CoFe/AlCZ catalyst with corresponding elemental mapping. These images reveal that after active metal deposition, the ordered mesoporous structure of catalysts was maintained. Also, high dispersion of active metals clusters (below 5 nm) over the surface of the alumina matrix was achieved. Deposited active phase did not form alloys, but instead consisted of single metal clusters.

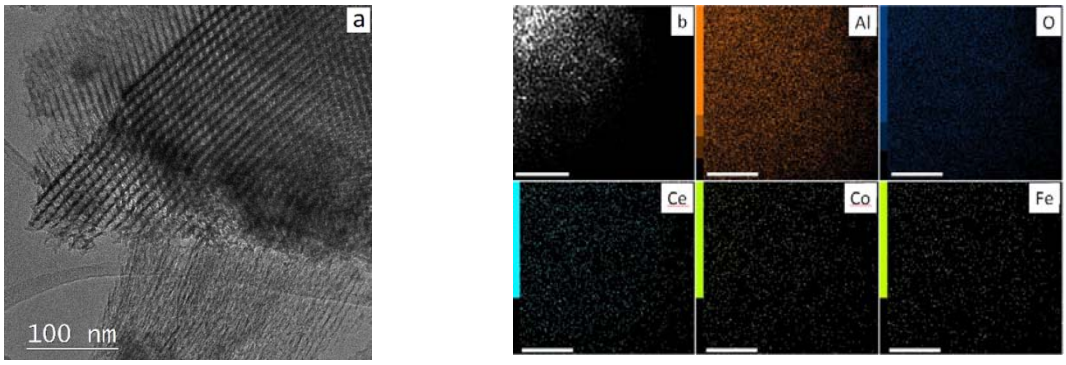

Figure 1. Ordered mesoporous morphology of the (a) AlCZ support and (b) TEM-EDX mapping of CoFe/AlCZ catalyst. Scale bar = 100 nm.

Results of catalytic tests for the most promising catalysts, NiFe/AlCZ and CoFe/AlCZ are presented in Fig 2 and Table 1. These materials exhibited stable activity during the 20 h TOS and H_2/CO ratios which are very close to the equilibrium values. On the other hand, a noticeable deactivation of NiW/AlCZ and CoW/AlCZ catalysts was identified. Also, a significantly lower H_2/CO ratio over these catalysts indicates the dominance of WGS reaction, which consumes a substantial part of H_2 to produce water.

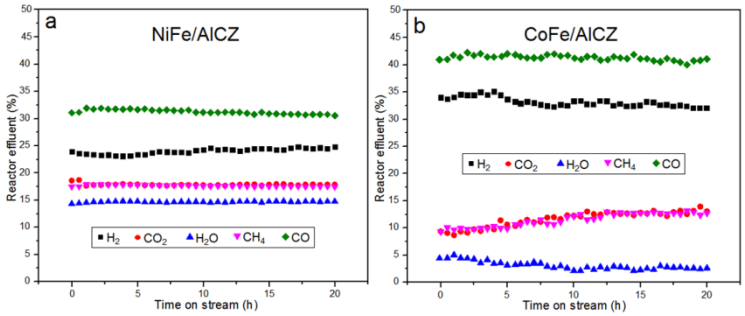

Figure 2. Reactor effluent as a function of time on stream for supported (a) NiFe and (b) CoFe catalysts.

Table 1. BET specific surface area, total pore volume of synthesized bimetallic catalysts along with achieved CH_4 and CO_2 conversions, H_2/CO ratio and accumulated carbon during 20 h catalytic tests.

Catalyst	BET specific surface area, m^2/g	Total pore volume, cm^3/g	X CH_4, %	X CO_2, %	H_2/CO ratio, /	C content, wt. %
NiFe/AlCZ	196	0.29	82	80	0.88	0.6
NiW/AlCZ	228	0.50	86	90	0.68	0.8
CoFe/AlCZ	256	0.57	89	91	0.84	1.2
CoW/AlCZ	220	0.49	87	78	0.56	4.7

4 Conclusions

The employed strategy of depositing bimetallic clusters within the pores of ordered alumina matrix in close proximity to reducible CeO_2-ZrO_2 nanoclusters proved a successful strategy for the development of stable and selective NiFe and CoFe catalysts for CH_4-CO_2 reforming reaction. The presence of W resulted in more pronounced deactivation and undesired WGS activity.

Keywords: magnetic, nanoparticles, palladium, selective, hydrogenation, alkynols

1 Introduction

Recently, magnetic nanoparticles (MNPs) attracted considerable attention as catalytic supports. They allow easy separation of catalysts from reaction mixtures and their repeated uses, resulting in energy conservation, more environmentally friendly processes and cheaper target products [1-4]. While developing magnetically separable catalysts, two important requirements should be taken into account: (i) narrow MNP size distribution due to the dependence of magnetic properties of NP size; (ii) in most cases the surface of MNPs should be functionalized due to the necessity of attachment of catalytic species to NP surface.

Monodisperse MNPs can be prepared by thermal decomposition of iron acetylacetonates or carboxylates in high-boiling solvents containing surfactants. However, surfactants can be replaced by functional ligands including polymers.

In this work we report several approaches to synthesis of iron oxide MNPs and their use as support for palladium-containing catalysts of alkynol hydrogenation (Fig. 1): thermal decomposition of iron-containing precursor [5]; ligand exchange method using functional acids containing multiple double bonds [6]; functionalization of MNP surface with polyphenylenepyridyl dendrons or dendrimers [7, 8].

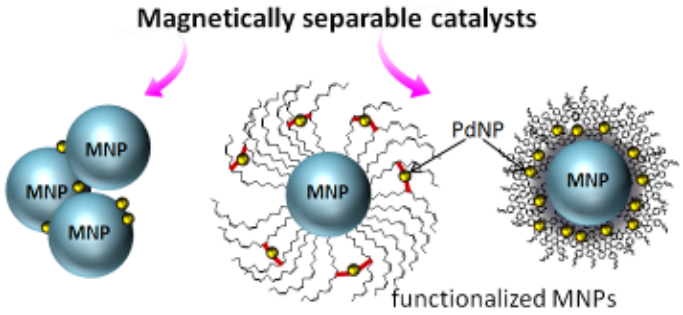

Fig. 1. Schematic representation of used catalytic systems

2 Experimental

In the present work $Pd(acac)_2$, $Pd(oac)_2$, $PdCl_2$ or $(CH_3CN)_2PdCl_2$ were used as Pd sources, and well-defined iron oxide NPs of different compositions as an iron source. Iron oxide NPs were prepared via the thermal decomposition of iron oleate in octadecane and eicosane as solvents, which were chosen to control the reaction temperature and achieve the desired NP size. In the case of MNPs functionalized with polyphenylenepyridyl dendrons/dendrimers of functional acids, $Fe(acac)_3$ was used as iron source. Synthesis was carried out either via ligand

exchange method or in the presence of desired dendrons/dendrimers. It is noteworthy that dendrons/dendrimers served for interdendrimeric stabilization of MNPs and at the same time for encapsulation of catalytically active Pd NPs.

Catalytic testing was carried out in selective hydrogenation of 2-methyl-3-butyn-2-ol (dimethylethynylcarbinol) to 2-methyl-3-buten-2-ol (dimethylvinylcarbinol), which is intermediate of such industrially important compounds as linalool and isophytol, and vitamins E and K, in isothermal glass batch reactor at ambient hydrogen pressure varying the solvent type, temperature and substrate-to-catalyst ratio.

3 Results and discussion

All the synthesized Pd/MNPs catalysts were shown to be promising in alkynol hydrogenation (up to 98% of selectivity at 95% of a substrate conversion, along with extremely high activity were achieved).

It important to note that in some cases, e.g. MNPs covered with functional acids containing multiple double bonds, two types of Pd NPs formation were found: intraparticle and interparticle. The latter was found to result in aggregation. Such an aggregation allowed fast magnetic separation which is necessary for the development of efficient magnetically separable catalysts. In the case of dendron/dendrimer functionalized NMPs, for certain dendron/dendrimer concentrations and structures, well-dispersible, multi-core, flower-like crystals were formed. Besides, aggregation also took place while adding palladium species and the shape and density of aggregates were found to depend on the rate of palladium addition.

Even when no functionalization of MNPs was performed aggregation of MNPs in the presence of Pd NPs occurred that was likely due to polarization forces.

It is noteworthy that independently of the type of functionality on MNP surface, for all the catalytic systems, it was found that samples, which were preliminarily reduced with hydrogen, were much more active and selective in comparison with unreduced samples as well as in comparison with traditional Lindlar catalyst.

4 Conclusions

The magnetic composites containing Pd species have been synthesized and tested in a model reaction of selective hydrogenation of dimethylethynylcarbinol. *Easy magnetic recovery of the catalysts, high selectivity and activity along with stability of their catalytic performance make them promising for a commercial use.*

Characterization of Electron-Acceptor Sites on the Surface of Sulfated and Chlorinated Alumina by EPR Using Spin Probes

Shuvarakova E.I.[1,2*], Bedilo A.F.[1,2]

Keywords: electron-acceptor sites, EPR, sulphated alumina, chlorinated alumina

1 Introduction

Aluminum oxide is widely used as a catalyst support. The surface of Al_2O_3 is known to have both acid and base sites of different types. Deposition of sulfates or chlorides on the γ-Al_2O_3 surface is known to lead to a substantial increase of its acidity and catalytic activity in acid-catalyzed reactions. The catalytic properties of sulfated alumina generally resemble those of sulfated zirconia, which is more widely known due to its higher acidity and catalytic activity. Meanwhile, low cost, high surface area, wide availability, and reasonable thermal stability make sulfated alumina an attractive catalyst for acid-catalyzed processes that do not require very high acid strength.

Spontaneous ionization of aromatic molecules is known since the 1960s. The presence of the active surface sites of different strength, capable of ionizing the aromatic molecules was suggested. Conventionally, they are divided into strong, medium and weak. Electron-acceptor sites of different strength can be characterized using aromatic probes with different ionization potentials [1, 2]. Our recent results suggest that such sites are most likely responsible for decomposition of halocarbons [3] and ethanol dehydration [4]. This study was devoted to analysis of relations between the concentrations of electron-acceptor sites and modifying components and mechanisms of processes taking place on different sites and adsorption of the used aromatic donor molecules.

2 Experimental/methodology

Sulfated Al_2O_3 samples with the different concentrations of SO_3 (2, 4, 8, 12, 16 wt.%) and chlorinated samples with Cl contents of 1, 2, 4, 8 wt.%. were studied. Two experimental techniques were used for characterization of electron-acceptor sites [2]. The former was to study changes of the concentration of paramagnetic particles over time at room temperature. The first measurement was carried out immediately after the activation of the sample. The following measurements were carried out every 24 hours for one week. The second technique was to study the changes in the concentration of paramagnetic particles after heating the activated samples with probes for 18 hours at 80°C.

3 Results and discussion

It was found that the concentration and the strength of electron-acceptor sites significantly grow with an increase of the sulfate concentration (Fig. 1). The strongest electron-acceptor sites tested with toluene immediately after adsorption were only detected with a concentration of SO_3 not less than 4%. The weakest sites tested with perylene presented on the surface of all the samples, with their concentration on 12% SO_3 sample being 3×10^{19} g $^{-1}$.

The study of chlorinated samples showed that there were no strong sites on their surface. Chlorination only led to minor growth of the concentration of the weak sites. Their concentration tested using perylene or anthracene after the heat treatment at 80°C increased only

by a factor of 2 on the sample 4% Cl^- compared to the unmodified support.

Recommendations on the use of spin probes for testing electron-acceptor sites with different strength are suggested. A mechanism of the polycondensation of aromatic probes on the surface electron-acceptor sites explaining experimental results and possible structures of such sites were proposed.

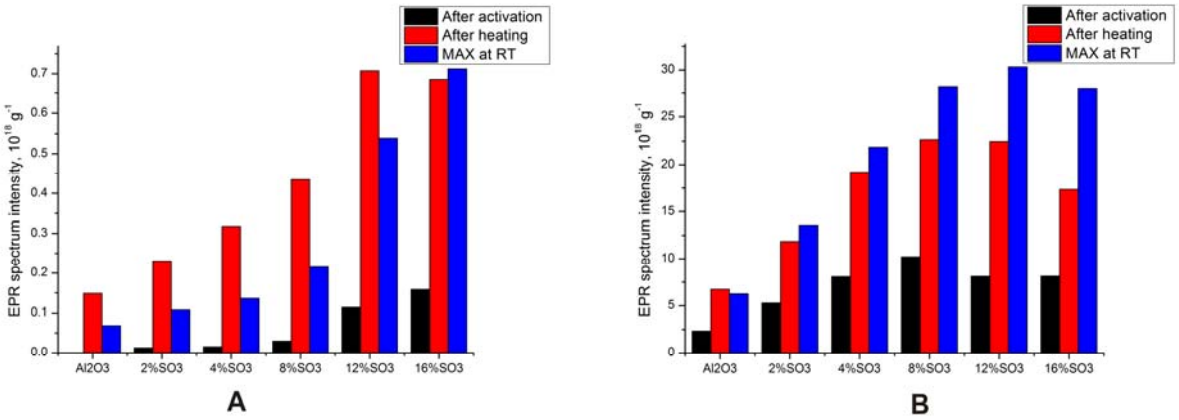

Fig. 1. Comparison of the EPR spectra intensities observed on alumina samples with different sulfate concentrations immediately after spine probe adsorption, after heating at 80 °C for 18 h and maximum concentration achieved at room temperature: A – toluene adsorption on strong sites, B – perylene adsorption on weak sites.

4 Conclusions

Alumina modification with sulfates was found to result in a gradual increase of the concentration of electron-acceptor sites characterized using the formation of radical cations from aromatic molecules with different ionization potentials. The strongest electron-acceptor sites tested with toluene immediately after adsorption were detected only on sulfated alumina with a concentration of SO_3 not less than 4%. Al_2O_3 chlorination only led to minor growth of the concentration of the weak sites.

Measuring the concentration of radical cations generated immediately after adsorption of a donor appears to be the most direct way of estimating the concentration of electron-acceptor sites with the corresponding strength. Apart from fast generation of primary radical cations on strong electron-acceptor sites and their following transformations, slow formation of EPR signal attributed oligomeric hydrocarbon species is observed. The rate of their formation depends on the concentration of sulfates and the used electron donor. This process seems to take place on weak electron-acceptor sites of the alumina surface and can be used to characterize them.

Keywords: structural, characterization, Ga_2O_3 oxide, Pt/γ- Al_2O_3 catalysts, DFA, PDF method

1 Introduction

The key aspect in catalysis research is understanding any structure–performance relationships. Characterization of catalytic materials is related with an ability to study nano-scale structures. There is significant drawback with common XRD methods, since they probe well-crystallized materials. Bragg peaks from nanocrystalline phases are broadened. Moreover, additional diffuse scattering is missed in standard XRD analysis, whereas it contains information on the local structure and defects. Alternative effective approaches take into account both the Bragg and diffuse scattering. Calculation of full profile of XRD pattern by means of Debye Function Analysis (DFA) allows modelling XRD pattern for crystallites of any size and shape [1-2]. Analysis of radial distribution function (RDF) of electron density or pair distribution function (PDF) is directed on atomic-scale structural studies [3]. This method is based on integral analysis of the full XRD pattern and reveals distribution of interatomic distances up to 1-3 nm. The possibilities of these methods to probe structure of catalytic materials are shown for some examples: 1) structural study of nanocrystalline γ-Ga_2O_3 oxide; 2) determination of local atomic structure of supported platinum in Pt/γ-Al_2O_3 catalysts.

2 Experimental

Calculations of XRD patterns were performed by the DFA method using the DIANNA software [2]. Experimental XRD patterns were obtained at a Bruker D8 Advance diffractometer (Cu $K_{\square}$ radiation, λ=1.5418Å) and at diffractometry stations (λ=0.703 Å and λ=0.368 Å) in the Siberian Synchrotron and Terahertz Radiation Centre (Novosibirsk, Russia). The RDFs or PDFs were obtained by the Fourier transformation of normalized scattering intensity [3].

3 Results and discussion

γ-Ga_2O_3

Nanocrystalline Ga_2O_3 oxides have been used as supports or catalysts. Gallia has a polymorphism somewhat similar to that of alumina. There is limited information on structure of the γ-Ga_2O_3 phase. High dispersion complicates structure solving. The XRD pattern of the γ-Ga_2O_3 oxide under study exhibits broadened and unresolved peaks (Fig. 1). The modelling by DFA method showed that the XRD pattern corresponds to a spinel type structure with vacancies in tetrahedral 8a and octahedral 16d cation positions and with additional cations in nonspinel 8b, 16c, 48f positions. The best fit was obtained for crystallites of a parallelepiped shape with dimensions of 0.8×1.6×1.6 nm (Fig.1). Analysis of PDF confirmed that area of atomic arrangement in the oxide did not exceed 1.5-2 nm in size; correlations in atomic arrangement fade at longer distances (Fig.1). Observed atomic correlations differed from those characteristic for the ideal spinel structure. Proposed model of defect spinel with filling spinel and nonspinel sites was more appropriate for describing the observed atomic ordering.

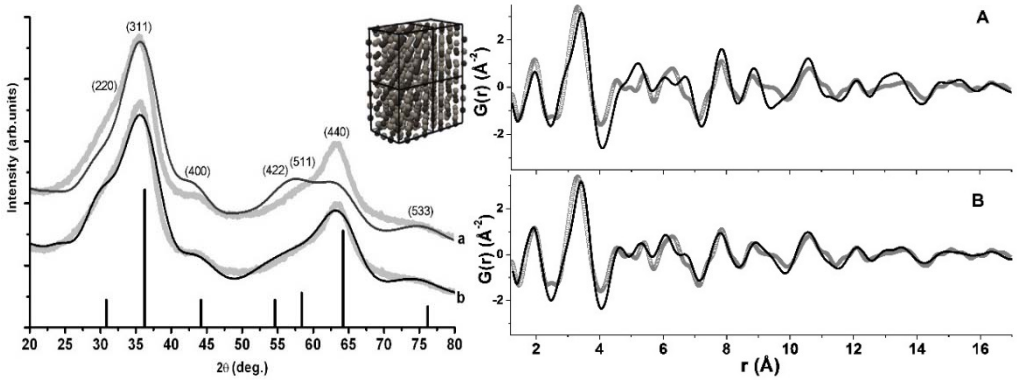

Fig. 1. Left side: experimental (gray line) and model (black line) XRD patterns for the γ-Ga_2O_3 oxide. Right side: experimental (gray circles) and model (black line) PDFs for the γ-Ga_2O_3 oxide. **a** - ideal spinel, **b** – cation deficient defect spinel.

Pt/γ-Al_2O_3

Analysis of differential curves (d-RDFs) between RDFs of the catalysts and support allows the local structure of supported nanoparticles to be determined. The atomic structure of supported platinum in the 0.75 wt % Pt/γ-Al_2O_3 catalysts was studied [4]. Both the metal Pt^0 and oxide PtO_x species were detected depending on catalyst preparation conditions (Fig.2). The data provided an insight into the structure of highly dispersed PtO_x species. The results supported recent suggestions about interaction between the platinum and alumina. The Pt atoms had atomic correlations with support atoms. In particular, the Pt atoms seemed to be strongly anchored to the cation vacancies in the γ-Al_2O_3 surface.

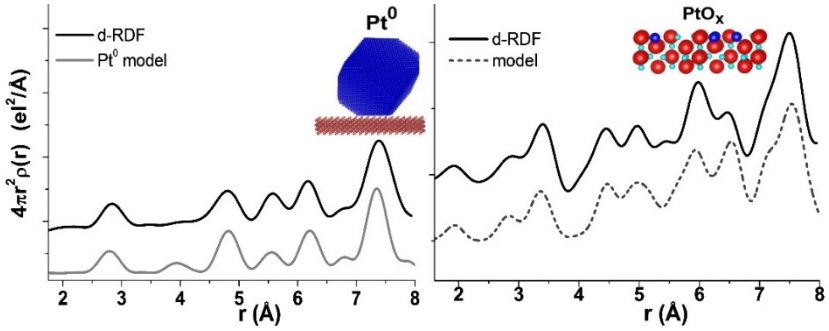

Fig. 2. Experimental d-RDFs describing the Pt local arrangement in the Pt/γ-Al_2O_3 catalysts in comparison with RDFs calculated for the Pt^0 phase and model of atomic ordering at insertion of Pt atoms into cation vacancies in the alumina surface.

4 Conclusions

The DFA and PDF methods are complementary powerful techniques for structural diagnostics of nanocrystalline catalytic materials. The PDF method allows one to reveal structure of supported nanoparticles, when it is applied on heterogeneous catalysts.

Keywords: natural zeolite, clinoptilolite, modification, mineral acids, organic acids, heteropolyacids

1 Introduction

It is known that hydrocarbon cracking is carried out on acidic centers, therefore ideal catalysts for this process are solid acids [1,2]. Zeolites, as solid acids are the main catalysts for the cracking of hydrocarbons.

2 Experimental/methodology

As the object of research natural zeolites of Shankanay field (Kazakhstan) was taken, in which the major rock-forming mineral is acid- and heat-resistant clinoptilolite.

Catalysts based on natural zeolite of Shankanay field were synthesized by modification with mineral acids, organic acids, and heteropolyacids (HPA).

Modification of natural zeolite samples (Kl) was performed by the method of Kerr in a Soxhlet apparatus. All samples were dried in an oven and calcined at 500 ° C for 4 hours in a muffle furnace. An acid modification conditions: 1.6-2 mm fraction of the zeolite, the ratio S:L of 1:10 (wt.), processing temperature 94-98ºC, the contact time to 10 hours. After a predetermined time, the samples were washed thoroughly from residual acid, dried to air-dry state.

3 Results and discussion

Modification of natural zeolite sample with various acids leads to structural changes of clinoptilolite. Acid activation of clinoptilolite increases its surface and pore volume, decreases average pore diameter, which in turn directly affect the properties of the active acid sites of the zeolite, as well as their distribution on the catalyst surface.

The study found that the catalysts obtained by modification of natural zeolite with various by nature acids, by the specific surface area starting from the lowest arranged in a row:

Kl > H4EDTA/Kl > HKl-1 > H4EDTA/HKl-1 > HSal/HKl-1 > PW12-HPA/HKl-1

Special attention deserves the abnormal growth of the surface when the modification with 10% PW12-HPA to 257.0 m2/g, since this value is much higher than for pure zeolite and HPA. Obviously, when HPA applied on the surface of the zeolite there is a deep interaction occurs. In addition, there is formation of new nanostructures that have been shown by TEM and SEM.

By volume of pores the catalysts starting from the lowest may be arranged in a row:

Kl > HKl-1 > HSal/HKl-1

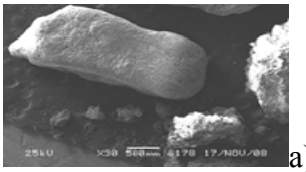
The pore distribution on the catalyst surface shifts toward micropores, or in other words, on the surface mainly micropores are found.

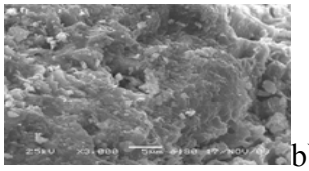
Obviously, the growth surface of the catalyst is due to the formation of new micropores.

Determination of surface micropores (Smc) also shows their growth from 2.49 to 38.07 m^2/g after modification with hydrochloric acid and to 67.84 m^2/g with sulfosalicylic acid.

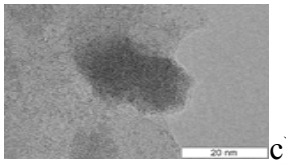
As a result of the XPS study it was found that when impregnating heteropolyacids of molybdenum and tungsten series, the zeolite framework partially decomposed with the formation of individual and Al-O- and Si-O- structures. Since conditions of the main elements of the zeolite varies a little. Molybdenum and tungsten in catalysts are in present as Mo (6+) and W (6+), respectively, which evidence of retaining heteropoly-like structure.

Morphology and microfeatures, elemental composition in the observed point, the distribution pattern of elements on the surface of initial clinoptilolite and its acid-modified forms examined by SEM (JSM-6X80) and TEM HR (JEM–2010) (Fig. 1.).



a)


b)



c)

Fig. 1. – Electron-microscopic image of zeolite samples: granules of natural zeolite; HKl-1, PW12-HPA/HKl-1.

According to electronic images of natural zeolite granules are irregular in shape (Fig. 1a) and are characterized by a specific structure consisting of irregularities and cracks, which causes the penetration of relatively large cations.

Surface of decationized clinoptilolite HKl-1 (Fig. 1b), characterized by inhomogeneity and the presence of multiple shallow channels, which have a layered structure.

When modification of zeolite with decationized HPA of Tungsten 12 series, there is a sharp increase in the specific surface area of the catalyst. Obviously, when HPA impregnated on the surface of the zeolite there is a deep interaction. Thus on the TEM HR images of catalyst homogeneous structures of HPA interspersed into the pores of the zeolite are visible. The dimensions of these structures are a few nanometers. Obviously, the occurrence of these nanostructures alters the catalytic properties, particularly cracking activity of the catalyst considerably increases, consequently the yield of liquid products of the cracking reaction, constituting mainly of the long-chain α-olefins increase.

By means of CO adsorption method of strength and concentration of acid sites were identified. In the series starting from lowest: HKl > 10%HSal/HKl > 10% PW12-HPA/HKl. There is a significant increase in the proportion of strong and very strong Bronsted acid sites. Strong acid sites are found at 10% PW12-HPA/HKl and HKl. Bronsted centers of the second type on 10%PW12-HPA/HKl by the shift are greater than HKl, although the concentration is less. Acid sites of the third type on the catalysts, approximately the same amount, but they obviously do not determine the activity of the cracking catalyst. The total concentration of strong acid sites on 10%PW12-HPA/HKl and sum of shifts at 340 cm^{-1} and 320 cm^{-1} is higher than on HKl. It should be noted that the increase in acidity correlates with high silicate modulus (SiO_2/Al_2O_3) of the zeolite sample.

4 Conclusions

Thus, by modification of natural zeolite with various acids, active hydrocarbon cracking catalysts for the synthesis of long chain α-olefins were designed. Due to low cost and availability of natural zeolite developed catalysts can be used on an industrial scale.

Keywords: self-sustained oscillations, methane, oxidation, oxygen bulk diffusion, nickel

1 Introduction

Nonlinear behavior, like self-sustained oscillations in the reaction rate, is an unusual and, nevertheless, well-known phenomenon in the heterogeneous catalysis. Sinusoidal or harmonic oscillations, relaxation-type oscillations, and chaotic behavior have been observed to date in approximately 40 catalytic reactions in a wide pressure range, from ultrahigh vacuum up to atmospheric pressure, over all types of catalysts, including single-crystals, polycrystalline foils, wires, and supported catalysts. Several mechanisms describing the rate oscillations for different reactions were proposed. However, the most of them is based on the Langmuir-Hinshelwood mechanism and do not take into account the diffusion in subsurface layers of catalysts. This study is devoted to theoretical analysis of the influence of the diffusion of oxygen atoms into nickel on the self-sustained rate oscillations in the catalytic oxidation of methane.

2 Methodology

The microkinetic scheme for the oxidation of methane over nickel was published elsewhere [1]. Parameters of elementary reactions, such as enthalpies and activation energies, were determined using a phenomenological approach suggested by E. Shustorovich [2]. Pre-exponential factors of elementary steps were evaluated in the framework of the transition state theory [3]. The diffusion coefficients of oxygen atoms in nickel were determined on the basis of experimental data. The mathematical model of the reaction consists of a system of ordinary differential equations and takes into account concentrations of surface intermediates, an oxygen concentration in subsurface layers, and the heat balance.

3 Results and discussion

The model of the catalytic oxidation of methane over nickel was amended with a step of the diffusion of oxygen atoms from the nickel surface into subsurface layers. It allows us to study the influence of this step on the characteristics of the oscillatory behavior. In full agreement with previous study [1] the model without the oxygen diffusion under certain parameters has oscillatory solution (fig. 1). In this case the oscillations starts without any delay. In contrast in the model with the oxygen diffusion we found a long induction period before arising the self-sustained oscillations. Similar effect was observed experimentally. Also we found that the concentration of oxygen in the subsurface layers of nickel oscillates synchronously with the concentrations of reaction products in the gas phase.

In both cases we found the partial pressure oscillations of products and reactants as well as the concentration oscillations of main intermediates on the catalyst surface. Simultaneously the catalyst temperature oscillated with the amplitude of several Celsius degrees. Typical oscillations are presented in fig. 1.

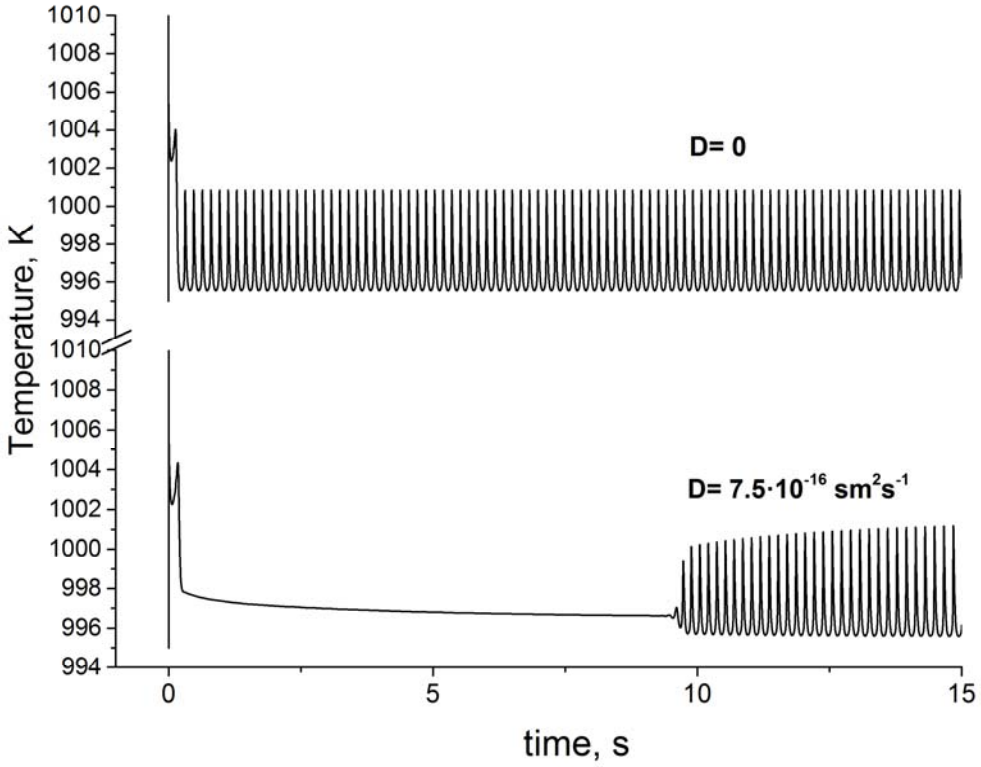

Fig. 1. Oscillations of catalyst temperature in the models of methane oxidation without (top) and with (bottom) oxygen diffusion. D is coefficient of oxygen bulk diffusion.

4 Conclusions

The addition of the oxygen diffusion into the model leads to the appearance of an induction period before the self-sustained rate oscillations. The concentration of oxygen in the subsurface layers of nickel oscillates synchronously with the concentrations of reaction products in the gas phase.

Keywords: OCM, oxidative coupling of methane, SEM-EDX

1 Introduction

The demand for chemicals and energy has been continuously increased in recent years as the result of industrial development and increasing concerns for greenhouse gas emissions. One of the promising alternatives for the production of basic chemicals and liquid fuels from natural gas is the oxidative coupling of methane (OCM) process, which converts methane into valuable hydrocarbons such as ethane and ethylene [1]. Although this process has been well-known for a few decades, there is still some scientific challenge to achieve a commercial OCM catalyst. Therefore, a great attention has been still paid on this issue by many researchers. Numerous attempts has been made utilizing various catalyst types, forms, reactors and operating conditions in order to enhance the OCM process. The silica supported active metals such as Mn and Na_2WO_4 as in $Na_2WO_4/Mn/SiO_2$ catalyst is one group of catalyst that has been suggested for this purpose [2]. In this work, SEM characterization of various forms of $Na_2WO_4/Mn/SiO_2$ catalyst for OCM reaction has been investigated to support the work performed to determine the most suitable catalyst form for this important reaction.

2 Experimental/methodology

The various structures such as particulate catalyst, wash coat monoliths and single monolithic structures of 2wt.%Mn/5wt.%Na_2WO_4/SiO_2 catalyst were prepared through three different methods (incipient to wetness to impregnation method, sol-gel method and direct hydrothermal synthesis method (MCM-41)). Scanning electron microscopy (SEM) coupled with energy dispersive X-ray spectroscopy (EDX) analysis was performed with Philips XL 30 ESEM-FEG instrument in our research center to observe the surface morphology of fresh and used catalysts.

3 Results and discussion

SEM results showed that Mn and Na_2WO_4 metals were uniformly dispersed on the surface of particulate catalyst prepared with incipient to wetness to impregnation method, while these metals were disorderly dispersed on the one prepared by sol-gel method; EDX results also verified these findings. Figure 1 shows the catalyst loadings on MCM-41 catalysts. As it is seen in Figure 1.b, there are large porous structures filled by Na (light color) as also verified by EDX analysis. Mn metals were also observed as grey stripes. EDX results also showed that Mn and WO_4 were better dispersed than Na metals.

Figure 2 shows SEM results of monosil structured catalysts. It is clearly seen that a good porous structure was obtained, and the catalyst (the white dots that was identified as NAby EDX analysis) was well dispersed on the cross sectional area normal to flow (Figure 2.c). On the other hand, it was found that these metals did not well diffuse into the monosil structure as it is seen from Figure 2.d, which shows a surface inside the monolith parallel to flow direction; the number of white dots are much smaller than that was observed in Figure 2.c. Both catalysts

performed slightly lower than the particulate catalysts in the reactions tests (at 700 °C with a CH_4/O_2 ratio of 10), and resulted about 10% C_2 (ethane and ethylene) yield as compare to 14% obtained with particulate catalyst.

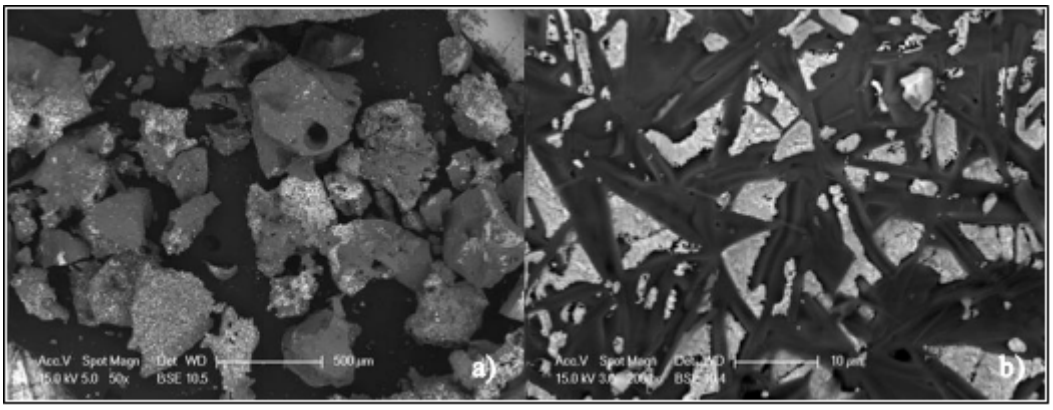

Fig. 1. SEM images of MCM-41 catalyst over 2wt.%Mn/5wt.%Na_2WO_4/SiO_2: a) 500 µm, b) 10 µm.

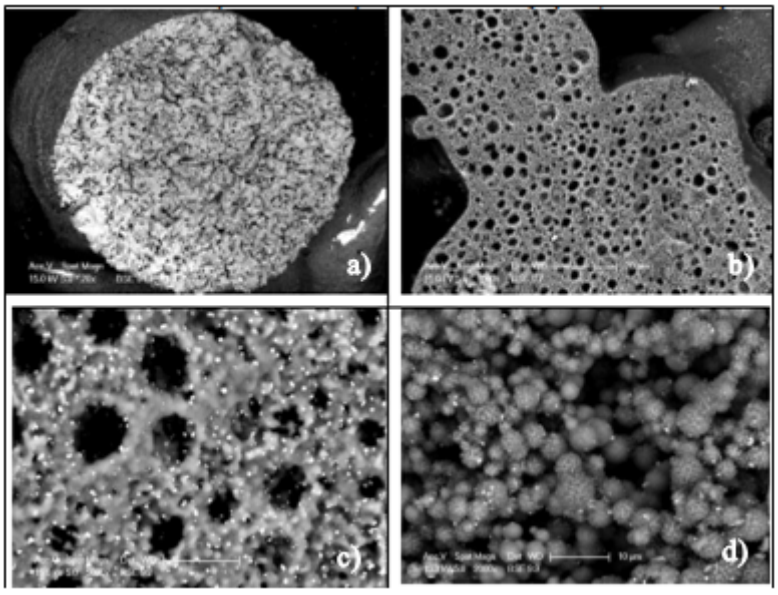

Fig. 2. SEM images of monosil catalyst over 2wt.%Mn/5wt.%Na_2WO_4/SiO_2: a) 1 mm, b) 20 µm in cross section normal to flow, c) 5 µm in cross section normal to flow, d) 10 µm in cross section parallel to flow.

4 Conclusions

SEM and EDX characterization of 2wt.%Mn/5wt.%Na_2WO_4/SiO_2 showed that the dispersion of Mn and Na_2WO_4 metals were quite different in different forms of the catalysts; this difference seems to affect the catalytic activity and therefore C_2 (ethane and ethylene) yield.

Keywords: cuprous, oxide, capping ligands, CO oxidation

1 Introduction

In the synthesis process, surfactant is often employed to provide the growth of nanoparticles and stable a certain crystal plane. Although several capping ligands were found to enhance the catalytic selectivity for some catalytic reactions, concerning the catalytic activity, all previously-reported capping ligands exert the surface-blocking effect to decrease the number of active surface sites accessible to reactants and subsequently the catalytic activity. [1,2] We comparatively studied the catalytic performances of Cu_2O octahedra with different amounts of PVP capping ligand in CO oxidation. Very unexpectedly, PVP was found to significantly enhance the catalytic activity of Cu_2O octahedra, and the relevant mechanism was revealed.

2 Experimental/methodology

We have synthesized PVP-protected octahedral Cu_2O nanocrystals (denoted as o-Cu_2O-PVP). o-Cu_2O-PVP were treated in the stream of mixed gas (C_3H_6:O_2:Ar=2:1:22) at 200°C for 30min and 120min and then cooled down to room temperature with Ar gas stream to acquire partial PVP-protected Cu_2O octahedra (denoted as o-Cu_2O-partial PVP) and PVP-free Cu_2O octahedra (denoted as o-Cu_2O) respectively. The catalyst diluted with SiO_2 was used to evaluate the catalytic activity and the reaction gas consisting of 2% CO and 1% O_2 balanced with N_2 was fed at a rate of 20 mL/min. The conversion of CO was calculated from the change in CO concentration of the inlet and outlet gases. XPS measurements were performed on an ESCALAB 250 high performance electron spectrometer using monochromatized Al Kα (hν = 1486.7 eV) as the excitation source. DRIFT spectra were measured on a Nicolet 6700 FTIR spectrometer equipped with an in-situ DRIFTS reaction cell with 64 scans and a resolution of 4 cm^{-1} using an MCT/A detector. The catalyst was heated at various temperatures with the reaction gas stream, and the chemisorption process was in-situ studied by the DRIFTS measurements performed till the chemisorption saturated.

3 Results and discussion

We have successfully developed a novel controlled-oxidation strategy to selectively remove full or part of the capping ligands on o-Cu_2O-PVP without the change of their composition, morphology, size, and surface structure. Fig. 1 (A) and (B) shows the catalytic performance of various Cu_2O nanocrystals in CO oxidation with stoichiometric oxygen (2% CO and 1% O_2 balanced with N_2). Very evidently, the capping agents on octahedral Cu_2O nanocrystals controls their catalytic performance in which o-Cu_2O-PVP is the most catalytically active among these nanocatalysts. The activity order is o-Cu_2O-PVP>o-Cu_2O-partial PVP>o-Cu_2O. The reaction mechanism of various Cu_2O octahedra is the same. In Fig. 1 (C) and (D), the intensities of o-Cu_2O-PVP in N 1s spectra are the same, however, the C-N bond at 287.6eV in C 1s spectra in o-

Cu_2O-PVP partially broke after reaction to form a N-CH-CH_2 moiety, which enhanced the O_2 adsorption on Cu_2O surface to increase the reaction activity. Fig. 2 shows the DRIFTS spectra acquired for the chemisorption of CO+O_2 on various Cu_2O catalysts at various temperatures. At 30°C, CO chemisorbs on coordinatively unsaturated Cu only at 2104 cm^{-1}. As the temperature increases, the chemisorption at 2184 cm^{-1} arises. CO and O_2 co-chemisorbs evidently on coordinatively saturated Cu at 2184 cm^{-1}, which is the intermediate species of CO reaction. At 140°C, the chemisorption of o-Cu_2O-PVP at 2184 cm-1 is the strongest. While o-Cu_2O-partial PVP, and o-Cu_2O have no catalytic activity at 140°C, the chemisorption at 2184 cm-1 weakened, which follows the activity order.

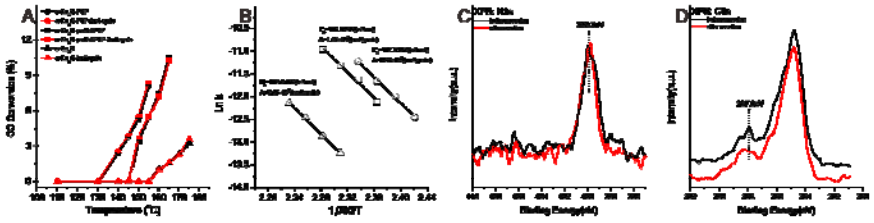

Fig. 1. (A) Catalysis performance, (B) Arrhenius plots of various Cu_2O octahedra in CO oxidation, (C) N 1s spectra, and (D) C 1s spectra of o-Cu_2O-PVP before and after reaction.

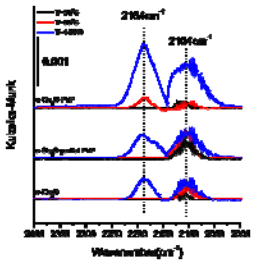

Fig. 2. DRIFTS spectra of CO+O_2 chemisorption on various Cu_2O octahedra at various temperatures. The gas CO adsorption is deducted.

4 Conclusions

We report the first time that PVP capping ligands on Cu_2O octahedra can significantly enhance their catalytic activity in CO oxidation. PVP partially decomposes with the breaking of the N-C bond of the N-CH-CH_2 moiety and the remaining group can enhance the O_2 adsorption on the Cu_2O octahedra surface. CO oxidation mechanism on the Cu_2O octahedra surface is identified to be the LH mechanism. This work shows that proper capping agent introduced in the catalyst synthesis can markedly improve the catalytic activity of gas-phase catalytic reactions, and it is of great significance to discover and research more high-effective catalysts and opens a new window to research the catalysis of nanocrystals.

1 Introduction

Metal nanoparticles have attracted much attention over the last decade due to their unique catalytic properties [1]. The properties of metal nanoparticles are strongly depended on the size, shape and support materials. Metal nanoparticles assembled in the cluster show higher catalytic activity due to high surface to volume ratio [2]. Although metal nanoparticles on solid supports have been successfully employed in catalysis, most systems undergo from shortcomings such as passivation of the surface, lack of long-term stability, low dispersibility which limit their capacity and applications [3]. Macrocyclic compounds are attractive compounds for the construction of supporting matrix for metal nanoparticles due to their easy modification, rich host-guest complexation properties and ability to self-assemblies both in solutions and on the surface. We have used aggregates of water-soluble resorcinarenes as templates for the synthesis of metal nanoparticles with different size and shape. The catalytic properties of the hybrid nanocomposites obtained will be discussed in the presentation.

Keywords: CO-PROX, CuO/CeO_2 catalysts, CO_2, TPD, TPD model

1 Introduction

Copper-ceria systems have been investigated as possible catalysts for CO preferential oxidation, proposed as purification step of H_2-rich streams for PEMFC application. The good performance of this class of materials has been related to synergistic interaction between copper and cerium oxide, the activity towards CO oxidation being essentially addressed to the copper oxide-ceria interfacial sites [1,2].Copper dispersion and interaction with ceria is affected both by CuO load and by catalyst preparation method [2,4,5], nevertheless a quantitative analysis of the extent of this phenomenon has never been attempted.

In this work we applied a combined (experimental/modelling) technique, we named Kinetically Modelled Temperature Programmed Desorption (KM-TPD) using CO_2 as probe molecule, to identify and quantify the active sites of copper-ceria catalysts with different Cu load prepared by wet impregnation or by solution combustion synthesis. The results of the KM-TPD showed that the model succeeded in quantitatively identifying the active sites for both CO and H_2 oxidation providing a good correlation with the catalytic activity and selectivity of the catalysts.

2 Experimental/methodology

Wet impregnated (CuCe-I) samples with a nominal CuO load equal to 0.5, 4 and 8 wt. % CuO and a solution combustion synthesized (CuCe-S) catalyst containing 4 wt. % CuO were prepared and calcined in air at 450°C for 2h.

The lab-scale set-up used for CO-PROX experiments was described elsewhere [6]. Catalytic tests were conducted at fixed contact time. H_2, CO and O_2 concentrations were fixed at 50, 0.5 and 0.9 vol.% respectively. Reaction temperature ranged from 80 to 200 °C.

The KM-TPD is based on experimental tests and modelling analysis of TPD, here applied to CO_2 desorption. Experimental CO_2 TPD tests were carried out by using a Micromeritics Autochem II 2020 analyzer. After contacting the sample for 45 min at room temperature with a 15 vol.% CO_2/He mixture and purging, it was heated at 10°C/min up to 300°C. The TPD model was developed to identify the number and the type of CO_2 species desorbing from different surface sites. In [6] more details on the governing equations and approximations used in the model are given.

3 Results and discussion

The CO_2 sorption capacity of the support is comparable to that of the CuO/CeO_2 catalysts suggesting a significant contribution of ceria. For impregnated copper/ceria catalysts [6] three different sites can be identified through CO_2 KM-TPD, associated respectively to i) cerium centres deeply modified by the strong interaction with copper active towards CO oxidation (θ_1), ii) not modified cerium centres (θ_2) and iii) copper centres in supported copper oxide active for H_2 oxidation (θ_3), respectively. The θ_2 sites are those more significantly affected by copper

coverage. Indeed, by increasing the CuO loading the amount of CO_2 adsorbed over these sites decreases up to the monolayer coverage (4 wt % CuO) suggesting that copper deposition partially covers these ceria sites not sufficiently balanced by new copper adsorption sites. On the other hand, the amount of H_2 oxidation centres increases exceeding the monolayer coverage.
The same sites were identified for the CuCe-S sample and a lower value of the activation energy of the CO_2 desorption step from the sites associated to CO-oxidation centers was found. Moreover, a more homogeneous distribution of copper sites was obtained for this sample compared to the impregnated catalyst with the same CuO load with an evident dominance of CO oxidation sites, likely promoted by a stronger interaction with ceria (figure 1).

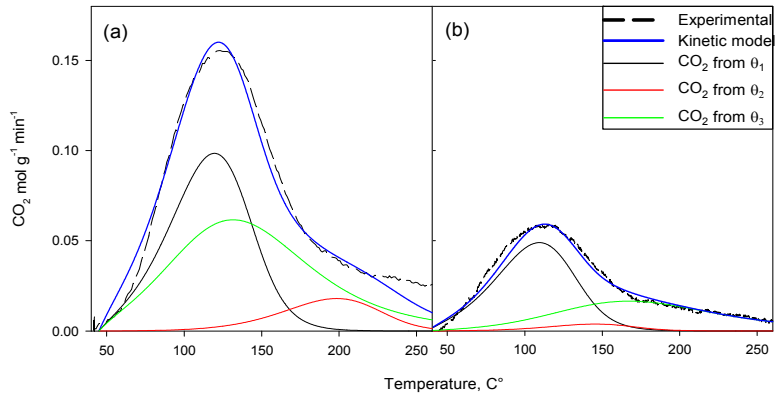

Fig. 1. CO_2-TPD profiles over CuCe-I (a) and CuCe-S (b) catalysts. Overall experimental and model profiles, CO_2 desorbed from each site as obtained by the model.

Both conversion and selectivity (not reported) are in agreement with the results of KM-TPD which well explain the different performances of the catalysts investigated in this work. In particular, the relative amount and the temperature range of sites assigned to CO and H_2 oxidation account for the activity and the selectivity found in the CO-PROX tests.

4 Conclusions

A technique based on the coupling between modelling and experiments of temperature programmed desorption of CO_2 is applied to determine the sites distribution of copper ceria catalysts prepared by different techniques and with different CuO load. The qualitative and quantitative evaluation of sites active for CO and H_2 oxidation very well agrees with the catalytic performance in CO-PROX of catalysts suggesting that this technique may be useful for kinetic study.

Photocatalytic Activity of Al-Doped TiO_2

Murzin P.D.[1*], Murashkina A.A.[2], Rudakova A.V.[1], Emeline A.V.[1], Ryabchuk V.K.[2], Tsyganenko A.A.[2], Bulanin K.M.[1]

Keywords: photoactivity, doped TiO_2, phenol, decomposition, characterization

1 Introduction

Titanium dioxide is a well-known material widely used for a variety of purposes as a photocatalyst [1]. In order to improve the photocatalytic activity of titania doping and co-doping by metallic and non-metallic impurities are used [2].

Activity enhancement of titania by aluminum addition has been poorly studied, and the results obtained by different authors are rather inconsistent. [3]

It has been shown [4] that the optimal metal dopant concentration for a photocatalyst of a given particle size varies from 0.01 at% to 1 at% independently on the metal dopant nature.

In the present work a series of Al-doped titanium dioxide samples synthesized by sol- gel method was studied.

2 Experimental/methodology

Seven samples with different aluminum content (0, 0.1%, 0.3%, 0.5%, 0.7%, 0.9% and 1.1%) were prepared. Photocatalytic activity was evaluated by the decomposition of phenol under irradiation by Xe lamp in aqueous suspension. Phenol concentration was determined by means of high-performance liquid chromatography.

Surface characterization was carried out by SEM, Raman spectroscopy, X-ray phase analysis, FTIR spectroscopy of adsorbed CO, specific surface area was measured by BET method.

3 Results and discussion

Figure 1 shows the dependence of initial phenol decomposition rate for the samples on the weight percentage of aluminum dopant. The dependence manifests a maximum at 0,5% of Al content.

The well-known decrease of particle size and increase of specific surface area of Al-doped samples from ~ 800 nm up to 50 nm and from 1.7 m^2/g up to 28 m^2/g, respectively, have been observed. The growth of dopant concentration leads to higher uniformity of grains, *i.e.* lower degree of aggregation.

No significant correlation between activity and selectivity (towards formation of phenol products such as hydrochinon and catechol) has been found.

These facts lead us to the conclusion that different types of active centers account for the activity enhancement with the increase of dopant concentration. The highest activity seems to be due to the optimal balance between particle size and aluminum concentration. Some of such active sites can be associated with the coordinately unsaturated Ti^{4+} or Al^{3+} cations detected by FTIR spectra of adsorbed CO.

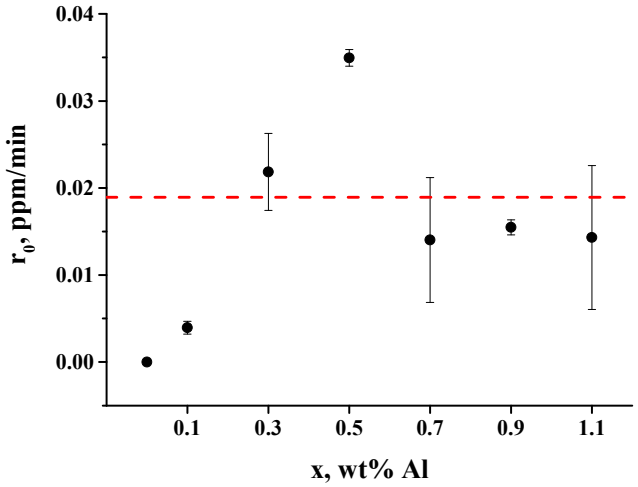

Fig. 1. The dependence of initial rate of phenol photodegradation reaction (r_o) for the x-Al-TiO_2 samples on the weight percentage of aluminum dopant (x). Dashed line marks the value of initial rate of phenol photodegradation for commercial TiO_2 Degussa P25.

Regardless to the mechanism of aluminum dopant effect on photocatalytic activity of titania, the results obtained let one to consider that the inconsistence results of different authors on the properties of Al-doped titania, might be caused by various balance between particle size and aluminum concentration.

4 Conclusions

The study of photocatalytic activity of Al doped TiO_2 sensitized by sol-gel method shows the existence of a maximum in the dependence of phenol degradation initial rate on aluminum dopant concentration near 0.5 %.

Aluminum doping seems to be a promising way to improve the quality of titania based photocatalysts.

Keywords: pyrolytic graphite, epitaxial graphene, atomic hydrogen, intercalation (without catalysts), surface graphene nanoblisters, thermal-elastic thermodynamic equilibrium

1 Introduction

There is a number of recent data on the surface nanoblister formation in highly oriented pyrolytic graphite (HOPG, Fig. 1) and epitaxial graphene (Fig. 2) under hydrogenation in atomic gaseous hydrogen (without catalysts). The process physics has been yet not enough studied.

2 Experimental/methodology

The thermodynamic analysis [1-3] of some recent experimental data (Fig. 1) has been done.

3 Results and discussion

Figure 1 shows the results of hydrogenation (**at 300 K and P(Hgas) ≈ 0.1 mPa, without any catalyst**) of surface layers of HOPG samples.

Similar STM, AFM and other data of different researchers for the epitaxial graphenes (Figure 2) have been also analyzed in [1-3] (the "open access" Journals).

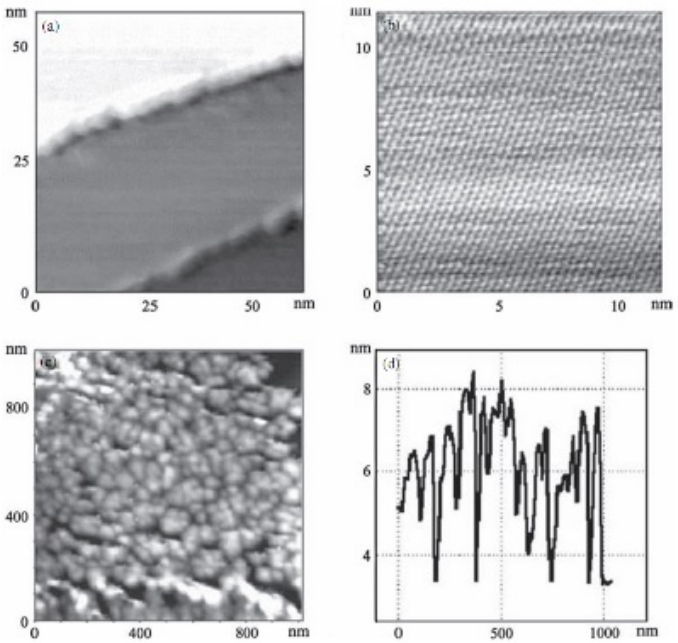

Fig. 1. STM and AFM data {Waqar (2007)} showing the hydrogen accumulation (intercalation) in HOPG with forming blister-like surface nanostructures; hydrogenation was done at 300 K and P(Hgas) ≈ 0.1 mPa, without any catalyst. The pressure of the molecular gaseous hydrogen (H2), "captured" inside the surface graphene nanoblisters, is of P(H2gas) ≈ 100 MPa); the compression effect is of 12 orders (from 0.1 mPa to 100 MPa), at the expense of the energy of association of hydrogen atoms to molecules "captured" inside the graphene nanoblisters (the quantitative interpretation) [1-3].

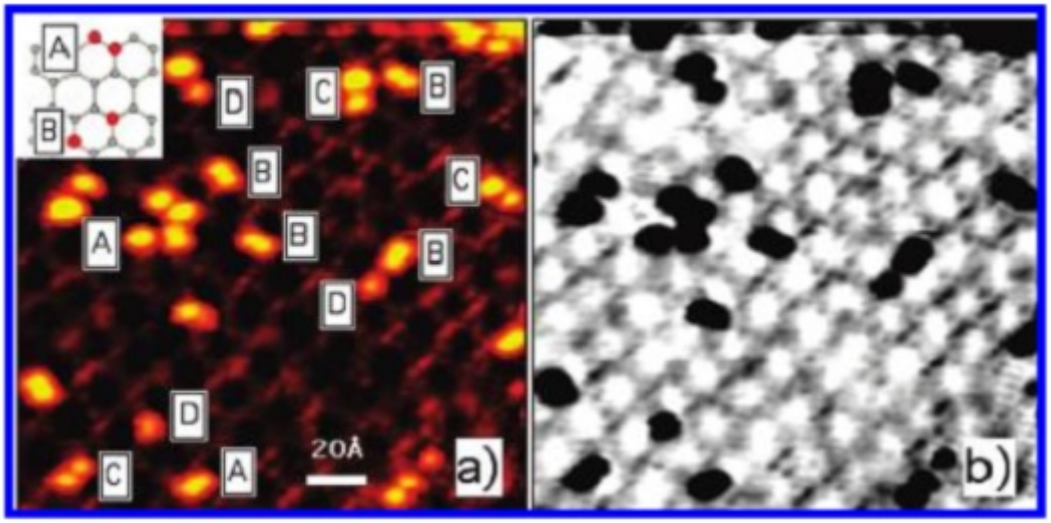

Fig. 2. (a) STM image of hydrogenated graphene/SiC {Balog et al. (2009)}. (b) Same image as in (a) with inverted color scheme, giving emphasis to preferential hydrogen adsorption on the SiC surface. Hydrogen dose at T(beam) = 1600 K, t = 5 s, F = 1012 – 1013 atoms/cm2s (P(Hgas) ≈ 0.1 mPa).

The very recent experimental data {Geim et al. (2014)} show that a hydrogen atom can not pass through a perfect graphene network. The analysis [1-3] of a number of experimental data (Figs. 1, 2) show that a hydrogen atom can pass through permeable defects in graphene, i.e. grain boundaries, their triple junctions and/or others.

4 Conclusions

The "thermodynamic forces" and energetics of forming of graphene nanoblisters (under atomic hydrogen treatment, without catalysts) in the surface HOPG layers (Fig. 1) and epitaxial graphenes (Fig. 2) have been quantitatively described, particularly, the conditions of the thermal-elastic thermodynamic equilibrium [1-3]. The physics of intercalation of H2 gaseous nanophase of a high density into graphene nanoblisters have been revealed [1-3]. It can be used for solving of the very current problem of the hydrogen on-board efficient and safety storage.

Keywords: graphite nanofibers, hydrogenation, solid hydrogen, intercalation, storage, spillover effect

1 Introduction

The spillover effect manifestation in hydrogenated carbon-based nanomaterials has been not enough studied up to nowadays, particularly, relevance for solving the current problem of the hydrogen on-board efficient storage.

2 Experimental/methodology

The thermodynamic analysis [1-3] of the related experimental data (Figs. 1, 2) has been done.

3 Results and discussion

Figure 1 shows the two steps ((a) and (b)) of hydrogenation (**at 300 K and $P_{(Hgas)}$ ≈ 0.1 mPa, without any catalyst**) of surface layers of a high oriented pyrolytic graphite (HOPG).

Similar STM, AFM and other data of different researchers for the epitaxial graphenes have been also analyzed in [1-3].

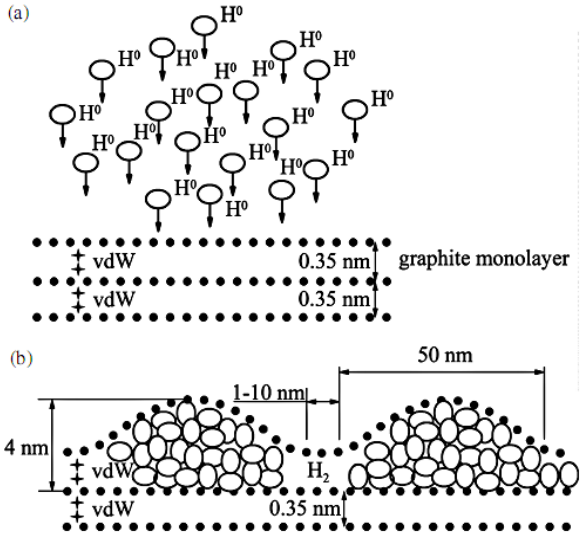

Fig. 1. Model {Waqar (2007) from STM and AFM data} showing the hydrogen accumulation (intercalation) in HOPG with forming blister-like surface nanostructures; **hydrogenation** was done **at 300 K and $P_{(Hgas)}$ ≈ 0.1 mPa, without any catalyst**. (a) Pre-atomic hydrogen (**$P_{(Hgas)}$ ≈ 0.1 mPa**) intercalation step. (b) Molecular gaseous hydrogen (H2), "captured" inside the surface graphene nanoblisters (**$P_{(H2gas)}$ ≈ 100 MPa**), after the intercalation step. Sizes are not drawn exactly in scale. **The compression effect is of 12 orders (from 0.1mPa to 100 MPa), at the expense of the energy of association of hydrogen atoms to molecules "captured" inside the graphene nanoblisters.**

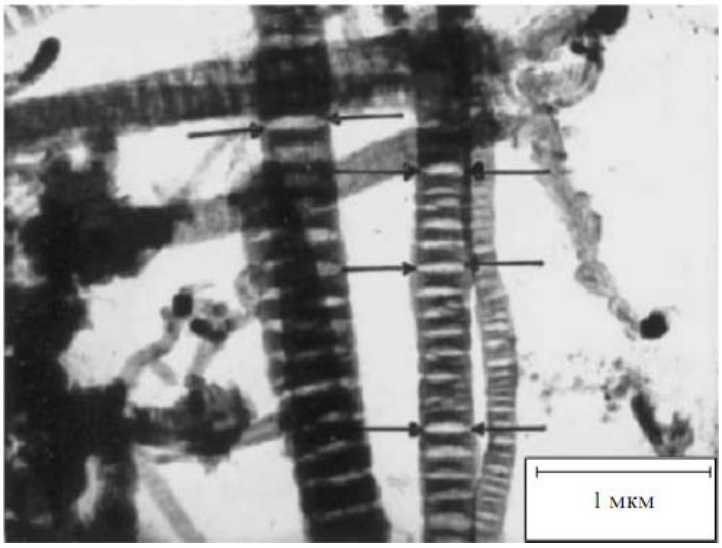

Fig. 2. Micrographs {Gupta et al. (2004)} of hydrogenated graphite nanofibers (**at 300 K and $P_{(H2gas)}$ ≈ 8 MPa,** with **Pd-catalyst**) after release from them (at 300 K, for 10 min {Park et al. (1999)} of intercalated high-density hydrogen (17 mass. % - the gravimetrical reversible hydrogen capacity). The arrows in the picture indicate some of the slit-like closed nanopores of **the lens shape**, where the **intercalated molecular solid hydrogen** nanophase (under pressure of **50 GPa**) was localized [1-3].

4 Conclusions

In the light of analysis [1-3], the spillover effect is obviously manifested in data {Gupta et al. (2004)} (Figure 2) and data {Park et al. (1999)}.

Keywords: sol-gel method, titania, silica, n-heptane, transformation, hollow, sphere catalysts, microtomography, UV-Vis DRS

1 Introduction

The preparation technique of new composite catalytic materials in the form of hollow spheres was developed. TiO_2-SiO_2 composites were modified by nickel and cobalt. After annealing, the spatial structure of sphere samples was studied by X-ray microtomography on a digital 3D microtomograph. The state of the cations of transition elements and titanium was characterized by UV-Vis DR spectroscopy. The catalysts were tested in the oxidation of n-heptane.

2 Experimental/methodology

A spherical material with the composition of TiO_2-SiO_2-M_xO_y, where M is Co (TSC-1 sample) and Ni (TSN-1 sample), obtained by sol-gel method, was used as a catalyst. Before testing, the catalyst was annealed at 400°C in air. The samples after annealing were named as tTSC-1 (with cobalt) and tTSN-1 (with nickel). The catalytic properties were studied in the model oxidation reaction of n-heptane oxidation. The flow set-up with a quartz tube reactor (the inner diameter of 4 mm) was used. The reactor was charged with 0.2 g of catalyst, the diameter of the catalyst spheres was 0.2-0.5 mm. The mixture containing 0.8% n-heptane in air was passed through the catalyst. The ratio of n-heptane to oxygen in the feed gas was 1/25. Feed space velocity was 4.5 L/h. The reaction temperature was varied from 110°C to 600ºC. Product analysis was performed on a Shimadzu FTIR-8300 spectrometer.

3 Results and discussion

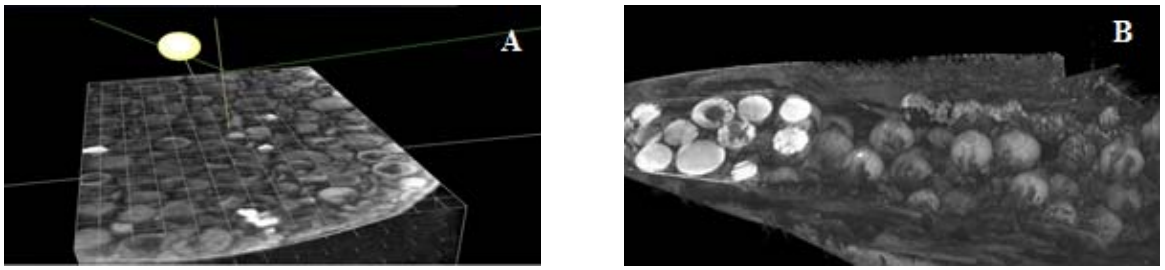

Fig. 1. Cross-sections of tTSC-1 (A) and tTSN-1 (B) sphere catalysts obtained by computer microtomography.

After annealing, the material represent a hollow spheres of a layered structure with the inner part of d-metal oxides coated by the layer with a composition of 70 mol.% Ti_xO_y + 30 mol.% Si_xO_y. Fig. 1 shows the examples of the cross-section of computer microtomography of tTSC-1 and tTSN-1 samples. Two structures are visually distinguished for tTSC-1 sample (Fig. 1-A): a dark color refers to the air-filled cavity of sphere, a lighter color refers to a complex oxide

framework with a composition of Ti_xO_y-Si_xO_y. Fig. 1-B shows that the inner part of tTSN-1 sample for the most part of spheres is filled, although there are individual hollow particles.

The UV-Vis spectra of both samples contain a band gap in the region of 28 000-32 000 cm^{-1} characteristic for TiO_2. The spectra of the samples in the visible region are characterized by absorption bands due to *d-d*-transitions of Co^{2+} and Ni^{2+} cations. The band at about 15 000 cm^{-1} for tTSC-1 sample refers to the Co^{2+} cations in tetrahedral oxygen coordination and, probably, corresponds to Co_3O_4 phase. The absorption band at about 14 000 cm^{-1} for tTSN-1 sample corresponds to Ni^{2+} cations in octahedral oxygen coordination in the state, probably, close to NiO.

Fig. 2 shows that the oxidation reaction for tTSC-1 sample starts at 250°C. The process goes predominantly in the direction of deep oxidation. Attention is drawn to the increase in the selectivity of olefins formation on this sample as the temperature rises above 500°C. The oxidation over tTSN-1 sample starts at 400°C, and the partial oxidation is observed at 400-450°C. The selectivity towards the partial oxidation products reaches 63% (the absorption bands used for products identification are given in Table 1). A deep destructive oxidation of n-heptane starts at temperatures above 550°C. The maximum conversion of heptane at 600°C over tTSC-1 sample is 80%. For tTSN-1 sample, the n-heptane conversion does not exceed 50%. For both samples, the cracking products (in particular, methane) are detected at temperatures above 500°C.

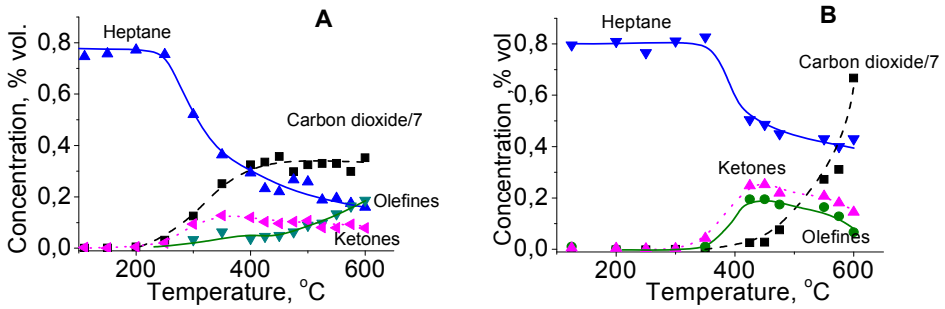

Fig. 2. Temperature dependences of n-heptane concentration over tTSC-1 (A) and tTSN-1 (B) samples.

Table 1. Characteristic IR absorption bands for products identification.

Wavenumber, cm^{-1}	Structural fragments	Vibration modes
3016	Methane	νCH stretching
1745	Ketones	νC=O stretching in ketones
1100, broad	alcohol ethers	νC-O-C stretching in complex ethers
945	HRC=CR'H	δC=CH bending, nonplanar

4 Conclusions

The technique of preparation of new composite catalytic materials in the form of hollow spheres was developed. The resulting catalysts were characterized by physical methods and tested in the oxidation of n-heptane. It was found that besides the destructive oxidation, the oxidative dehydrogenation of n-heptane and formation of partial oxidation products such as ketones and esters took place.

Keywords: gold, oxidative coupling, partial oxidation, acetaldehyde, methyl, acetate

1 Introduction

Gold has been considered as a relatively inactive metal in catalysis for a long time. However, pioneering studies in the last few decades demonstrated the unusual catalytic properties of the gold nanoparticles in oxidation reactions [1,2]. Furthermore, structurally-tuned heterogeneous gold catalysts demonstrate high selectivity in partial oxidation reactions [3]. In order to optimize the performance of these uniquely active and unusually selective catalytic materials, mechanisms of the catalytic reactions on the gold surfaces need to be understood at the molecular level. Selective oxidation and oxidative coupling reactions of alcohols and aldehydes result in the production of commercially valuable partial oxidation products such as esters which are of high demand by the chemical industry. In the current work, partial oxidation reaction of acetaldehyde on the Au(111) model catalyst surface is investigated and the formation of acetic acid and methyl acetate which can be formed due to C-C bond activation is demonstrated.

2 Experimental/methodology

Experiments were performed in a custom-made ultra-high vacuum (UHV) chamber which is equipped with X-ray Photoemission Spectroscopy (XPS), Low Energy Electron Diffraction (LEED), Infrared Reflection Absorption Spectroscopy (IRAS) and Temperature Programmed Desorption (TPD)/ Temperature Programmed Reaction Spectroscopy (TPRS) capabilities. Atomic oxygen on the Au(111) model catalyst surface was formed by ozone decomposition.

3 Results and discussion

Figure 1 shows TPRS results of acetaldehyde on the oxygen pre-covered Au(111) surface. In the current experiment, 0.004 L (Langmuir) of O_3 was initially dosed onto the clean Au(111) surface at 140 K followed by 0.4 L acetaldehyde exposure at 90 K. Desorption channels for anticipated products (i.e. m/z = 18, 28, 29, 32, 43, 44, 45 and 59) were simultaneously monitored during the temperature-programmed reaction. In the figure, desorption peaks at 141 K in the m/z = 28, 29, 43, and 44 channels are associated with the chemisorbed acetaldehyde. This assignment is in agreement with acetaldehyde desorption from the clean (oxygen-free) Au(111) surface. Desorption features located at 171 K in the figure, particularly for the m/z= 29, 43 and 59 desorption channels can be predominantly assigned to methyl acetate (MA), the oxidative coupling product. Desorption temperature and fragmentation pattern of MA were also confirmed by temperature programmed desorption (TPD) spectrum of chemisorbed MA on the clean Au(111) surface. In order to form MA, C-C bond in acetaldehyde molecule must be broken and the formation of MA demonstrates that oxygen pre-covered Au(111) surface activates C-C bond. On the other hand, desorption signals appearing at 226 K in m/z = 29, 43, 44, 45 channels indicate acetic acid desorption. Intensive desorption signals appearing at higher temperatures are attributed to decomposition of polymerization products of acetaldehyde.

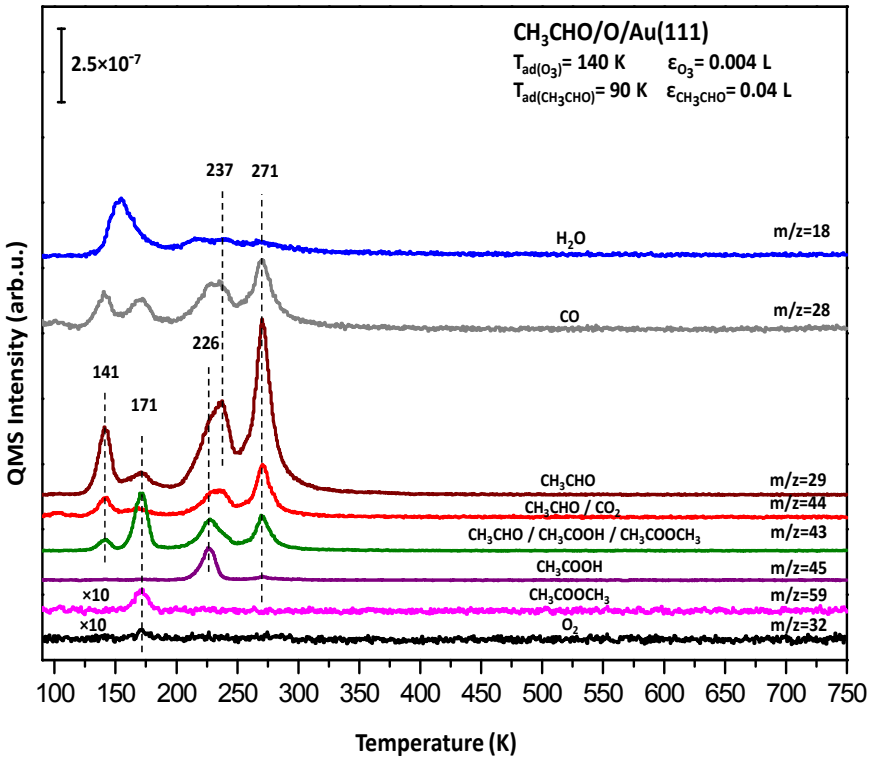

Fig. 1. TPRS profiles for the selected desorption channels obtained after 0.004 L ozone exposure on the clean Au(111) model catalyst surface at 140 K followed by 0.04 L acetaldehyde exposure at 90 K.

4 Conclusions

In the current work, partial oxidation of acetaldehyde on the oxygen pre-covered Au(111) model catalyst surface is investigated. We show that for low oxygen coverages, two different partial oxidation products namely, methyl acetate and acetic acid can be generated without the formation of significant quantities of carbon dioxide. Since the formation of methyl acetate implies C-C bond cleavage; the experimental detection of methyl acetate among the products of acetaldehyde oxidation demonstrates that oxygen pre-covered Au(111) model catalyst surface can activate C-C bonds.

Commercial Experience of Operating FCC Unit with Low Catalyst-To-Feed Ratio and the Reduced REO Content in the Catalysts

Levinbuk M.I.[1,2*], Maksimov I.S.[2]

1 - A.V. Topchiev Institute of Petrochemical Synthesis RAS, Moscow, Russia

Keywords: FCC, catalyst-to-feed ratio, rare earth oxides, microspherical, catalysts, feed, conversion

1 Introduction

FCC units operated worldwide differ by the quality of feed, feed space velocity, catalyst-to-feed mass ratio and contact time. Significant increase of capital investments is defined by the material changes in these parameters. Therefore, when increasing the unit capacity, one needs to select an individual catalysts type for every existing FCC unit, which provides the required product yields and quality of the target products.

2 Experimental/methodology

The constructional features of the Unit provide the optimal yield of gasoline when using traditional catalysts with reduced capacity compared to its design value.

During the period from 2000 to 2011 the average daily load of the Unit was gradually increased by approximately 20 %. Special selection of cracking catalysts have maintained a high gasoline yield 54.0 wt% as well as high yields of olefins C_3 (5.5 wt%) and C_4 (7.0 wt%), while the catalyst-to-feed ratio was steadily reduced to 4.6 without an extensive modernization of the existing Unit equipment.

In the period from 2000 to 2011 the zeolite surface area of equilibrium cracking catalysts was increased from 60 to 114 m^2/g, and at the same time REO content was decreased from 1.50 to 0.97 wt%.

The refiner operating the Unit has developed plans to increase the processing depth. The planned reconstruction of the crude oil distillation units will increase the production of vacuum gas oil. Therefore the designed Unit capacity will be increased by 20 %.

A group of specialists with BASF support has conducted the research aimed at the selection of catalysts that can be operated at a new value of catalyst-to-feed ratio. Having taken into account the long experience in this field, a new catalyst composition was proposed.

Some catalyst samples were synthesized for testing. The zeolite surface area of tested samples was 134 m^2/g, and REO content was 0.78 wt%. The activity of the samples was determined on an ACE unit (Advanced Cracking Evaluation unit) at the conditions typical for commercial FCC units.

3 Results and discussion

The experimental results obtained on the industrial catalyst used in 2011 together with the two synthesized catalyst samples are presented in Fig. 1,2. Using the trends shown in Fig. 1 it is possible to choose a cracking catalyst which allows not only to maintain but also to increase the gasoline yield, at decreased catalyst-to-feed ratios. Similar trends for the feed conversion are shown in Fig. 2.

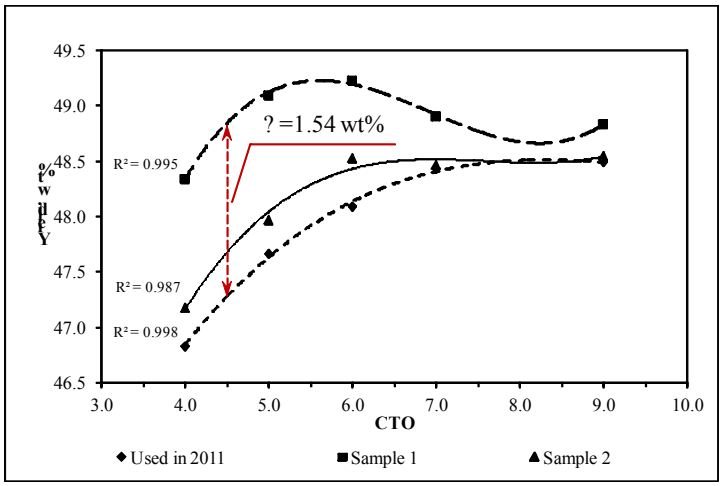

Fig. 1. Gasoline yields for analyzed samples on ACE unit

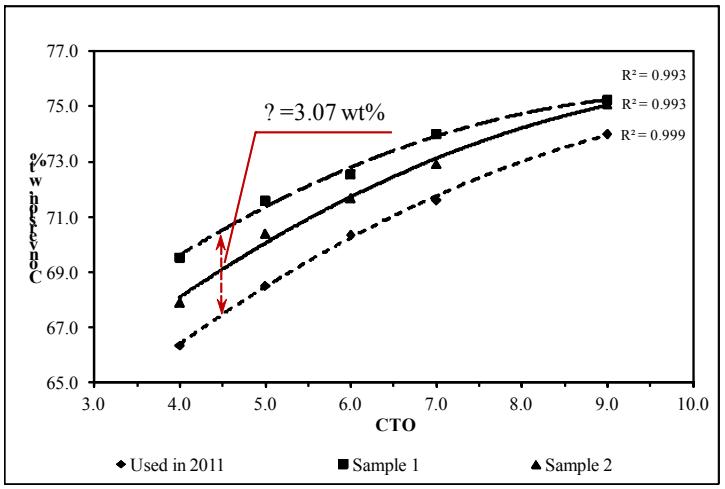

Fig. 2. Conversion change for analyzed samples on ACE unit

4 Conclusions

Enhancement of the FCC Unit capacity led to the development of catalysts with reduced REO content and increased quantity or quality (modulus) of zeolite component in the sample for the purpose of maintaining constant basic product yields at low catalyst-to-feed ratio without considerable reconstruction of the Unit equipment.

Decrease the REO content could be balanced by the increased zeolite content in the catalyst. Therefore, the stability of active zeolite as well as zeolite matrix durability start to play a dominating role.

When choosing a catalytic cracking catalyst, it is crucial to consider the catalyst-to-feed ratio, conditioned by the design of the FCC unit. By defining the interrelation of catalyst-to-feed ratio and catalyst properties the use of existing equipment can be effectively maximized.

For the development of FCC catalysts without REO it is necessary to carry out a set of studies on special modification of Y zeolite.

Keywords: palladium nanoparticles, phosphonium ionic liquids, stabilization, Suzuki reaction

1 Introduction

Palladium nanoparticles (PdNPs) stabilized by ionic liquids (ILs) have been successfully used in catalysis [1, 2]. Among the myriads of ILs the phosphonium salts especially sterically hindered ones have been less studied.

Catalytic activity of PdNPs depends on their size as well as on their environment in the solution. The interactions between nanoparticle and stabilizer molecules are important for understanding the mechanism of the nanoparticle stabilization. Varying structure (nature) of stabilizer we can influence on type of stabilization and as a consequence on catalysis efficiency.

2 Experimental

A series of sterically hindered phosphonium ionic liquids (PILs) with different length of alkyl chain was synthesized according to the previously reported technique [3]. The structure of obtained phosphonium salts was proved by X-Ray analysis (Fig. 1). There was found that alkyl chain elongation leads to the ordering of the PIL packing.

PdNPs were obtained *in situ* by stirring palladium acetate in ethanol in PIL presence without any additional reducing agents.

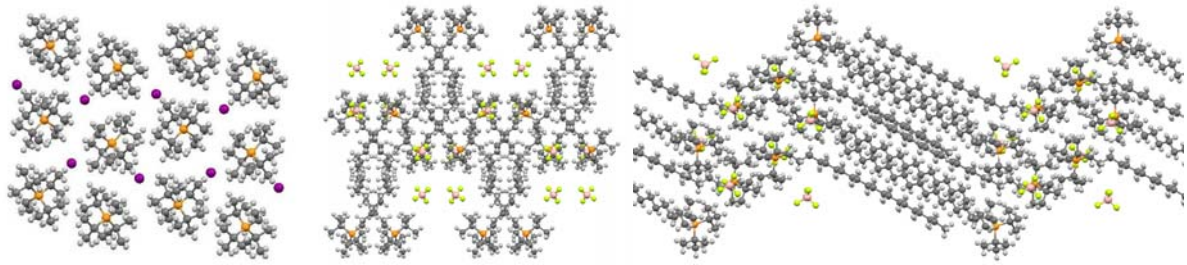

Fig. 1. Crystal packing of PILs.

Suzuki cross-coupling of 1,3,5-tribromobenzene and phenylboronic acid (Fig. 2) was chosen as a model reaction. Sterically hindered PILs allow carrying out the coupling reaction in mild conditions.

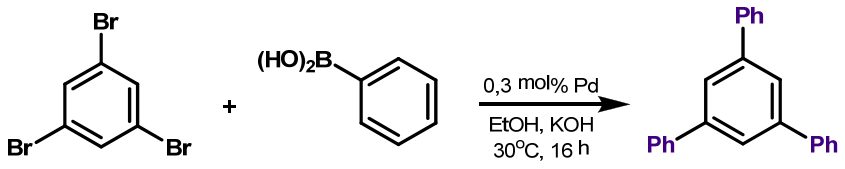

Fig. 2. Suzuki cross-coupling reaction.

3 Results and discussion

We have found that varying the length of the linear alkyl substituent of the sterically hindered phosphonium salt allows tuning catalytic activity of PdNPs. The structure and supramolecular organization of PIL determine its behaviour in solution and the efficiency of the catalytic composition.

PILs contained short linear alkyl substituents provide predominantly electrostatic stabilization of PdNPs, PILs with long alkyl chains – steric stabilization. Catalytic system on both of them demonstrate low activity that can be explained by high stability of formed PdNPs. Phosphonium salts contained medium length linear alkyl chains realize the balance between electrostatic and steric types of stabilization that favours the best combination of stability and activity of PdNPs.

4 Conclusions

Sterically hindered PIL contained alkyl chain of medium length allow to reach optimal combination of stability and activity of formed PdNPs. Achieved balance between electrostatic and steric types of nanoparticle stabilization is necessary condition for the effective catalysis.

Keywords: ultrasonic spray pyrolysis, catalyst preparation, CNF

1 Introduction

At present, carbon nanomarerials (carbon nanotubes and nanofibers) are of great value due to its exceptional properties. Most commonly they are characterized via chemical resistance, mechanical strength, large surface area and high aspect ratio. Carbon nanofibers (CNF) are known to be successfully applied as modifying agents in diverse composites and materials.

Chemical vapour deposition (CVD) of hydrocarbons is widely used for CNF synthesis. The process is implemented on dispersed particles of the iron subgroup metals (Fe, Co, Ni) and their alloys with other elements. There are different techniques for catalyst preparation such as mechanochemical activation of metal oxides, co-precipitation of precursor salts, and impregnation of supports. Unfortunately, all listed methods are known to have the certain drawbacks concerning ecological and environmental aspects as well as difficulties in obtaining active particles with controllable size and distributions. From the other hand, all issues mentioned should be addressed when developing technology for scaled-up synthesis of CNF.

From this point of view, one of the most interesting and prospective approaches is related to using an ultrasonic spray pyrolysis (USP) of precursor solutions. USP offers a great flexibility in a continuous flow process for the synthesis of novel materials on large scale. Additionally, the controllable size and composition of active particles along with high purity grade should be noted as advantages of this preparation method [1]. Usually the process involves the following procedures: atomization of precursor solution (suspension) by ultrasonic nebulizer; drying of sprayed droplets in a preheated chamber; collection of formed particulate matter by a cyclone, filter bag or electric field precipitator [2].

2 Experimental/methodology

A series of Ni-Cu-Mg-O catalysts have been prepared using ultrasonic spray pyrolysis. A piezoelectric element (1.7 MHz, 30 W) of a domestic humidifier was used as an ultrasonic generator. More detailed description of the experimental setup is given in [3]. The precursor aqueous solution contained the dissolved nitrates of nickel, copper, and magnesium. The total concentration of salts was varied in the range of 0.1–5 wt.%. The aerosol particles were transferred by the air flow to the furnace preheated to 250°C. The fast drying of micron droplets of the solution in the furnace resulted in the formation of very fine particles (including those of submicron size); the particles were trapped using a domestic electric precipitator.

The USP-prepared samples were heated at 550°C; the treatment resulted in decomposition of nitrates and formation of the corresponding oxides. Two different heating procedures were used: (1) the sample was placed in a muffle and treated at 550°C for 30 min; (2) the sample was heated from room temperature to 550°C at a rate of 5°C/min. All prepared catalysts were tested in the synthesis of CNFs by propane decomposition at 700°C. Catalyst samples and synthesized CNF material were analyzed by scanning electron microscopy (JSM-6460). The morphology of the carbon product was examined by TEM using a JEM 1400 instrument, Jeol (Japan).

3 Results and discussion

Results of the performed studies are schematically presented in Fig. 1. It can be seen that the concentration of salts in precursor solution plays a defining effect on formation of spherical particles of the catalyst being synthesized. At the minimum concentration of solution (0.1%) the smallest (> 1 μm) dense spherical particles with rather narrow size distribution were formed. The increase in a concentration leads to enlargement of particle diameter accompanied with widening of the size distribution. One more important factor to be mentioned is related to a heat treatment conditions. Heating of samples in mild conditions with slow T-ramping rate makes it possible to preserve spherical shape and initial dispersion of particles upon decomposition of nitrates into mixed oxides. On the contrary, rapid elevation of calcination temperature results in considerable sintering of spheres into fused porous system. Treatment regime was found to affect the morphology and texture of synthesized CNFs. Thus, USP sample prepared from low-percentage solution catalyzes the growth of carbon fibers of close diameter with preferable feather-like morphology. Other USP catalysts encouraged the formation of carbon fibers in wider range of diameters with a decreased morphological purity.

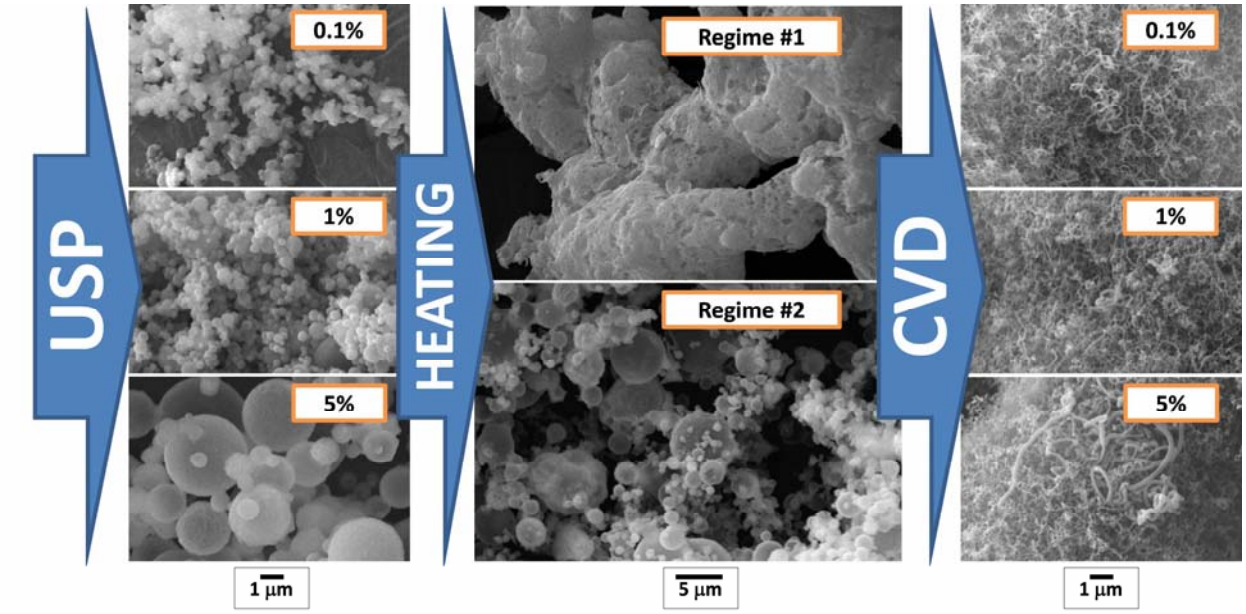

Fig.1. Principle scheme for USP catalyst preparation and CNF synthesis.

4 Conclusions

An alternative method of catalyst preparation for synthesis of carbon nanofibres was proposed on the basis of ultrasonic spray pyrolysis. The simplicity of setup installation along with easy control of particle size of synthesized catalysts makes such method very attractive. The regime of the heat treatment was found to have a significant effect on particle size distributions and, ultimately, upon the textural and morphologic features of CNF.

This study was supported by Russian Academy of Sciences (project № V.45.3.5).

Keywords: low-temperature CO oxidation, coprecipitation, palladium ceria, tin, oxide

1 Introduction

At present, palladium-ceria based catalysts are widely used for many catalytic processes, including neutralization of industrial harmful gases and exhaust gases of vehicles. Among these gases one of the most toxic is carbon monoxide, which is necessary to neutralize in a wide temperature range – from room temperature up to 1000 °C. These conditions increase the requirements for thermal stability of CO oxidation catalysts. In this work we present physico-chemical study of Pd-ceria catalysts modified by tin which are capable to be active in CO oxidation at 0 °C after the calcination procedure at 1000 °C.

2 Experimental/methodology

The synthesis of Pd/CeO_2 catalysts was performed by coprecipitation of Pd and Ce nitrates by NaOH, while catalysts Pd/CeO_2-SnO_2 were prepared by oncoming precipitation using precursors $(NH_4)_2[Ce(NO_3)_6]$ and $Pd(NO_3)_2$ (acidic solution) with $Na_2[Sn(OH)_6]$ (alkaline solution). After the precipitation the samples were dried and calcined in air in a wide temperature range (at 450 - 1000 °C).

A complex of physical methods (HRTEM, XRD, XPS, Raman spectroscopy) was used to establish the microstructure, composition and electronic state of components in the prepared catalysts after their calcination or after their treatment in the reaction media. The catalytic properties of the samples were examined by temperature programmed reaction in $CO+O_2$ (TPR-$CO+O_2$ or light-off method) and in CO (TPR-CO) using plug flow reactor with mass-spectrometric analysis of the gas mixture.

3 Results and discussion

The coprecipitation synthesis with subsequent calcination at high temperatures was shown to give the formation of two palladium states: PdO nanoparticles ($E_b(Pd3d_{5/2})$ = 336.5 eV) and Pd^{2+} ionic state in the form of $Pd_xCe_{1-x}O_{2-\delta}$ solid solution ($E_b(Pd3d_{5/2})$ = 338.0 eV) [1]. The ratio between PdO and $Pd_xCe_{1-x}O_{2-\delta}$ phases depends on the calcination temperature due to their strong interaction and dissolution of PdO nanoparticles inside ceria lattice. Also, TPR-CO showed the formation of low-temperature high reactive oxygen state, which was attributed to the surface compounds of palladium and ceria PdO_x(s)/Pd–O–Ce(s) characterized by $E_b(Pd3d_{5/2})$ = 336.1 eV. High catalytic activity is provided by highly dispersive palladium states, which are not stable at T> 800-900°C, turning into Pd°, PdO and CeO_2 nanoparticles.

Introduction of tin into the catalysts structure led to enhancement of the catalytic properties after thermal activation at 900-1000 °C as it can be seen from Fig. 1 (a) comparing Pd/CeO_2 and

Pd/CeO_2-SnO_2 catalysts activity. Investigation of the Pd/CeO_2-SnO_2 samples showed that the high reaction rate correlates with the presence of highly dispersive palladium states in these catalysts attributed to surface palladium compounds and ionic palladium in the composition of $Pd_xCe_{1-x-y}Sn_yO_{2-x-\delta}$ solid solution, respectively. The higher thermal stability of such palladium states was explained by increasing the stability of the defective structure of the support. TEM investigations showed existence of smaller support particles in modified catalysts owing to formation of a microdomain structure representing a fluorite phase particles ($Ce(Sn)O_2$) stabilized on the surface of $Sn(Ce)O_2$ particles with rutile structure (Fig. 1 b-c).

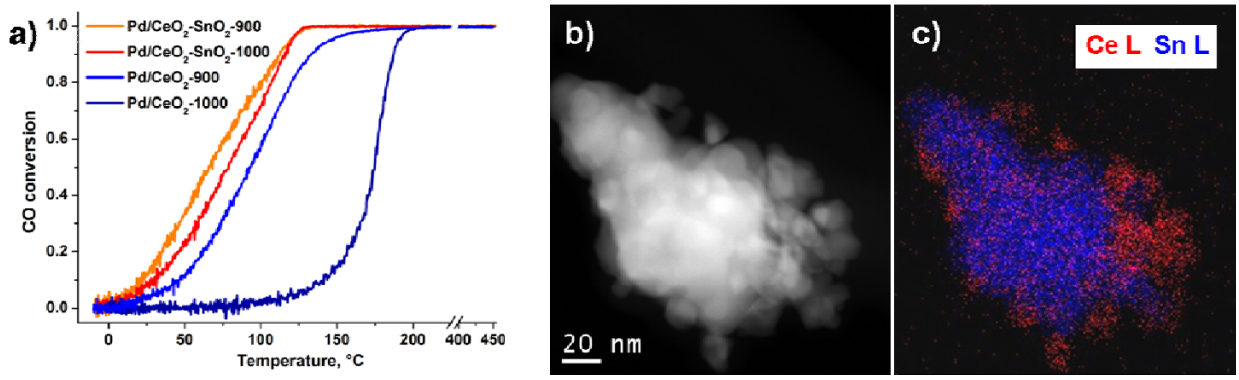

Fig. 1. (a) Temperature dependences of CO conversion of Pd/CeO_2 and Pd/CeO_2-SnO_2 (Sn/Ce = 50:50) catalysts calcined at 900 and 1000 °C; (b-c) HAADF-STEM image and corresponding EDX-mapping pattern (CeL signal is shown in red, SnL signal is shown in blue) of the Pd/CeO_2-SnO_2-900 catalyst.

XPS investigation allowed us to establish that in the case of Pd/CeO_2-SnO_2 catalyst the thermal activation effect was related to segregation of Pd^{2+} ions to the subsurface layers of fluorite phase providing formation of surface species PdO_x(s)/Pd–O–Ce(s). Discussing mechanism of low-temperature CO oxidation, the coincidence of activation energies in CO oxidation for both catalysts suggests the same nature of the active sites and the reaction mechanism. Thus, the Pd-ceria surface species PdO_x(s)/Pd–O–Ce(s) are believed to determine CO oxidation rate in low-temperature region.

4 Conclusions

Using the procedure of oncoming precipitation the Pd/CeO_2-SnO_2 catalysts for low temperature CO oxidation were synthesized for the first time. These catalysts are characterized by high activity with unusually high thermal stability at temperatures up to 1000 °C. Formation of microdomain structure is shown to provide high thermal stability of catalytically active phases including the surface PdO_x(s)/Pd–O–Ce(s) species which determine the reaction rate.

Application of the Nanopowders of Ni, Co and their Alloy Prepared by a Method of Plasma-Mechanochemistry for the Reaction of the Carbon Dioxide Conversion of Methane

Tavadyan L.A.[1], Grigoryan R.R.[1], Arsentev S.D.[1*], Aloyan S.G.[2]

1 - Institute of Chemical Physics, Academy of Sciences of Armenia, Yerevan, Armenia
2 - Institute of General and Inorganic Chemistry, Academy of Sciences of Armenia, Yerevan, Armenia

Keywords: catalysis, nanopowder, mechanochemistry, methane

1 Introduction

Because of their small sizes, nanopowders show a number of unique properties, which are of interest for researchers in various areas of modern science [1, 2], particularly, in the development of active and stable catalysts for the process of the carbon dioxide conversion of methane (CDCM) [3, 4]:

$$CH_4 + CO_2 = 2H_2 + 2CO \ (\Delta H° = 247 \text{ kJ/mol}).$$

The product of CDCM is synthesis gas, which serves as a raw material for the production of valuable organic compounds and motor fuels. Furthermore, CDCM can be an effective method for the utilization of methane and carbon dioxide, which produce the greenhouse effect [5, 6].

2 Experimental

Fig. 1 shows the reaction module designed for the synthesis of nanomaterials. It consisted of two cylindrical mechanoreactors (*1*, *2*) with an inside diameter of 50 mm and a length of 100 mm made of corrosion resistant steel.

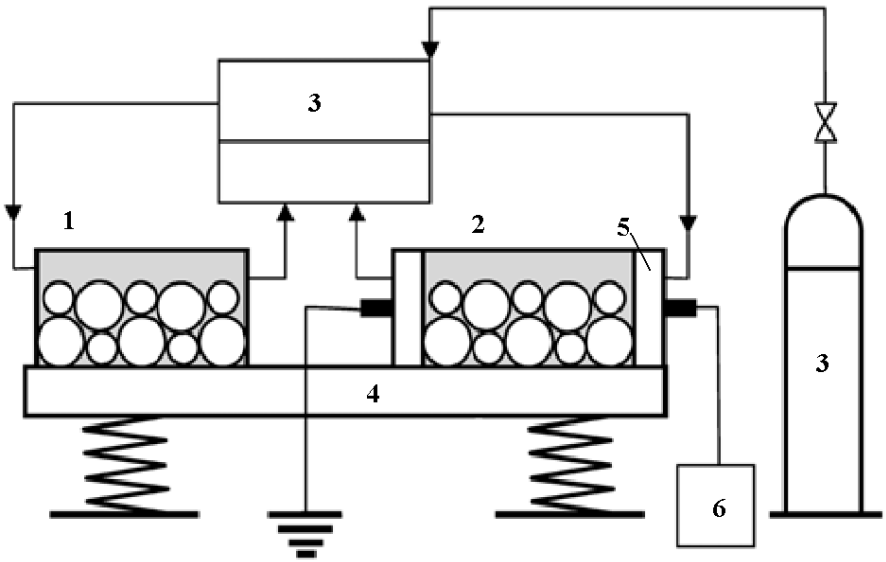

Fig. 1 - Reaction module: (*1, 2*) reactors, (*3*) gas inlet and outlet system, (*4*) vibrating mill, (*5*) end disks with electrodes, and (*6*) highvoltage pulse generator.

Metal balls (R6M5 steel) 8 mm in diameter were used as grinding bodies, which filled 3/4 of the reactor volumes. Crushing was performed in an atmosphere of argon in vibrating mill *4* at

a vibration frequency of 25 Hz and an amplitude of 4 mm in the following two regimes: mechanochemical (reactor *1*) and plasma-mechanochemical (reactor *2*). For supplying high voltage, reactor *2* was equipped with two end teflon disks with central metal hollow electrodes *5*. High voltage (30 kV; 50 Hz; current, ~200 μA) was generated with the converter *6*.

3 Results and discussion

The experiments performed under analogous conditions showed that CDCM did not occur in a reactor filled with a quartz glass up to a temperature of 960°C. With the use of nickel nanopowder as a catalyst, the reaction began at 500°C. The degrees of CH_4 and CO_2 conversion were similar in the test temperature range, and at 830°C they reached 99.4 and 99.7%, respectively. A few hours after the beginning of the reaction, the balance on carbon (the amount of CO formed at a specified conversion of methane and CO_2) was disrupted because of the formation of condensation products (coke formation) on the catalyst surface and the catalytic activity of nickel nanopowder decreased.

On Co nanopowder, the reaction began at 550°C, and the conversion of CH_4 at 850°C did not exceed 30%; that is, this nanopowder was less active than the nickel sample. In this case, in contrast to the nickel catalyst, the cobalt catalyst did not lose its activity for a long time, and it gradually decreased only 300 h after the onset of reaction because of the coking of the surface. Thus, the cobalt catalyst is less active than the nickel one, but it is more resistant to poisoning by condensation products.

The reaction on the Ni-Co alloy obtained by the mechanochemical method came into play at 400°C and the degrees of CH_4 and CO_2 conversion at 870°C were 65 and 70%, respectively. However, the sample lost its catalytic activity after 5 h. With the use of a Ni-Co alloy prepared by the plasma-mechanochemical method, the process also began at 400°C, but the conversions of CH_4 and CO_2 at 870°C were as high as 90 and 99.5%, respectively, at the product ratio H_2 : CO = 1.2–1.4, which is close to the results given in [3].

Thus, a comparison between the results obtained on the Ni-Co alloys shows that the nanopowder, obtained by the plasma-mechanochemical method, has higher catalytic activity and retained it for a long time.

We also studied the possibility of regenerating a catalyst based on the Ni–Co alloy coked upon CDCM with hydrogen at a temperature of 400°C. The results, obtained using X-ray diffraction analysis showed that regeneration with hydrogen at 400°C for several hours leads to the disappearance of the peak of graphite. At this the restoration of the initial catalyst activity takes place. In the course of reduction with hydrogen, the formation of methane was detected, which became less significant with time.

4 Conclusions

Thus, in this work, we studied the catalytic activity of the nanopowders of Ni, Co and their alloys in the process of the carbon dioxide conversion of methane. Nickel nanopowder was found the most active but unstable CDCM catalyst, which rapidly loses its activity as a result of the formation of condensation products on its surface. The nanopowder of the Ni-Co alloy synthesized by the plasma-mechanochemical method is an active, selective and stable CDCM catalyst. The regeneration of the Ni-Co alloy catalyst with hydrogen at a temperature of 400°C for several hours leads to the restoration of its initial activity.

Effective Acidities of Heterogeneous Catalysts in Various Liquids in Relation with their Catalytic Activity

Carniti P., Prati L., Gervasini A.*

Università degli Studi di Milano, Dipartimento di Chimica, Milano, Italy

* antonella.gervasini@unimi.it

Keywords: solid acid catalysts, acid catalysis, intrinsic acidity, effective acidity, liquid, chromatography

1 Introduction

Acid catalysis is by far one among the most important area of catalysis by industries in all sectors of chemical manufacturing. Solid acid catalysts are applicable to a *plethora* of acid-promoted processes in organic synthesis, material transformation, depollution reactions, and so forth with well-known advantages over the gas or liquid acid catalysts. Solid acids can be described in terms of their Brönsted/Lewis acid sites, strength and number of these sites. High product selectivity can depend on the fine-tuning of these properties selectivity. For example, hydrolysis reactions generally require medium acid strength sites, while dehydration, esterification and alkylation reactions require strong acid sites [1,2].

In this context for all the liquid-solid catalytic reactions, particular attention has to addressed to the reaction solvent. The nature and properties of the solvent (polarity, proticity, hydrophlicity, solvating ability, etc.) can affect the acidity of the catalyst surface by interaction (coordination, H-bond, chelation, etc.) with the present Brönsted/Lewis acid sites. The nature of the acid sites and the relative proportion between Brönsted/Lewis surface sites can be modified upon the solvent-surface interaction. Moreover, due to solvent-surface interaction, the acid strength of the sites can be altered; generally, it decreases, with consequences on the activity and selectivity of the catalyst.

For all that has been said above, the determination of the *effective* acidities of acid catalysts measured in different liquids is of high importance for the correct choice of the *best* acid catalyst (in terms of amount of acid sites and site strength) for given liquid solid acid-reactions. For example, only few solid acids are known to be able to maintain lively acid sites in water [3] and only few catalysts are suitable for valorization reactions of polysaccharides to obtain useful chemicals, like 5-hydroxyfurfurol, furfural, levulinic acid, etc.

We would like to present here our recent results on the study of *effective* acidities of several catalysts and supports measured in various liquids, like water, methanol, 2-propanol, hydro-alcoholic mixtures, among others, and the observed relations with catalytic activity in some liquid-solid reactions of biomass valorization, running in the same liquids.

For such measurements, basic solutions of 2-phenylethylamine (PEA), chosen as molecular probe, in the selected liquid, have been used. The measurements can carry out according with a complete recirculation mode or according with a pulse method [4]. The numerical treatment of the collected data permitted obtaining not only the amount of the *effective* acid sites with evaluation of the fraction of strong acid site in a given liquid, but also thermodynamic or kinetic parameters relevant to the acid-base adsorption phenomenon.

2 Experimental/methodology

The sample studied are both bulk and supported acid catalysts: niobium oxide (NBO) and niobium phosphate (NBP) (kindly furnished by CBMM from Brasil); and other synthesized catalytic materials: a ternary compound containing Nb_2O_5, 2.5 wt.%; P_2O_5, 2.5 wt.% and SiO_2, 95 wt.% (NbPS), niobia supported on silica, and on silica-zirconia oxides (Nb, 10 wt.%); metal

nanoparticles (Pt, Co, and PtCo) deposited on acidic mixed-silica oxides (silica-alumina, silica-niobia, silica-titania, and silica zirconia (with 5 wt.% Al, Nb, Ti, and Zr).

The liquid-solid acid-base titrations have carried out by using 2-phenylethylamine (PEA) as basic probe in a modified liquid-chromatographic (HPLC) composed of a pump and an UV-detctor; the sample powder was put at the place of the chromatographic column (Fig. 1A). With the line, it was possible to operate in complete recirculation mode, and a typical step-chromatogram was obtained from the titrations (Fig. 1B), or in dynamic mode obtaining a tipycal pulse-chromatogram (Fig. 1C).

The choice of liquid used to dissolve the basic probe affects the result of the titrations. Cyclohexane with apolar and aprotic characteristics was chosen to determine the *intrinsic* acidity of the samples, due to complete absence of interaction with the surfaces functionalities. With the other liquid used (water, methanol, 2-propanol, hydro-alcoholic mixtures), which are able to coordinate, solvate, and make interactions with the acid sites of the surfaces, *effective* acidities of the samples were determined.

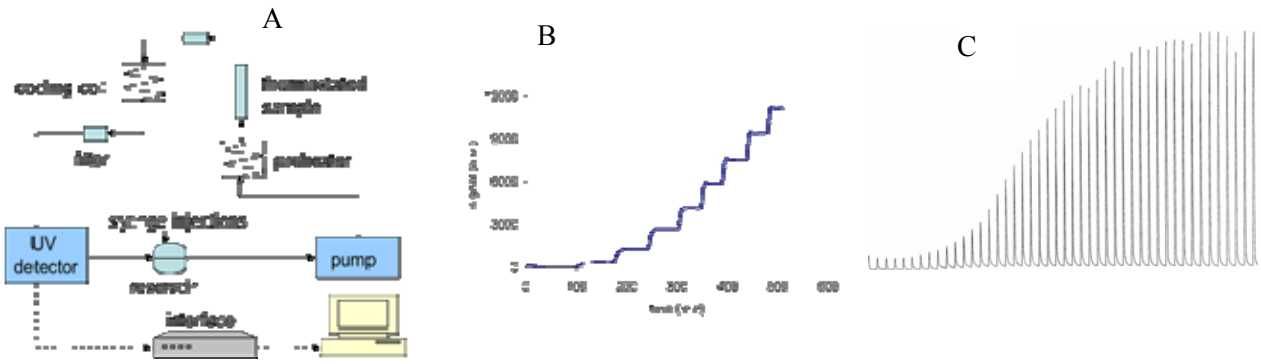

Fig. 1. Scheme of the HPLC line used for the liquid-solid titrations (A); chromatograms obtained for experiments in total recirculation mode (B) and in pulse mode (C).

3 Results and discussion

On several catalysts, examples of *effective* acidity measured in the same reaction solvent in relation with their catalytic activity will be presented.

For example, NBO and NBP are known water-tolerant acid catalysts, for this, they have been used in reactions of disaccharide (sucrose, cellobiose, maltose), and polysaccharide (inulin) hydrolysis and sugar (fructose) dehydration [5]. NbPS is more acidic than NBO and NBP, when it is titrated in cyclohexane (0.600, 0.403, and 0.207 mequiv/g for NbPS, NBP, and NBO, respectively), while in water NBP and NBO have higher *effective* acid sites than NbPS (0.192, 0.350, and 0.126 mequiv/g on NBO, NBP, and NbPS, respectively). As expected, NbPS loses part of its acidity in water due to the presence of silica that does not possess any acidity in water. This behaviour has consequences on the catalytic activity, as observed in the studied reactions.

Niobia dispersed on an acid support (silica-zirconia) is effective for the acid conversion of xylose to furfural, due to the water-tolerant acid properties of the niobia phase. As higher the niobia dispersion (prepared by sol-gel) as better the catalytic performances, which could be associated with the highest amount of strong *effective* acid sites.

Keywords: surfactants, acetylcholine, montmorillonite, cellulose, chitosan, oxidation, polymerization

1 Introduction

The phenomenon of micellar catalysis has been known for a rather long time and applied in many processes, but the significant influence of surfactants on the mechanism of hydrocarbon oxidation was found and studied only in recent decades [1-3]. Surfactants (S) form with hydroperoxides (LOOH) mixed micelles {*n*LOOH–*m*S} and the behavior of hydroperoxides in these mixed micelles determines the influence of the surfactants on oxidation. Cationic surfactants (S+) are found to catalyse decomposition of hydroperoxides into free radicals.

For the combinations of different hydroperoxides and S+ it has been established that {*n*LOOH–*m*S+} systems generate radicals rather actively at moderate temperatures in both organic and aqueous media [2,4,6], according to the following sequence:

$$nLOOH + mS+ \Leftrightarrow \{nLOOH–mS+\} \rightarrow LO_2^{\cdot}$$

Thus, mixtures S+ and LOOH can be used as a lipophilic and hydrophilic initiating system.

In this study the development of catalytic systems for radical generation based on this property of cationic surfactants is presented. The possibility of heterogeneous catalysts, prepared by adsorption of S+ on solid carriers, has been explored as free radical initiating systems for oxidation and radical polymerization processes.

2 Experimental/methodology

The carriers (M) - montmorillonite (Cloisite Na, USA), (MC)-microcrystalline cellulose (Evalar, RF), and (CH)-chitosan (Fortex, RF) were used as purchased. The well known S+ - cetyltrimethylammonium bromide (CTAB, Fluka) was taken to prepare catalysts as follows: a solid carrier was placed into the CTAB solution of known concentration in chloroform for 10 hours under stirring; then a carrier was separated from solution, washed out with clean chloroform and all the chloroform fractions were combined. The washed solid residue was dried under the flow of warm air. The CTAB residue, obtained after evaporation of chloroform, was weighted to determine CTAB adsorption (Γi) on a carrier.

The model chain reaction of limonene oxidation [2,3] was used to estimate the catalytic activity of heterogeneous catalysts in hydrocarbon oxidation. The polymerization of styrene, containing 0.05 M cumene hydroperoxide (CHP), was a model reaction to examine the catalysts in radical polymerization. The rates (R) of both chain reactions are described by the equation: $R = a\,[LH]R_i^{0,5}$, where R_i is the radical initiation rate, $a = k_p/(2k_t)^{0,5}$ is the ratio of rate constants for chain propagation (k_p) and termination (k_t). Oxygen uptake was measured by volumetric method in limonene oxidation; the polymerization rate was determined by microcalorimetry using DAC-1-1. With known rate constants for both processes [2,4,7] the initiation rate was calculated according to: $R_i = (R/([LH]\cdot a)^2$.

We studied the possibility of polymerization on the surface of glass covered by CTAB monolayer as well. The property of polymer layer obtained was determined by AFM method using Bruker AFM FastScan in ScanAsyst+PeakForceQNM mode.

3 Results and discussion

Table 1 demonstrates the adsorption of CTAB on montmorillonite, cellulose, and chitosan as well as the rates of initiation, calculated on the base of measured rates of styrene polymerization and limonene oxidation carried out in the presence of 4%(weight) heterogeneous catalysts.

Table 1. Adsorption CTAB on carries and radical generation rates during polymerization of styrene and oxidation of limonene, catalyzed by heterogeneous catalysts (4%); 60°C.

Catalyst	Adsorption, Mol/g	$R_i \cdot 10^7$, Mol/(L·s) Styrene polymerization	$R_i \cdot 10^7$, Mol/(L·s) , Limonene oxidation
-	-	0.42	0.58
M/CTAB	$5{,}71\ 10^{-4}$	0.76	2,54
MC/CTAB	$1{,}85\ 10^{-4}$	7.5	20,2
CH/CTAB	$1{,}72\ 10^{-5}$	4.8	0,82

So far as hydroperoxides are potential source of radicals, cumene hydroperoxide (0.05M) was used in styrene polymerization and limonene hydroperoxide (0.2M) was added to limonene (2M) in chlorobenzene.

Unlike a less adsorption of CTAB on cellulose and chitosan the polymerization rates with these catalysts were found to be in several times higher than that with M/CTAB. The rates of free radical generation via catalytic limonene hydroperoxide decomposition decrease in the sequence: MC/CTAB > M/CTAB >CH/CTAB. The increase of catalytic effect of cationic surfactant on the cellulose surface and the role of hydroperoxide nature in colloid catalytic system are discussed.

By means of AFM the adsorption of CTAB on glass surface and properties of polystyrene layer formed on the surface immersed in the solution of tert-butyl-hydroperoxide in styrene were studied. At AFM image of the surface, which was immersed in styrene, well-marked areas of the polystyrene film with the characteristic Young's modulus, was detected, while, on the AFM image of the surface, not in contact with styrene, only traces of preparation - the areas covered with CTAB and free glass were found.

4 Conclusions

All heterogeneous carriers, covered with CTAB monolayer, catalyse the decomposition of hydroperoxides into free radicals and initiate radical chain processes in olefins containing hydroperoxides. It can be used for covering of complicated heterogeneous surface by polymer layer and for production of nanocomposites by the vinyl monomer radical polymerization initiated with the colloid heterogeneous system of LOOH and a nanodispersed carrier hydrophobizated with a cationic surfactant.

High Active Cr-Al Oxides Catalyst for the Ozone Friendly Freons Synthesis: Pretreatment Conditions and Kinetic Study

Isupova L.A., Simonova L.G., Zirka A.A., Larina T.V., Reshetnikov S.I.*

Boreskov Institute of Catalysis, Novosibirsk, Russia

* reshet@catalysis.ru

Keywords: pretreatment, chromium–aluminum catalyst, chladones, kinetics

1 Introduction

In recent decades, considerable efforts have been focused on the synthesis of chladones having zero ozone depletion potential. The most promising in this regard are chladones of the ethane row (HFC-134a, HFC-125). Numerous patents are devoted to the processes of production of HFC-125 and the catalysts [1-3] containing usually chromium (III) compounds. These catalytic systems can be used and for synthesis of the chladone of the next generation HFC-1234yf (2,3,3,3-tetrafluoropropene) having zero ozone depletion (ODP) and low global warming (GWP) potentials [4]..

In Boreskov Institute of catalysis the high active Cr_2O_3/γ- Al_2O_3 catalyst in comparison with the industrial (Russia) Cr-Mg catalyst was developed. It is well-known that the activity and selectivity of catalysts strongly depend not only on the catalysts composition, method of precursor preparation but n pretreatment conditions as well.

In this work, we studied the influence of the pretreatment conditions (temperature and gas composition) on the physicochemical and catalytic properties of the chromium–aluminum catalysts. Kinetic study of most active catalysts in pentafluoroethane (HFC-125) sinthesis by the gas-phase hydrofluorination of tetrachloroethylene.

2 Experimental

Catalyst (precursor) containing 95 wt % chromium oxide (on Cr_2O_3 basis) and 5 wt % Al_2O_3 were prepared by the addition of a mixture of $CrCl_3$ and $AlCl_3$ solutions to a solution of ammonia (9%) at a constant pH and a temperature. After the completion of precipitation, the suspension was aged for 1 h, washed with distilled water, filtered, and dried in air at 110–120°C for 12 h.

The catalytic activity of samples in the fluorination of tetrachloroethylene to pentafluoroethane was determined using a flow reactor with a fixed catalyst bed (grain size of 0.25–0.5 mm) in the kinetically controlled region at 320–370°C, 0.4 MPa, reactant molar ratios of HF: tetrachloroethylene = (10–20) : 1, and a residence time of 1–3 s. The activity was estimated in terms of the first-order reaction rate constant $k = -\ln(1 - X)/\tau$, where X is the tetrachloroethylene conversion (in mole fractions) at the residence time τ [5].

3 Results and discussion

The prepared catalyst sample (precursor) was heattreated between 165 and 600°C using two different procedures: in nitrogen or in air. The thermal behavior of the Cr–Al samples in nitrogen and air in the temperature range 110–600°C were studied by thermal and X-ray diffraction analyses, uv-vis diffuse reflectance spectroscopy, and specific surface are measurements.

It was obtained that the temperature and gas composition of pretreatment strong effect on the specific surface area and activity of the catalysts (Fig.1). As the temperature of heat treatment in nitrogen is increased, this sample undergoes gradual dehydration and, at ~300°C,

when the residual water content decreases to ~10 wt % (~0.5 (mol H_2O/Cr^{3+}), S_{sp} begins to increase. At 400°C, the residual water content is 4.7% and S_{sp} is close to its maximum. As the temperature is raised to 500°C, S_{sp} remains approximately invariable. The increase in S_{sp} due to the dehydration of the sample is accompanied by an increase in catalytic activity. This is in agreement with the view that the thermolytic loss of hydroxyl groups results in the formation of coordinately unsaturated, catalytically active surface species (Cr^{3+} and O^{2-}).

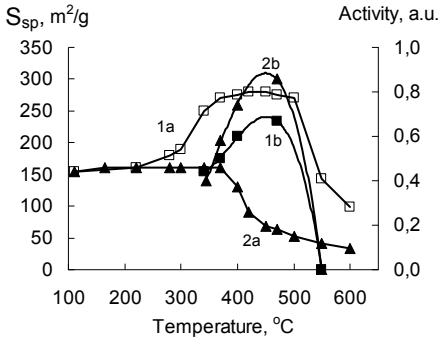

Fig. 1. Influence of the treatment temperature on the specific surface area and activity of the catalysts: (*1a*) S_{sp}, N_2; (*1b*) activity, N_2; (*2a*) S_{sp}, air; (*2b*) activity, air.

The dehydration of chromium hydroxide and the highly exothermic oxidation of Cr^{3+} to oxides with $CrO_{1.9}$ stoichiometry occur in the temperature range from 200 to 370°C (the heat treatment in air). Between 370 and 400°C, $CrO_{1.9}$ decomposes to less oxidized forms $CrO_{1.5}$. Very exothermic rystallization yielding coarse α-Cr_2O_3 crystals occurs at 410–420°C. The oxidation–decomposition processes $CrO_{1.5} \leftrightarrow CrO_{1.9}$ are reversible for noncrystallne fine_particle chromium oxides. Coarse α-Cr_2O_3 crystals contain no reversibly oxidizable chromium species that are the most active in the catalytic hydrofluorination of chloroalkanes. The oxides having reversibly oxidizable chromium exhibit high activity in hydrofluorination, but they are unstable and decompose readily to $CrO_{1.5}$ above 370°C. The highly active catalyst should have a large specific surface area and low concentrations of deactivating impurity anions and water along with the optimal oxidation state of chromium. This can be explained by the following processes occurring in the oxidation medium:

$$Cr_2O_3(am.) \xrightarrow{200-370^0 C} Cr\,O_{1.9}(am.) \xleftrightarrow{370-400^0 C} Cr\,O_{1.5}(am.) \xrightarrow{410-420^0 C} \alpha\text{-}Cr\,O_{1.9}(cr.)$$

4 Conclusions

The physicochemical properties of the Cr_2O_3/γ- Al_2O_3 catalysts obtained by heat treatment of the sample (precursor) in nitrogen and air between 110 and 600°C and their influence on the catalytic activity in tetrachloroethylene hydrofluorination was studied by the TA, TPD, X-ray diffraction, BET, and DRS methods. It was shown that the temperature and gas composition of precursor pretreatment strong effect on the specific surface area and activity of the catalysts. The $CrO_{1.9}$ compounds are more active than $CrO_{1.5}$. For more active catalyst sample kinetic study was performed.

A Computational Approach to Understand the Promotional Effect in Ni-Fe Bimetallic Catalyst

Ray K.[1*], Pandey D.[1], Singh B.[2], Prasad R.[2], Deo G.[1]

1 - Department of Chemical Engineering, Indian Institute of Technology Kanpur, Kanpur, India

Keywords: Ni-Fe bimetallic catalyst, Ni-Fe, alloy, CO_2 hydrogenation, density of states (DOS)

1 Introduction

Supported Ni-Fe bimetallic catalysts with a specific Ni to Fe ratio was found to possess superior catalytic activity for CO_2 hydrogenation to CH_4 compared to supported monometallic Ni catalyst [1]. It was proposed that the formation of suitable alloy played a dominant role in the enhancement in catalytic activity. In the present communication computational (DFT) and experimental studies were undertaken to gain insights into the enhancement due to metal alloys.

2 Methodology

Catalyst synthesis, characterization and testing during the CO_2 hydrogenation reaction were similar to those reported previously, except that the total metal was 15 weight percent [1]. The rate for CO_2 conversion was converted to TurnOver Frequency (TOF). The surface-slab model and closed packed (111) surface were chosen for computational studies. The three synthesized catalysts, $100Ni/Al_2O_3$, $75Ni25Fe/Al_2O_3$ and $50Ni50Fe/Al_2O_3$, were represented by Ni(111), $Ni_3Fe(111)$ and NiFe(111) surfaces. The theoretical calculations were performed within density functional theory framework using CASTEP code [2]. The generalized gradient approximation was used to include the exchange-correlation effects. The surface relaxations play an important role due to lower coordination in the surface layers, and thus, we have relaxed top two layers of all slabs until the residual forces were less than 0.01 eV/Å. The Brioullin-Zone sampling was done using 4×4×1 k-mesh within Monkhorst-Pack scheme [3]. The plane wave cut-off energy of 360 eV was employed.

3 Results and discussion

Characterization and reactivity data of the three catalysts and surfaces are presented in Table 1. The shift in the XRD 2θ values was indicative of Ni-Fe alloy formation. Table 1 also revealed that the rate significantly increased for the supported Ni-Fe catalysts.

Table 1. Characterization (experimental and theoretical) of catalysts

Catalyst	XRD		H_2-TPD (µmole/g)	Rate (µmole/g.s)	ε_d of surface Ni atoms (eV)	w_d of surface Ni atoms (eV)
	hkl	2θ				
$100Ni/Al_2O_3$	Ni(111)	44.5°	82	51	-1.28	-2.25
$75Ni25Fe/Al_2O_3$	$Ni_3Fe(111)$	44.2°	115	162	-1.31	-2.28
$50Ni50Fe/Al_2O_3$	NiFe(111)	44.0°	124	124	-1.33	-2.30

Four properties were considered for electronic characterization of the DOS of d electrons: the d-band center ($\boldsymbol{\varepsilon_d}$), d-band width ($\mathbf{w_d}$), upper d-band edge ($\boldsymbol{\varepsilon_u}$) and DOS at Fermi level (E_F) [4-6]. The $\boldsymbol{\varepsilon_d}$ and $\mathbf{w_d}$ of surface Ni atoms were calculated and the values are given in Table 1. The $\boldsymbol{\varepsilon_d}$ gradually decreased and shifted further away from E_F compared to pure Ni. The $\boldsymbol{\varepsilon_u}$ and DOS at E_F of Ni_3Fe and NiFe shifted significantly from Ni and a small difference of these two properties

between Ni_3Fe and NiFe is also existed. Furthermore, the ε_u of the surface Ni atoms for Ni_3Fe and NiFe was below E_F. As previously reported shifting of ε_d away from E_F also resulted in lowering of DOS at E_F [7]. The lowering of ε_d (and DOS at E_F) and ε_u suggested higher filling and weaker chemical bonding between the adsorbate and surface Ni atoms [4, 5]. Thus, the adsorption was expected to be weaker on the bimetallic catalyst compared to Ni.

To correlate the reactivity and electronic characterization data the TOF of catalysts was plotted as a function of ε_u and DOS at E_F as shown in Fig. 1. The results reveal that there exists an optimum value of these two properties that maximizes the TOF. Such variations suggest that the key reactant and other intermediate species have an optimum adsorption bonding on the surface giving rise to a maximum TOF for the $75Ni25Fe/Al_2O_3$ catalyst.

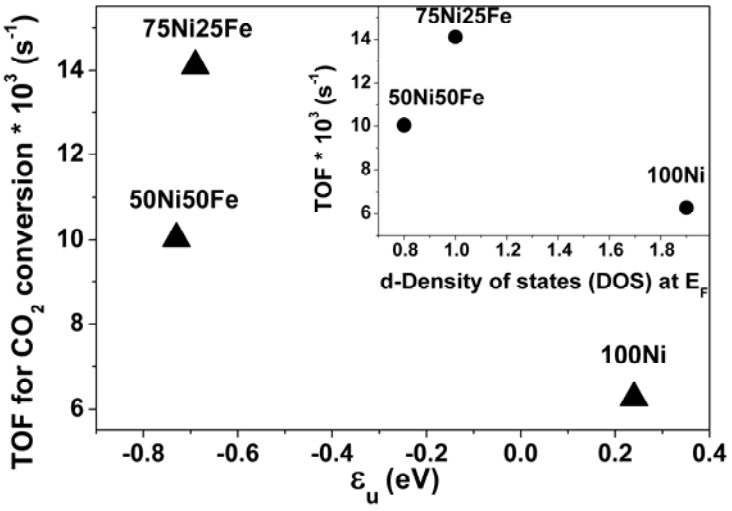

Fig. 1. Plot of TOF vs. ε_u and (inset) TOF vs. d-DOS at E_F (considered at 0.0 eV). Reaction conditions: T = 523 K, P = 1 atm, CO_2:H_2 = 1:24, W/F_{CO2} = 10.3 kg_{cat}-h/kg-$mole_{CO2}$

4 Conclusions

The enhancement in catalytic activity for two bimetallic catalysts over pure Ni was due to the formation of alloy. For the alloys the electronic nature of the surface Ni atoms gets perturbed. An optimum value of ε_u and DOS at E_F of the surface Ni atoms appears to be the cause for the improved catalytic activity of the Ni-Fe bimetallic catalyst of a specific Ni to Fe ratio.

Origin of the Spontaneous Formation of Cobalt Nano-Islands under Fischer Tropsch Conditions and Mechanistic Consequences

Banerjee A.[1], Gunasooriya G.T.K.K.[2], Saeys M.[2*], Otyuskaya D.S.[2]

1 - Department of Chemical and Biomolecular Engineering, 4 Engineering Drive 4, National University of Singapore, Singapore

2 - Laboratory for Chemical Technology, Ghent University, Gent, Belgium

Keywords: Fischer Tropsch synthesis, reconstruction, nano-islands, B5 step sites, CO activation

1 Introduction

Fischer-Tropsch synthesis transforms synthesis gas, a mixture of CO and H_2, to long-chain hydrocarbons and water. In recent years, interest in Fischer-Tropsch synthesis as an attractive route to convert natural gas, coal and biomass to clean transportation fuels, has surged. Supported cobalt catalysts are often preferred due to their high activity, selectivity towards long chain hydrocarbons, and low CO_2 selectivity. The structure and coverage of catalyst surfaces under reaction conditions differs dramatically from ideal clean surfaces. To begin to elucidate catalyst activity and selectivity, computational catalysis needs to build realistic surface models and consider coverages under reaction conditions. Cobalt catalysts undergo a massive reconstruction under Fischer-Tropsch (FT) conditions as observed by STM [1] creating defect sites that play a key role in activity and selectivity [2].

2 Methodology

To build realistic models, the thermodynamic stability of various surface structures was modelled using density functional theory with the revised Perdew-Burke-Ernzerhof-Van der Waals functional, and taking into account the effect of temperature, pressure and coverage. With this approach, the site preference and CO adsorption is accurately described on several transition metal surfaces [3]. Transition-state structures were obtained with the climbing-image Nudged Elastic Band method, and vibrational frequencies confirmed the nature of the transition states.

3 Results and discussion

Though surface carbon atoms are thermodynamically unstable on Co terraces under Fischer Tropsch conditions (+40 kJ/mol), they adsorb very strongly at B5 step sites. The unique stability of these square-planar carbon species can be attributed to the local aromaticity of the Co_4C unit [4]. The presence of square planar carbon oxidizes the neighbouring Co with a calculated Co 2p binding energy of 780 eV, and therefore enhances CO adsorption at those sites [5]. The oxidation of a small fraction of the surface Co has been correlated with FT activity [6], but was never attributed to the formation square-planar carbon. The synergistic adsorption of carbon and CO and the high CO coverage make it thermodynamically favourable to break up Co terraces and create step sites (Figure 1a), driving the formation of islands [5]. The size and shape of the nano-islands follows from a detailed balance between favourable step creation and unfavourable corner creation. The calculations predict that, under FT conditions, triangular islands of ~1.8 nm and containing 28 Co atoms are the most stable, in agreement with STM data [1]. The reconstruction is sensitive to the reaction conditions and our model explains why no reconstruction was observed in a recent study under mbar conditions [7]. Electron count

arguments related to the local aromaticity furthermore limit the coverage of square-planar carbon at the B5 sites to 50%, leaving B5 sites available for reaction (Figure 1b).

C-O scission is a key step in the FT mechanism, and occurs either by direct cleavage of CO at defect sites, via a hydrogen-assisted pathway, or after formation of a C-C bond via the CO insertion mechanism. Our kinetic study [2] shows that the propagation mechanism for the CO insertion mechanism is consistent with available experimental kinetic data [8,9]. However, the initiation and termination steps for the CO insertion mechanism remain to be elucidated. In this work, we analyse various reaction paths for the formation of the chain-initiating CH species at the edge sites of the nano-islands. The calculations suggest that C-O activation proceeds with an overall barrier of about 120 kJ/mol and has a rate in line with experimental kinetic data.

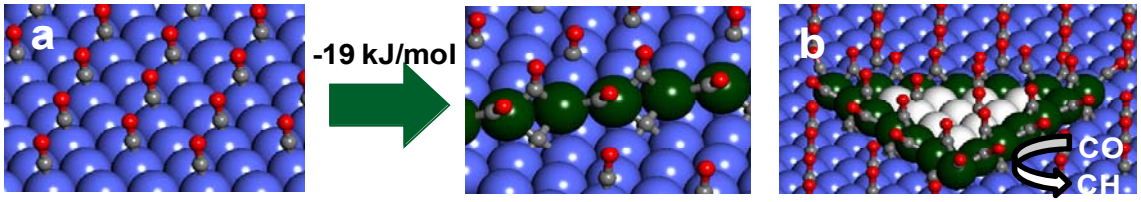

Fig. 1. (a) Break-up of CO-covered terraces to form C and CO-covered step sites is favourable with a Gibbs free energy of -19 kJ/mol Co step sites. (b) CO dissociation at the B5 sites of the Co28 nano-islands is kinetically fast, creating chain-initiating CH species.

4 Conclusions

Cobalt catalysts undergo a massive surface reconstruction under Fischer-Tropsch conditions to form nano-islands. Though the energy penalty to create step sites is substantial, the unusual stability of square-planar carbon at the B5 steps and the increased CO adsorption energy and high CO coverage at the step sites together make it highly favourable to create step sites under Fischer-Tropsch conditions. The most stable nano-islands contain 28 Co atoms and have a diameter of 1.8 nm. The edges of these nano-islands are not fully covered, leaving active sites for facile CO dissociation.

Keywords: XPS, charging effects, metal nanoparticles catalyst support

1 Introduction

X-Ray photoelectron spectroscopy (XPS) is the universal and very informative tool of catalysts investigations. Due to the extremely small depth of analysis (from units to tens of nanometers) it provides the information about the uppermost layers of the catalyst and – when *in situ* mode is applied – about the adsorbed layer composition. The data on the elemental analysis, oxidation states of observed elements, chemical composition of adsorbed moieties, etc. obtained from XPS measurements are widely used in the studies of the preparation, activation, exploitation and ageing of the model and industrial catalysts.

The detection of the chemical state alterations of the small fraction of the element(s) of interest by the registration of subtle changes of the shape and/or position of photoelectron peaks is probably most beguiling capability of XPS techniques for the exploration of the supported metal catalysts. Yet there is important instrumental drawback when metal nanoparticles at oxide supports are studied by XPS. Namely, under X-Ray irradiation the surface of poorly conductive samples accumulates the positive charge (so-called "surface charging") that directly affects the kinetic energies of emitting photoelectrons and, therefore, the positions of XPS peaks. The magnitude of such "charging shift" can be comparable or even exceed the values of chemical shifts tabulated for the metals in different oxidation states. The effect becomes more prominent when the monochromatic primary excitation is used due to the substantially lower flux of the background (inelastically scattered) electrons generated by X-Ray source. For instance, when compensating flux is absent, tantalum oxide sample exhibits the surface charging shift of Ta4f peak for more than 60 eV.

It is obvious that in such cases the conventional spectra processing by using the position of C1s peak from adventitious carbon for re-calibration is hardly acceptable. Instead, the instrumental charge neutralization is recommended by XPS experts. Yet by variation of flood gun (charge neutralizer) parameters one can arbitrarily achieve any position of the chosen photoelectron peak within the some limited range on the binding energy (BE) scale. On one hand, it raises another experimental problem: how to determine the proper or "correct" level of the charge compensation. But on the other, it gives to the scholars the new spectroscopic tool to probe the specimen surface.

2 Experimental/methodology

The XPS experiments were performed on a SPECS spectrometer equipped with PHOIBOS-150 MCD-9 hemispherical energy analyzer, monochromatic AlKα X-ray gun and FG 15/40 flood gun. Various flood gun parameters (emission current and electron flux energy) were used to achieve the different charge neutralizing modes.

The set of various supports (Sibunit, alpha-alumina, carbon coated alumina, Si, Zr, Ta, W oxides with relatively low specific area (ca. 10 m^2/g) as well as Pt and Pd model catalysts

prepared using these supports were investigated to elucidate the influence of surface conductivity and uniformity on the efficiency of the charge neutralizing.

3 Results and discussion

The data show that the magnitude of the charge shift depends on the power balance between X-ray and electron beam (flood gun) sources. The variation of low energy electron flux density at constant X-Ray Gun power shifts the photoelectron peaks of non-conductive support elements as expected. However, the spectral behavior of the same supports but covered with metal nanoparticles is more complicated. The support spectra are usually consists of two components: one responds to the changing flood gun power like the clean support does, but another reveals substantially lower value of "charging shift". Moreover, the fraction of the latter component in the spectra correlates with both the amount of the metal detected by XPS at the surface of the support and the surface resistivity of the support material. Then, for alumina supported Pd catalyst (0.5% wt) such spectral feature of Al2p signal is as low as 10% of total intensity while for 0.5% wt Pd/WOx sample the whole signal of W4f line shifts evenly when flood gun power is changed.

Thus, the deposition of metal particles on the surface of the non-conductive supports corrupts its homogeneity (in terms of conductivity) so that it becomes possible to elucidate the patches of the specimen surface with different affinity to electron. Literally, metal particles act like "antennas" receiving beta-radiation from outer source – most likely due to the sharp distortion of the equipotential lines of electrostatic field. Therefore, some additional information on the surface density (population) of the metal particles at the support surface could be derived by the variation of charge neutralizer power – thus turning the surface charging from enemy to the ally of the scholar.

4 Conclusions

The induced differential charging of the surface of supported metal catalysts is proved to provide the additional information on the properties of the supported metal catalysts. It becomes possible to evaluate the population density of metal nanoparticles at the support surface, and therefore, to estimate the average size of such particles directly from the spectroscopic data.

Kinetics of Activation Fischer-Tropsch Iron-Based Catalysts under CO and CO/H_2 Flows

Kazak V.O.*, Chernavskii P.A., Pankina G.V.

MSU, Faculty of Chemistry, Moscow, Russia

* vladislavkazak@gmail.com

Keywords: iron, nanoparticles, Fischer-Tropsch synthesis, kinetics of carburization

1 Introduction

Fischer-Tropsch synthesis (FTS) is an alternative method to produce a variety of chemicals as hydrocarbons and oxygenate from syngas [1]. Both cobalt and iron are used as FTS catalysts, but iron is more preferable because of their low cost, high resistance to poisons and possibility to work under low H_2/CO ratio. It is known that iron carbides are active phases in FTS iron-based catalyst [2]. Recently, it was established that activity and selectivity of iron catalyst depend on the composition of the mixture by which catalyst activated [3-5], but the reasons are still unclear.

In our research, we investigated the kinetics of carburization FTS iron catalysts in the atmosphere of both carbon monoxide and syngas ($CO:H_2$ = 1:1) by *in situ* magnetometric method.

2 Experimental

Both samples were obtained by incipient wetness impregnation of iron nitrate ($Fe(NO_3)_3 \cdot 9H_2O$) aqueous solution. Two different commercially available (CARiACT, Fujisilysia Chemical Ltd.) silica gels namely Q-15 and Q-50 with average pore size 15 and 50 nm respectively were used as supports. After impregnation procedure catalysts were dried 4 h in air flow under 80°C and then they were calcined 4 h in air flow under 400°C.

Elemental analysis of prepared catalysts carried out by energy-dispersive X-ray microanalysis (EDX). X-ray diffraction spectroscopy (XRD) was used for determination of phases and average particles size of calcined samples.

Kinetic measurements were conducted by *in situ* magnitometric method [6]. All experiments were made under isothermal conditions. 20 mg of sample was heated up to desired temperature (250 or 350°C) in argon flow and then argon flow was changed to a selected activation mixture (CO or $CO+H_2$). During experiment sample's magnetization was detected.

3 Results and discussion (font style: Times New Roman bold 12pt)

It was shown by EDX microanalysis that content of iron is 14.8 and 15.4 wt. % for Fe/Q-15 and Fe/Q-50 respectively. Only hematite (Fe_2O_3) phase was detected by XRD analysis of prepared samples. Average particle size of hematite calculated from Scherrer equation is 11 and 30 nm for Fe/Q-15 and Fe/Q-50 respectively.

Results of kinetic measurements are given in Fig 1. Kinetic curves of the activation process under 250°C have a sigmoid form for both CO and $CO+H_2$ flows. On the contrary, magnetization sharply rises up, then passes through a maximum and finally slowly decreases in the case of the activation under 350°C. Kinetic curves obtained under 350°C are described in a proper manner by a simple model of consecutive irreversible processes (Table 1):

$$Fe_2O_3 \xrightarrow{k_1} Fe_3O_4 \xrightarrow{k_2} \chi - Fe_5C_2$$

$$C_{Fe_3O_4} = C^0_{Fe_3O_4} \times \frac{k_1}{k_1 - k_2} \times \left[\exp\left(-k_2 t\right) - \exp\left(-k_1 t\right)\right]$$

It should be noted that these processes are a number of topochemical reactions and both k_1 and k_2 are effective constants of complex processes. Obtained data have shown that rates of both processes and final magnetization are lower in the case of $CO+H_2$ activation than in the case of CO activation. It's known that wustite (FeO) might be generated during reduction of hematite (Fe_2O_3) in the presence of hydrogen. We assumed that in the case of activation by $CO+H_2$ wustite produces and reacts to silica gel with formation of paramagnetic iron silicate (Fe_2SiO_4). Moreover, the effect of the presence of hydrogen in activation mixture is stronger for smaller hematite nanoparticles.

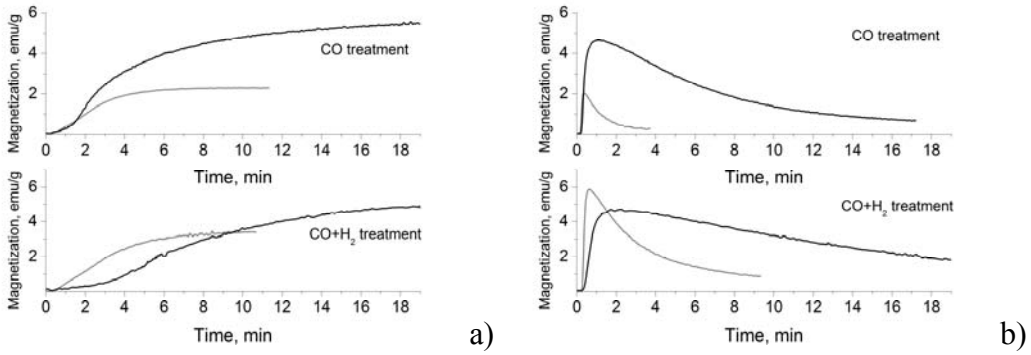

Fig. 1. Kinetic curves of Fe/Q-15 (gray lines) and Fe/Q-50 (black lines) activation under 250°C (a) and 350°C (b).

Table 1. Results of least square fitting of kinetic curves obtained under 350°C by suggested model.

Catalyst	k	in CO flow	in $CO+H_2$ flow
Fe/Q-15	k_1	0.17	0.135
	k_2	0.0138	0.0045
Fe/Q-50	k_1	0.0646	0.0283
	k_2	0.00229	0.00099

4 Conclusions

Kinetics of carburization FTS two iron catalysts with different particle size was investigated. It was shown that the composition of activation mixture dramatically effects on the kinetics of carburization FTS iron-based catalysts. The size effect of activation processes was established.

Keywords: *in-situ*, monitoring, SERS, filter papers, recyclable dip-catalyst

1 Introduction

The use of NPs for catalyst in solution is usually limited by the need to maintain their colloidal stability, as well as reusability, under typically harsh reaction conditions. One general approach that is often applied to overcome this limitation comprises the integration of NPs within various kinds of solid supports, leading to nanocomposites with greater stability and recyclability. Recently, we and other research groups have introduced ordinary filter paper as a suitable support material for NPs as it offers several advantages apart from particles stability, such as low-cost, biodegradability, flexibility and availability. Additionally, since the nanoparticle-paper interaction is mainly driven by electrostatics, surface charge further hinders high surface loadings and therefore prevents the nanoparticle self-assembly. These limitations could be overcome if the doping process is promoted from non-aqueous NP dispersions. We report a fast strategy that can easily be extended to large scale fabrication of robust and recyclable "dip-catalysts" with the ability to exhibit strong SERS activity. Furthermore, "dip-catalysts" can be also used to probe the progress of the reaction on the catalytic surface by monitoring the fingerprint signals of reactants and products through SERS.

2 Experimental/methodology

Firstly, fabricate the monodisperse and high concentration of gold NPs as the previous method. Then, the filter paper were cut into the designed area, and dipped into the solution of the gold NPs while dried soon by the hair drier. "dip catalysts" was dried in the hoven at 60^{o}–C overnight. Finally, after evaluation and characterization of the "dip catalysts", we have in-situ monitored the conversion of nitrothiophenol (4-NTP) into animothiophenol(4-ATP) on the surface of the "dip catalysts" through surface enhanced raman scattering (SERS).

3 Results and discussion

In the Fig.1, the time evolution of the Raman scattering modes of 4-NTP (1343 cm^{-1}) and 4-ATP (1593 cm^{-1}) allowed us to quantify the fraction of reactant (4-NTP) and product (4- ATP) at various reaction times. The reaction kinetics were treated as a pseudo-first order reaction ($NaBH_4$ concentration is in large excess with respect to 4-NTP) and we applied the steady-state approximation (since the evidences show that the intermediate reacts very fast).The steady-state approximation requires that the reaction rate of the second step will be larger than the first one, and therefore the formation of the intermediate 4,4'-dimercapto-azobenzene (4,4'-DMAB) should be the rate determining step. The fit of the exponential decrease of the 1343 cm^{-1} band to a first order equation resulted in a rate constant for the first step (k_R) of 5.09×10^{-3} s^{-1}. Therefore, the product formation, i.e. the band located at 1593 cm^{-1}, should show an exponential increase with time, also with a first order rate constant (k_P) similar to that for the first step (k_R). The good agreement between both reaction rates (5.09×10^{-3} s^{-1}vs.6.57×10^{-3} s^{-1} for k_R and k_P, respectively)

indeed demonstrate that no formation of the intermediate.

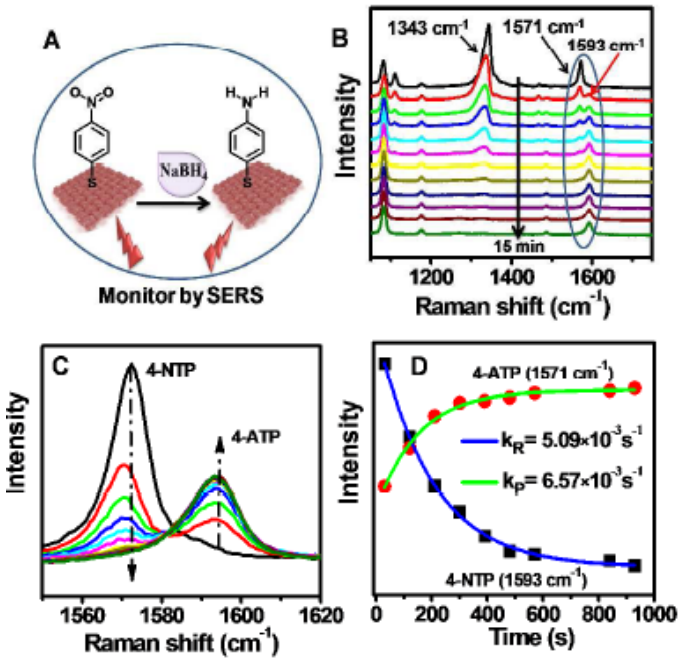

Fig.1. shows the scheme of the While acting as catalysts, Au NP-loaded paper composites display excellent surface enhanced Raman scattering (SERS) efficiency, allowing the real-time monitoring of chemicalreactions. [1]

4 Conclusions

In conclusion, we report a new type of bifunctional "dip-catalyst" based on Au NPs loaded on filter paper, which can be prepared by simple dip-coating of paper in concentrated Au NPs dispersions in toluene. The catalyst shows excellent recyclability with unchanged catalytic efficiency for more than 20 consecutive cycles. In addition, the catalytic substrate exhibits high SERS efficiencies that allow us to monitor the progress of reactions occurring on catalytic surfaces through the detection of SERS signals of reactants and products. The present work is expected to open new ways of application of multifunctional NP-loaded paper, not only for heterogeneous catalysis but also for monitoring reaction progress by SERS.

Graph Machine Based Advanced Data Modelling for High-Throughput Zeolite Catalyst Screening

Goulon A.[1], Faraj A.[1], Leflaive P.[2*]

1 - IFP Energies nouvelles, Rueil-Malmaison, France
2 - IFP Energies nouvelles, Solaize, France

* philibert.leflaive@ifpen.fr

Keywords: high-throughput, structural, encoding, QSAR, neural networks, zeolite, adsorption, enthalpies

1 Introduction

Zeolites are widely used as catalysts in the refining and petrochemical industries. However the lack of accurate models for predicting hydrocarbons adsorption on molecular sieves prevents using these models for statistical learning together with high throughput experimentation.

This work aims at developing a QSAR (Quantitative Structure Activity Relationship) model for zeolite catalysis having a new structure. This model is used within a high throughput iterative screening loop to determine hydrocarbons adsorption enthalpies on different molecular sieves.

2 Model construction

In a classical Quantitative Structure-Activity Relationship (QSAR) approach, molecules and catalysts are generally described using vectors composed of a large set of molecular and catalysts descriptors. In this work, an alternate approach is used as we suppose that all the required information for the molecule (reactant) encoding is contained within its structure, which is mathematically coded as a graph and further as a function (called Graph Machine) with the same mathematical structure. A description of this approach can be found in [1]. Since no molecular descriptors are used, the collection, computation and selection of these descriptors, which is often a major issue in QSAR applications, is no longer required.

In this previous work, Graph Machines (GM) were only associated with the molecules, then only allowing the prediction of the adsorption enthalpies of other molecules on the same solid. In this work, these functions were changed so that they both characterize the reactants and the zeolite catalysts. The solids have been characterized by one or more descriptors, considered in GM as external data : one or more tag(s) which take(s) the value(s) of the descriptor(s) associated with the solid is added at each node of the graph. The obtained GM function characterizes then both the molecule and the solid. Four descriptors were used : Unit Cell Size (UCS), Sanderson's intermediate electronegativity, the number of cations and their ionic radius.

3 Virtual high-throughput screening of zeolite catalyst

The new GM/QSAR model was applied in a virtual high-throughput screening to determine the adsorption enthalpy at zero coverage of 12 hydrocarbons (9 alkanes and 3 aromatics) on 10 cation exchanged faujasites with various Si/Al ratios. Experiments are carried out by series of 12 experiments. The experimental data used are those published by Canet et al. in [2,3].

The developed model is first used to choose an initial set of experiments (3 series of 12 experiments). The experimental results are then used as a training set for the model. The system then enters within a high throughput iterative process where the model is used for both the design of a new series of 12 experiments and result (adsorption enthalpy of a given molecule on a given solid) prediction. Figure 1 shows the variation of the mean and max. error values between experimental data and model prediction for the complete experimental space. It can be seen that with only 50% of the total number of experiments, adsorption enthalpies can be accurately

predicted with a mean error as low as 3 kJ/mol.

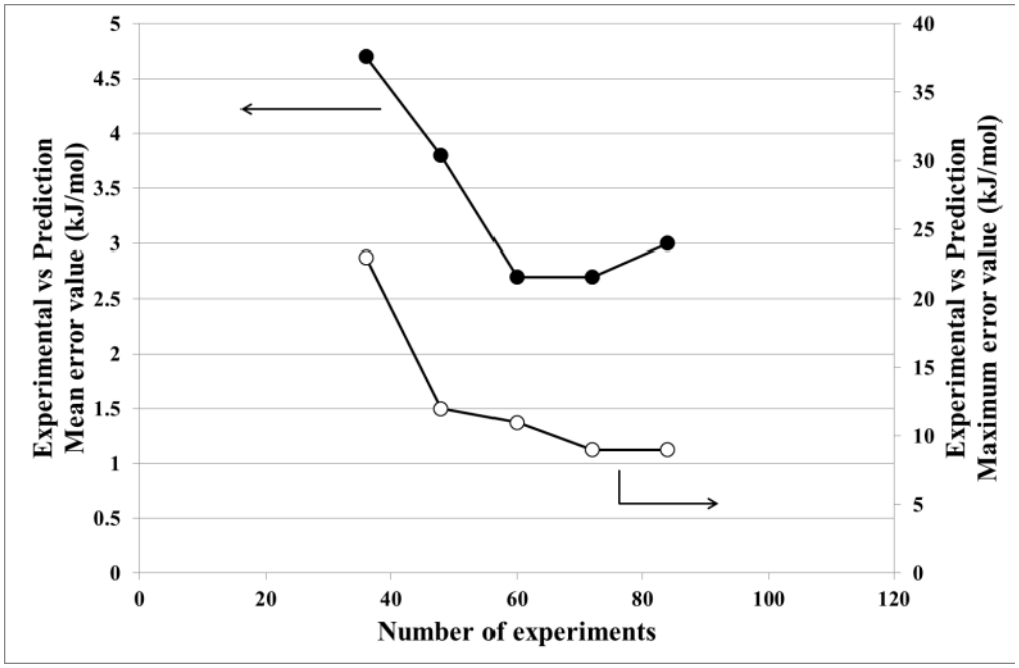

Fig. 1. Evolution of the mean and max. error values (kJ/mol) between experimental data and model prediction for the complete experimental space (120 experiments).

Finally, the predictive ability of the QSAR model was tested using a "leave one out" derived methodology by successively removing one solid after the other from the experimental data base. The results, reported in table 1, were satisfactory for all solids but prediction was better for alkanes than for aromatics.

Table 1. Error values (kJ/mol) between experimental data and model prediction after removal of one solid from the experimental data base. The adsorption enthalpies of the different hydrocarbons on the removed solid are estimated with model trained with all the other experimental data.

Catalytic Methane Decomposition Using Iron-Lanthanum Catalysts: Effect of Fe Loading on Activity Performance

Ibrahim A.*, Al-Fatesh A., Khan W., Fakeeha A., Abasaeed A.

Chemical Engineering Department, College of Engineering, King Saud University, Riyadh, KSA

* aidid@ksu.edu.sa

Keywords: conversion, Fe-loading, lanthanum, methane decomposition

1 Introduction

The catalytic methane decomposition ($CH_4 \rightarrow C+H_2$) produces carbon oxides–free hydrogen and carbon nanomaterial [1]. Hydrogen is presently seen for halfway point as a promising energy route in both power generation and transport sectors [2,3]. The conventional processes: steam reforming, partial oxidation, and auto-thermal reforming of natural gas incur excessive costs in purification of hydrogen from coproduced carbon oxides [4,5]. In the present work, thermo-catalytic methane decomposition was studied to promote the catalytic activity and stability for simultaneous production of pure hydrogen and elemental carbon. The produced nanotubes avail in numerous new technologies. Iron supported on Lanthanum catalyst was used to measure the activity performance. Effect of different active metal loadings on hydrogen and carbon yield at 700□C was investigated.

2 Experimental/methodology

Iron supported over lanthanum catalysts were prepared by wet impregnation technique. Various iron loading 20%, 30 and 40% were used. The samples were prepared under constant stirring and fixed temperature of 80°C for 3 h. After that, cooled and dried overnight at 120°C. The samples were then subjected to calcination pretreatment at 500°C for 3 h before taking them to the reactor. The experiments were performed in a fixed bed micro tubular reactor at 700°C, atmospheric pressure and F/W= 66 $mL.min^{-1}.g_{cat}^{-1}$. For each run the catalyst was first activated under H_2 flow (40 $mL.min^{-1}$) at 500°C for 2 h. For composition determination, the outlet gases were passed through online gas chromatography. Catalysts were characterized by BET and TGA techniques.

3 Results and Discussion

The catalytic performance of iron supported catalysts Fe//La_2O_3 at 700°C for 3 h time-on-stream (TOS) is presented in Fig. 1. The supported Fe catalysts with various Fe loading were tested at atmospheric pressure. The activity measurement was obtained from the conversion of methane and the textural and characterization properties of the catalysts were measured by BET and TGA. Fig. 1 depicts that the initial methane conversion increased with the increase of the Fe loading as result of the increase in the active sites. Therefore, 11.0, 33.6 and 42.0% conversions were obtained using 20%, 30% and 40% Fe/La_2O_3 catalysts respectively. The activity performance of 20%Fe/La_2O_3 was the least and decreased progressively with time due to the carbon formation while, the activity for 30 and 40% Fe/La_2O_3 increased as time of reaction increased. The final conversion values for 30% and 40% Fe/La_2O_3 became 62.5 and 65.0 %. The increase of conversion with reaction time was attributed to the deposition of the carbon that affected the space velocity of the outlet gases. Hence, it was apparent from results that the 40% Fe catalyst showed relatively high methane conversion compared with both 20% and 30% Fe catalysts.

Table 1 shows the results of specific surface areas and amount of coke deposits over spent catalysts The BET surface area of fresh Fe/La_2O_3 and therefore activity enhancement were increased with the increase of Fe loading. On the other hand the surface area of the spent catalysts increased

after reaction as result of carbon deposition. The carbon formation also increased with the increase of Fe loading. The activity test and characterization results revealed that the catalyst containing 40wt% Fe over La_2O_3 support presented relatively better catalytic performance among all the tested catalyst.

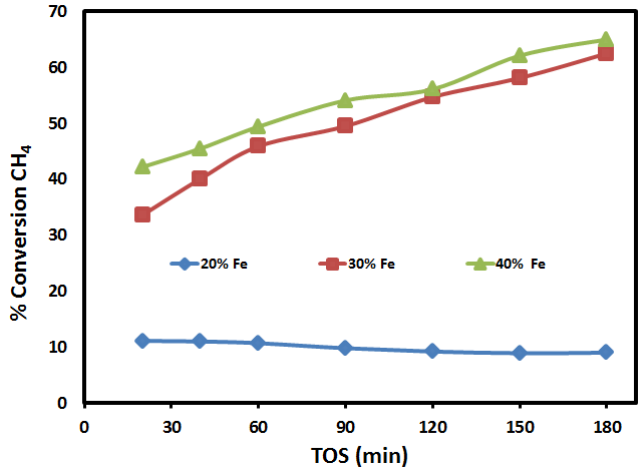

Fig. 1. CH_4 conversion for Fe-La catalysts at 700°C

Table 1. BET surface area and Carbon formation (TGA)

Catalyst loading	Fresh S_{BET} (m^2g^{-1})	Used S_{BET} (m^2g^{-1})	Carbon (%)
20%Fe/La	6.1	10	9.9
30% Fe/La	15.5	42.3	61.8
40% Fe/La	20.1	51.8	75.4

4 Conclusions

In the present study, Catalytic methane decomposition using Fe based catalysts supported over La_2O_3, has been investigated. The results revealed that Fe supported catalysts produced pure hydrogen and nanotubes. 40% Iron catalysts gave relatively better conversion and stability performances.

1 Introduction

Minimizing the deactivation of supported metal catalysts by coke is a major challenge for the catalytic science, which can have a far-reaching impact on many industrial applications. Coke deposits are typically formed from deeply dehydrogenated hydrocarbon precursors either by polymerization/aromatization reactions or by the growth of graphitic carbon from C1 species. Moreover, the graphitic carbon can grow via different mechanisms, depending on the solubility of carbon in the active metal. In this study, the grapheme formation and burning is investigated on Pt/Mg(Al)O_x catalysts. Due to the basicity of the support and low solubility of carbon in Pt, the coke deposits formed on these catalysts are comprised exclusively of grapheme sheets which are continuously shifted from Pt nanoparticles onto the support surface. It is demonstrated herein that the process of burning off these chemically-uniform graphene deposits is rather complex, and its kinetics is governed by the reaction/transport interplay.

2 Experimental/methodology

Pt/Mg(Al)O_x catalysts were prepared by wet impregnation of $Pt(acac)_2$ onto calcined Mg(Al)O_x precursors [1]. In atmospheric flow TPO experiments, freshly reduced catalysts were coked in a 60 ml/min atmospheric pressure flow of 5% C_3H_8 in He for 15 minutes at 923 K. After coking, the catalyst was cooled to room temperature in He and then heated up to 873 K in the flow of 100% O_2 with a linear temperature ramp. Experiments were repeated with the ramps of 5, 7, 10, and 15 K/min to evaluate the activation energies using Kissinger plots. Spent catalysts after coking and after partial burn-off of coke were analysed ex-situ using HRTEM imaging and Raman spectroscopy. In TAP pulse-response experiments, freshly reduced catalysts were subjected to a series of C_3H_8 pulses at 923 K until no changes were observed in the conversion of propane and the yield of propylene. The coke formed during this pulse-sequence was burned-off at a constant temperature by pulsing pure O_2 while monitoring the CO_2 signal.

3 Results and discussion

When fresh catalysts were exposed to the propane feed, a short period of extrinsic relaxation was observed, during which the selectivity towards propylene was low and the main product was methane [1]. By the end of the relaxation period, non-selective hydrogenolysis sites were mostly blocked by coke, and the reaction proceed with near 95% selectivity towards propylene. The coke deposited under reactive conditions for 15 minutes was subjected to TPO, resulting in two CO_2 peaks at ~660 K and ~808 K. The activation energies of carbon burn-off were estimated as 107 and 185 kJ/mol, respectively. In another experiment, the TPO treatment was discontinued after the exhaustion of the first, low-temperature peak, and the catalyst was quenched to room temperature. Both, completely coked and partially regenerated samples were examined by HRTEM and Raman, which confirmed the deposition of graphene sheets on Pt

nanoparticles and support (Fig 1D).

From TPO patterns, it was reasonable to suggest that the low-temperature peak corresponds to coke on Pt sites, while the high-temperature peak corresponds to coke on the support. However, HRTEM revealed that coke burned within the low-temperature peak included the coke from both locations. The remaining coke corresponding to the high-temperature peak was located in tight encapsulating layers around large nanoparticles [2] and in the pockets of the support surface devoid of small Pt nanoparticles (Fig 1C,D).

During the burn-off of coke deposits in the isothermal pulse mode (TAP), the CO_2 response exhibited two distinct peaks. The earlier peak appears at the same time throughout the pulsing sequence (Fig 1A,B). The later peak drifts to much later times, as more and more coke was burned. These results suggest that a transport process of either oxygen or carbon is involved in the production of CO2 corresponding to this later peak.

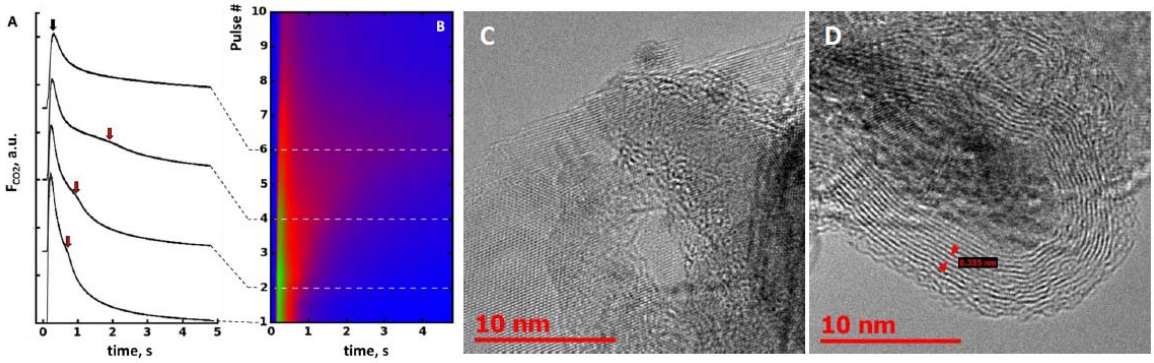

Fig. 1. Oxidation of graphene on Pt/Mg(Al)O_x catalysts: (A) CO_2 response during pulsed oxidation in TAP. Notice the evolution of the slower peak marked with red arrow; (B) Overview of the entire oxidation pulse sequence. CO_2 intensity as a function of time (x-axis) and pulse number (y-axis); (C) Residual coke in Pt-poor regions after burning of the low-temperature peak in TPO experiments; (D) Residual coke encapsulating large Pt nanoparticles.

4 Conclusions

The deposition and oxidation of graphene sheets were investigated by TPO, isothermal pulsed oxidation in TAP, HRTEM, and Raman spectroscopy. Based on our findings it can be concluded that even chemically-uniform graphene deposits on the surface of supported Pt catalysts may result is a complex oxidation behaviour controlled by a transport/reaction interplay. The assignment of distinct TPO peaks is not straightforward and does not follow simplified concepts such as coke on metal vs coke on support. Instead, the peaks are distinguished based on a commensurate availability of oxygen and carbon within the complex landscape of the catalyst surface. This results will contribute to better understanding of the coking process and to optimizing the catalyst regeneration protocols.

Keywords: electron-acceptor sites, EPR, 1-chlorobutane dehydrochlorination, MgO, Al_2O_3

1 Introduction

One of the most intriguing properties of many heterogeneous acid catalysts is their ability to generate spontaneously organic radical cations upon adsorption of aromatic electron donors [1]. ZSM-5 zeolites and sulfated zirconia materials possessing exceptionally strong electron-acceptor sites capable of ionizing compounds with very high ionization potentials, such as benzene (IP = 9.2 eV) [1]. The existence of weaker electron-acceptor sites with electron affinities ~ 7 eV in large quantities on the surface of many conventional oxides is no less remarkable. Electron-acceptor sites of different strength can be characterized using aromatic probes with different ionization potentials [1, 2].

It was shown earlier that the catalytic activity in dehydrochlorination of 1-chlorobutane over nanocrystalline MgO substantially increases with time due to the MgO conversion to $MgCl_2$ [3]. This increase coupled with a surface area decrease indicates that more active sites are formed on the surface during this reaction. Recently we reported that weak electron-acceptor sites formed due to the MgO halogenation might be responsible for solid-state reaction between nanocrystalline MgO and CF_2Cl_2 [4]. In this study we characterized weak electron-acceptor sites formed during 1-chlorobutane dehydrochlorination using perylene and anthracene as spin probes, and found a good correlation between their concentrations and the catalytic activity.

2 Experimental/methodology

Nanocrystalline and commercial MgO and Al_2O_3 samples were studied in catalytic dehydrochlorination of 1-chlorobutane. The samples were placed in an EPR sample tube, activated in an argon flow for 1 h at the reaction temperature, and subjected to reaction with 1-chlorobutane. 1-Chlorobutane conversion to a mixture of butenes was monitored by gas chromatography. After the reaction was carried out for the desired time, the sample was quickly cooled down to room temperature and filled with a 2×10^{-2} M solution of perylene or anthracene in toluene. The concentration of electron-acceptor sites was determined by integration of the EPR spectra registered immediately after the spin probe adsorption and after additional heating at 80°C for 18 h.

3 Results and discussion

The catalytic activity of nanocrystalline aerogel-prepared MgO was found to increase significantly during the 1-chlorobutane dehydrochlorination reaction, which is accompanied by modification of the MgO surface and bulk with chloride ions. No electron-acceptor sites were observed on the surface of initial MgO samples. They appeared only during the reaction. Their concentration normalized per unit mass gradually increased during the reaction due to the surface chlorination. A good correlation was observed between the catalytic activity and the

concentration of weak electron-acceptor sites (Fig. 1). Commercial MgO sample was substantially less active and showed much lower concentration of electron-acceptor sites.

Al_2O_3 samples are characterized by substantial concentrations of electron-acceptor sites [2]. This made this material much more active, so that similar chlorobutane conversion was achieved at temperature lower by 50°C than on nanocrystalline MgO. The catalytic activity and the concentration of electron-acceptor sites increased during the first 20 min on stream due to the surface chlorination that is known to increase the concentration of electron-acceptor sites [5]. Again a good correlation was observed between the catalytic activity in dehydrochlorination of 1-chlorobutane and the concentration of weak electron-acceptor sites.

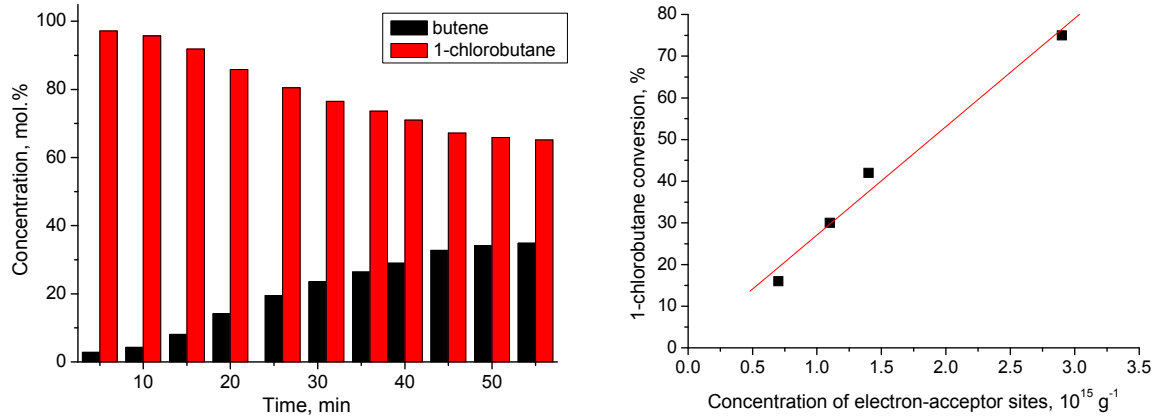

Fig. 1. Concentrations of butene and 1-chlorobutane vs. time on stream for 1-chlorobutane dehydrochlorination over nanocrystalline MgO at 250°C (left) and correlation between the catalytic activity and intensities of EPR spectra observed immediately after perylene adsorption (right).

4 Conclusions

This is the first study where the concentrations of electron-acceptor sites were measured during a catalytic reaction. It is shown that the concentration of weak elector-acceptor sites correlates with the catalytic activity. The obtained results indicate that weak electron-acceptor sites tested using perylene may be the active sites accounting for 1-chlorobutane dehydrochlorination in the active state of the catalysts. It seems to be very important to study possible correlations between the concentrations of electron-acceptor sites and catalytic activity of various catalytic reactions believed to take place on surface acid sites to elucidate the possible role of electron-acceptor sites in these reactions.

Keywords: electron-acceptor sites, acid catalysts, destructive, sorption, EPR

1 Introduction

One of the most intriguing properties of many heterogeneous acid catalysts is their ability to generate organic radical cations upon adsorption of aromatic electron donor molecules [1]. ZSM-5 zeolites and sulfated metal oxides posses exceptionally strong one-electron acceptor sites capable of ionizing compounds with very high ionization potentials, such as benzene (IP = 9.2 eV) [1, 2]. The existence of weaker electron-acceptor sites with electron affinities ~ 7 eV in large quantities on the surface of alumina and some other metal oxides is no less remarkable [2].

Catalysts possessing the strongest electron-acceptor sites show outstanding activity in acid-catalyzed reactions. Earlier we suggested that such strong acceptor sites might be responsible for skeletal isomerization and cracking of light alkanes over sulfated zirconia [3]. We also reported that the catalytic activity of doped alumina catalysts in such conventional acid-catalyzed reaction as ethanol dehydration correlated with the concentration of weaker acceptor sites [4].

In the current communication the properties of electron-acceptor sites of acid catalysts will be explored and their possible structure will be analyzed using DFT quantum chemical simulations. The concentrations of electron-acceptor sites of different strengths were measured for the first time in the course of reaction with the catalytic activity and performance in solid-state destructive adsorption processes. Recommendations on the use of spin probes for testing electron-acceptor sites with different strength will be suggested.

2 Experimental/methodology

Nanocrystalline and commercial MgO, VO_x/MgO and Al_2O_3 samples were studied in catalytic dehydrochlorination of 1-chlorobutane and destructive sorption of CF_2Cl_2. The samples were placed in an EPR sample tube, activated in an argon flow for 1 h at the reaction temperature, and subjected to reaction with the flow containing either the CF_2Cl_2 or 1-chlorobutane at desired temperature. 1-Chlorobutane conversion to a mixture of butenes was monitored by gas chromatography. After the reaction was carried out for the desired time, the sample was quickly cooled to room temperature and filled with a 2 x 10^{-2} M solution of perylene or anthracene in toluene. The concentration of electron-acceptor sites was determined by integration of the EPR spectra registered immediately after the spin probe adsorption and after additional heating at 80°C for 18 h. Quantum chemical simulations were carried out by DFT method using Gaussian 09 software, B1B95 hybrid functional and 6-31+G(d,p) basis set.

3 Results and discussion

The electron-acceptor strength of conventional acid sites usually believed to exist in acid zeolites is below 1 eV and is definitely not sufficient to account for their experimentally observed electron-acceptor properties. We simulated stronger acid/electron-acceptor sites by increasing the distance between the acidic proton and its counter ion. Our simulations show that

such polarization sites are stronger than the conventional sites, but their electron affinity never exceeds ~ 6 eV. This value was obtained for sites where the proton is moved away from the compensating framework ion sufficiently far that it no longer feels the presence of the counter ion. Their acidity is comparable with those of hydronium ions and conventional strong liquid acids. In fact, our calculations show that the strength of such sites is just right for protonating ethanol. So, such sites may account for the activity of conventional solid acid catalysts such as catalytic activity of Al_2O_3 in ethanol dehydration reported to correlate with the concentration of weak electron-acceptor sites [4].

Stronger acceptor sites with electron affinity approaching the experimentally observed value for the strongest electron-acceptor sites (~ 9 eV) could be simulated only as superelectrophilic sites containing two adjacent extra protons solvated by the oxide matrix. Their acidity is sufficient for protonation of light alkanes similar to the one observed in liquid superacids. So, they are likely to account for the activity of sulfated zirconia in this reaction.

Weak electron acceptor sites were found to be formed on the surface of nanocrystalline MgO destructive adsorbents during their solid-state reactions with CF_2Cl_2. This reaction is characterized by an unusual long induction period [5]. Their activity was observed to correlate with the concentration of weak electron-acceptor sites tested by anthracene or perylene.

The catalytic activity of nanocrystalline aerogel-prepared MgO was found to increase significantly during the 1-chlorobutane dehydrochlorination reaction, which is accompanied by modification of the MgO surface and bulk with chloride ions. No electron-acceptor sites were observed on the surface of initial MgO samples. They appeared only during the reaction due to the surface chlorination. A good correlation was observed between the catalytic activity and the concentration of weak electron-acceptor sites. Substantial concentrations of electron-acceptor sites present on Al_2O_3 surface [2] made this material much more active in dehydrochlorination. Similar chlorobutane conversion was achieved at temperature lower by 50°C than on nanocrystalline MgO. Again a good correlation was observed between the catalytic activity in dehydrochlorination of 1-chlorobutane and the concentration of weak electron-acceptor sites.

4 Conclusions

According to the results of our simulations, the experimentally observed high electron affinity of solid acid catalysts can be explained assuming that dissociation to the positive and negative charges occurs on their surface during activation. The resulting sites are remarkably similar in their properties to the species resulting from the electrolytic dissociation of strong homogeneous acids and superacids and accounting for their reactivity. For the first time the concentrations of electron-acceptor sites were measured during catalytic and solid-state reactions. The experimental correlations between the concentrations of the electron-acceptor sites and the catalytic activity in reactions catalyzed by acids suggest that these reactions are likely to occur on such sites rather than on more abundant traditional acid sites. Such sites also seem to be responsible for at least some bulk solid-state reactions.

1 Introduction

"It would be very easy to make an analysis of any complicated chemical substance; all one would have to do would be to look at it and see where the atoms are. The only trouble is that the electron microscope is one hundred times too poor." With this statement R. Feynman has already highlighted the future importance of transmission electron microscopes (TEMs) in 1959.

Nowadays Cs corrected TEMs are powerful enough to obtain point resolution below 50 pm.[1,2] However, direct imaging of light elements next to heavy elements remains complex. In probe corrected scanning transmission electron microscopy (STEM) recent developments tackle this challenge, resulting in the revival of the annular bright field (ABF) detector. In contrary to the contrast detected by the high angle annular dark field (HAADF) method, the ABF detector is also sensitive to light elements.[3,4]

2 Results and discussion

Using the ABF detector, we investigated orthorhombic (Mo,V) oxides crystallized in a structure analog to the M1 structure (ICSD no. 55097) of MoVTeNb oxide. The obtained micrographs were compared with Rietveld refined X-ray diffraction (XRD) and electron paramagnetic resonance (EPR) data. Figure 1 shows an ABF image where the oxygen atoms brighten up. Furthermore we directly measured metal-oxygen bond angles and discussed the oxidation states of the metal centers. Our results prove Feynman´s prediction.

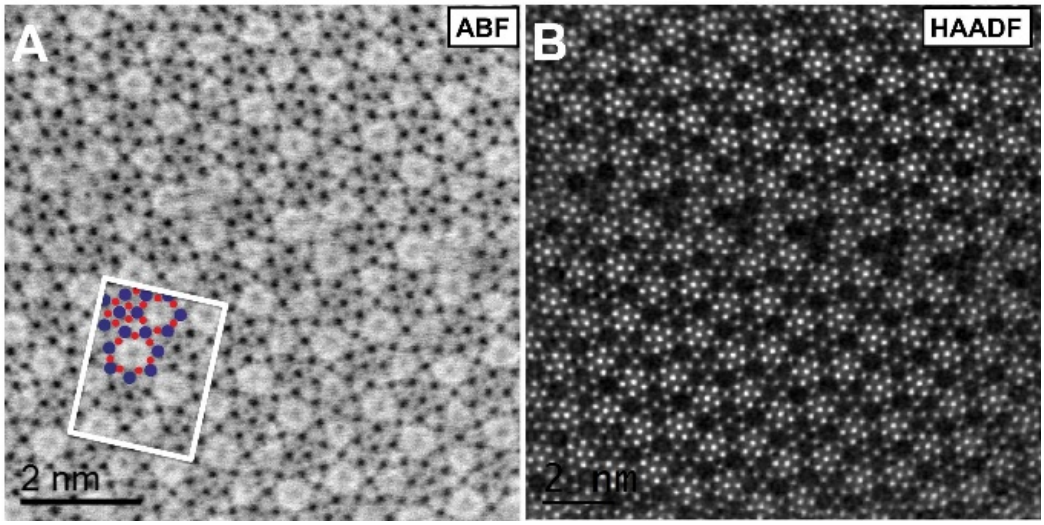

Fig. 1. (A) ABF-STEM image of $(Mo,V)O_x$. The white rectangle displays the orthorhombic unit cell. Metal sites are highlighted blue and oxygen atoms are labeled red. (B) Corresponding HAADF image.

3 Conclusions

Seeing where the atoms are, generates in particular in heterogeneous catalysis a deeper understanding of the functionality of materials on the way towards tailor-made catalysts.

State and the Catalytic Properties of Cu/ZSM-5 in Selective NO Reduction with Propane

Shutilov R.*, Zenkovets G., Gavrilov V.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* shutilov@catalysis.ru

Keywords: Cu/ZSM-5, state and location of copper containing component, SCR of NO with propane

1 Introduction

One of the most common methods of removing nitric oxide from gaseous emissions is the selective catalytic reduction (SCR) of NO to N_2 with propane, over Cu/ZSM-5 catalysts. Is spite of the extensive investigations of the physicochemical and catalytic properties of Cu/ZSM-5 catalysts for a long time, the optimal characteristics of these catalysts have not been determined. Significant factors in the catalytic properties of Cu/ZSM-5 catalysts are the state of copper ions and their location in the zeolite structure. A promising line of investigation of the Cu/ZSM-5 catalysts in order to improve their catalytic properties is to successively study and optimize the main catalyst formation stages with various copper containing precursors. Here, we report the state of copper in the Cu/ZSM5 supported catalysts prepared with ammonia solutions of copper nitrate of different structure and the catalytic properties of these catalysts in the SCR of NO with propane.

2 Experimental

Cu/ZSM-5 catalysts were prepared by ion exchange of the HZSM-5 with Si/Al =17 with aqueous ammonia solution of copper nitrate with NH_4OH/Cu = 23 and 2, which were prepared by dissolving of $Cu(NO_3)_2$ $3H_2O$ (Aldrich) in aqueous ammonia with a preset ammonia concentration. The zeolite was immersed into a solution with a given NH_4OH/Cu ratio and stirred at room temperature for 24 h. The copper concentration in all cases was 10 g/L, the ratio of solution volume to zeolite weight was 10.

Catalysts were investigated with UV-Vis (DRS), IR, ESR, H_2-TPR. Activity measurements in SCR of NO with propane were carried out in fixed-bed quartz flow reactor under steady state conditions. Temperature was measured in the 200–500 °C range, GHSV was 42000 h^{-1}. The reaction mixture was 340 ppm NO, 0.15 vol % C3H8, and Ar as the balance. The NO conversion rate at reaction temperatures of 300 and 400 °C were calculated.

3 Results and discussion

It was shown in [1] that at NH_4OH/Cu = 23 in aqueous ammonia solutions of copper nitrate tetraammine copper association species axially bonded by hydroxyl groups and a weak exchange interaction between Cu^{2+} ions (CC I) are formed. At NH_4OH/Cu = 2–3, Cu^{2+} association yields species with hydroxyl groups in the equatorial plane, water and ammonia molecules in the axial positions, and a strong exchange interaction (CC III) (Fig. 1).

The amount of sorbed copper on zeolite under equilibrium conditions was much larger for CC III than for CC I (3.25 wt % against 1.72 wt %). Investigation of the distribution of copper in the pore space of zeolite by sorption methods and IR spectroscopy of adsorbed CO demonstrated the location copper species mainly on the surface of mesopores formed by the packing of zeolite nanocrystallites. In the Cu/ZSM-5 sample prepared using CC I, the total copper concentration determined by IR spectroscopy is close to the concentration determined by chemical analysis (97%). In the catalyst obtained using CC III, the total copper concentration

determined by IR spectroscopy is 59% of the concentration determined by chemical analysis. This distinction due to CC III yielding larger clusters in which only part of the copper ions is accessible to CO being chemisorbed [2].

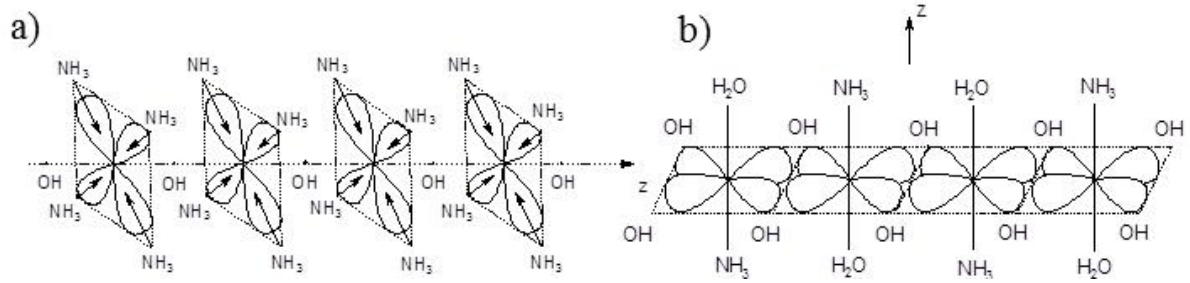

Fig.1 The structure of copper complexes CC I (a) and CC III (b).

The activity of Cu/ZSM-5 obtained using CC I increase with an increasing copper content from 0.5 to 1.72 wt %. The catalyst with 3.15 wt % Cu/ZSM-5 prepared using the CC III is more active than the best of the sample based on CC I (Tabl. 1). The reaction rate per gram of Cu for the catalysts prepared using CC I changes only slightly as the copper content increased. For the catalyst prepared using CC III, the reaction rate is lower than the W values for the catalysts obtained using CC I [3].

Table. 1 Catalytic properties of the Cu/ZSM-5 samples prepared by ion exchange using the CC I and CC III solutions (reaction rates W_m and W were calculated for 275°C)

Cu, wt. %	Type of CC	$T_{X=50\%}$, °C	W_m, 10^{-7} mol NO $g_{cat}^{-1}min^{-1}$	W, 10^{-5} mol NO $g_{Cu}^{-1}min^{-1}$
0.5	CC I	368	2.0	3.9
1.05	CC I	310	3.3	3.6
1.72	CC I	284	6.5	3.8
3.15	CC III	267	9.5	2.9

The main factors determining the catalytic properties of Cu/ZSM5 in the SCR of NO with propane is the optimum size of the copper species located on the zeolite surface that ensures the highest accessibility of the active component to the reactants and the optimum degree of covalence of the Cu–O bond in the species.

4 Conclusions

Catalytic properties of the Cu/ZSM-5 catalyst prepared by ion exchange of the HZSM-5 with aqueous ammonia solution of copper nitrate can be tuned by varying the nature of copper precursor (CC I or CC III). These factors have a significant effect on the copper species located on the surface of zeolite. In the SCR of NO with propane the highest reaction rate per gram of Cu attainable on the catalyst prepared from CC I. This due to the optimum size of Cu^{2+} oxide clusters, which ensures that a large proportion of the active component is have an optimum degree of covalence for the given process involved in the reaction and the copper–oxygen bonds.

In situ XRD Study of Oscillations during the Methane Oxidation over Palladium and Nickel Foils

Saraev A.A.*, Vinokurov Z.S., Shmakov A.N., Kaichev V.V., Bukhtiyarov V.I.

Boreskov Institute of Catalysis, Novosibirsk, Russia

* asaraev@catalysis.ru

Keywords: oscillations, *in situ* XRD, methane oxidation, nickel, palladium

1 Introduction

One of the most interesting and unusual phenomena of catalysis is the rate self-sustained oscillations [1]. To date approximately 70 oscillating heterogeneous catalytic systems are known. Among them are oscillations in the oxidation of light alkanes over transition metals which attract special attention in the last years due to practical importance [2]. The understanding of the origin and the mechanism of these oscillations can open the possibility to perform the catalytic processes more effectively using the unsteady-state operation.

A number of different mechanisms that predict and interpret oscillations in the different heterogeneous catalytic reactions have been developed over the last 30 years [1]. Unfortunately, these findings were mainly based on UHV studies and cannot be directly transferred to technical catalysis. Also the mechanism of originating oscillations at the atmospheric pressure was suggested for methane oxidation over Pd and Ni [3,4]. Nevertheless, in the last case the mechanisms are discussed without any direct evidence. Here we present the first results of an in situ study of the oscillations in the methane oxidation over Pd and Ni foils at the atmospheric pressure. We used time-resolved XRD in situ technique, i.e., while oscillations take place, simultaneously with mass-spectrometry and catalyst temperature measurements.

2 Experimental

The kinetic experiments were performed in a flow quartz reactor. A palladium or nickel foil catalysts were placed in the reactor, and the reactor was inserted and heated in a tubular furnace. The catalyst temperature was measured by a K-type thermocouple spot welded to the center of nickel or palladium foils. The reaction was carried out under atmospheric pressure in a feed gas mixture ($Ar/CH_4/O_2$). The output gas composition was analyzed with a mass spectrometer SRS UGA-100, which was connected to the end of the reactor through a heated stainless steel capillary provided for the pressure reducing. The mass spectrometry data and the catalyst temperature were simultaneously recorded by a real-time data acquisition software. The methane, oxygen, and argon flows were regulated separately with mass-flow controllers Horiba SEC-Z500.

In situ XRD-MS experiments were carried out at the “High Precision Diffractometry” station at Siberian Synchrotron and Terahertz Radiation Center (Novosibirsk, Russia). The diffractometer was equipped with high temperature reaction chamber Anton Paar XRK-900, which allows measuring diffraction patterns within temperature range from RT to 900°C at different environments. The time-resolved XRD experiments were performed using position sensitive parallax-free linear OD-3M detector. X-ray wavelength of 1.724 Å was set by a single reflection from flat perfect crystal monochromator Ge(111). The methane, oxygen, and argon flows were regulated separately with mass-flow controllers Sierra SmartTrak-50. The catalyst temperature was measured by a K-type thermocouple.

3 Results and discussion

The relaxation oscillations in the methane oxidation over palladium were observed in a temperature range of 350-500°C. In case of a nickel foil used as a catalyst the oscillations were observed in a higher temperature range of 650-900°C. It is worth noting that in both cases the oxygen deficient gas mixture was used. The periodic changes in the reactant concentration were accompanied by synchronous variations of the catalyst temperature. In case of Pd during the oscillations the periodic evolution of CO_2 and H_2O and no changes of CO and H_2 signals were observed. It means that the total methane oxidation take place. In case of Ni the products of both the partial and total methane oxidation were detected. The regular oscillations appeared after an induction period, which are characterized by a very low activity of the catalysts. The activated catalyst did not have the induction period. According to SEM the operation of the catalysts under reaction conditions resulted in a development of a rough and highly porous surface structure due to strong restructuring of both the palladium and nickel foils.

Using in situ XRD allows us to find that the phase (and chemical) composition of the surface layer of the palladium and nickel catalysts changes during the oscillations. The periodic changes of XRD reflex intensities corresponding to Pd, PdO, and "PdC_x-like" phases were accompanied by synchronous variations of the catalyst temperature. In the low active state the catalyst surface was oxidized, and transition to the high active state occurred simultaneously with the formation of metallic phase on the catalyst surface. The rise of metallic reflex was accompanied by rising the additional reflex corresponded to a different phase with the larger lattice parameter than the one of metallic phase. We consider that this reflex is due to the formation of "PdC_x-like" phases (a small amount of carbon dissolved into subsurface layers).

On the contrary, for the nickel catalyst no nickel carbide features was detected by XRD. Only XRD reflexes corresponding to Ni and NiO were observed, their intensities were changing in antiphase. It is evident that in the high active state the surface layer of nickel is metal; a transition to the low active state is accompanied by the formation of a surface layer on NiO.

The using in situ techniques for the characterization of catalyst during a reaction under study is more preferable than a classic ex situ approach because it is able to reveal information about the active and inactive catalyst states. This information is invaluable for developing the reaction mechanism.

4 Conclusions

Thus, our study has clearly confirmed that the originating of oscillations in the catalytic oxidation of methane over Pd as well as Ni is determined by the periodic oxidation/reduction of palladium/nickel surface. It was previously shown that a similar mechanism for the self-sustained oscillations is realized in the oxidation of propane on Ni in a deficiency of oxygen at pressures of about 1 mbar [2]. To the best of our knowledge, it is the first direct experimental evidence for the redox mechanism of triggering rate in the oxidation of light alkanes over a transitional metal in the kinetic oscillations.

Temperature Behayiour of the Silane and Germane Molecule Fractures Adsorbed by a Growth Surface in an Epitaxial Process

Orlov L.[1,2], Ivin S.[2*]

Keywords: silane, germane, pyrolysis, kinetics disintegration, growth process, hydrogen

1 Introduction

The effects of the interaction of hydride molecular beams with an epitaxial surface and accompanying phenomena at the gas–solid interface underlie the molecular_beam epitaxy method which is used to solve various problems of microelectronics and nanoelectronics. In the high vacuum layer epitaxy method using high purity chemical compounds as molecular sources, layers are grown under conditions of surface-bond saturation with decomposition products of carrier gas molecules in a relatively wide range of growth temperatures. Under these conditions, the epitaxial_growth process is closely related to trapping mechanisms and features of the pyrolysis of molecules adsorbed by the epitaxial surface. It is clear that it is impossible to achieve the required result in the technology without a detailed understanding of the entire set of processes occurring on the growth surface. Therefore, not only heightened interest in the purely practical problems associated with the fabrication of perfect epitaxial structures has been recently observed in publications, but also particular attention has been paid to an analysis of phenomena occuring on the growth surface of silicon wafers and the layer growth and doping mechanisms. This problem, even in the simplest case of a single component system, is strongly complicated when using molecular flow sources due to the specificity and the diversity of physic-chemical processes in the vicinity of the two phase boundary.

2 Methodology

We discussed the kinetic models of silicon and germanium hydride molecule decomposition on a surface under conditions of epitaxial SiGe layer growth and determined the characteristics of the main kinetic constants responsible for the molecule decomposition rate on the growth surface. A relatively simple technique was developed, which allows not only estimation of the concentrations of molecule fragments adsorbed by the surface, but also an analysis of the dependence of the main kinetic parameters on the gas temperature and pressure in the reactor [1]. Kinetic analysis is most commonly performed using monomolecular pyrolysis models simplified as much as possible. Physicochemical and kinetic models based on this approximation provide quite acceptable understanding of the basic mechanisms of processes and reactions on a wafer surface and allow the possibility of determining the most important kinetic constants, but have also some disadvantages. In this work we are studying the layer growth models considering details of molecule pyrolysis on the growth surface which involve more than one radical fractions by the surface at different sorption process. The difficulties arising in the case of unambiguous description of the corresponding kinetic and temperature dependences are most often associated with the necessity to involve additional experimental data (if such are available), in particular, on the surface concentrations of individual molecule fragments adsorbed by the growth surface. In some cases, problems can also be caused by the cumbersomeness of numerical calculations based on analysis of a set of nonlinear kinetic equations, including a large number of independent parameters [2].

3 Results and discussion

The objective of this study is to derive relations allowing calculation of the disintegration rates of molecule fragments adsorbed by a silicon-germanium growth surface during its interaction with a molecular beams, based on the data of performed technological experiments and kinetic equations. It seems also important to determine the interrelation of the adsorbed molecule decomposition rate to other kinetic coefficients and to understand the effect of selection of the molecular decomposition model on the temperature dependences of the corresponding kinetic coefficients. In contrast to previously considered decomposition models of monosilane SiH_4 and disilane Si_2H_6 [2] molecule with one stable radical on a silicon_wafer surface, in the present study we assume that the hydride molecule is decomposed into at least two different surface radicals, which corresponds to the experimental data obtained by infrared (IR) spectroscopy [3] and mass spectrometry [4]. These results allowed us to study also the peculiarities of the kinetics molecule disintegrations of the gas silane-germane mixture on the SiGe growth surface and to determine the basic kinetics parameters in this process for the temperature range of 450–800°C. The effect of the mechanism of the adsorption of hydrogen atoms and various conditions of their transfer from the molecule to the growth surface on the temperature dependences is considered too. For the disilane pyrolysis, we showed that the disintegration model on two nonidentical fractions (Si_2H_6=SiH_3+SiH_2+H) is best at all hydrogen atoms transfer with molecule on the Si surface. Artifacts which arise on the studied dependences in a high temperature region at use of the one component model (Si_2H_6 = 2SiH_3) [2] for two component model vanish. The characteristic temperature dependences for the disintegration rate of molecule fragments for the disilane (a) and gas mixture (SiH_4+GeH_4) (b) have been studied. We determined the molecular disintegration rates for silane-germane mixture that is shown on figure 1.

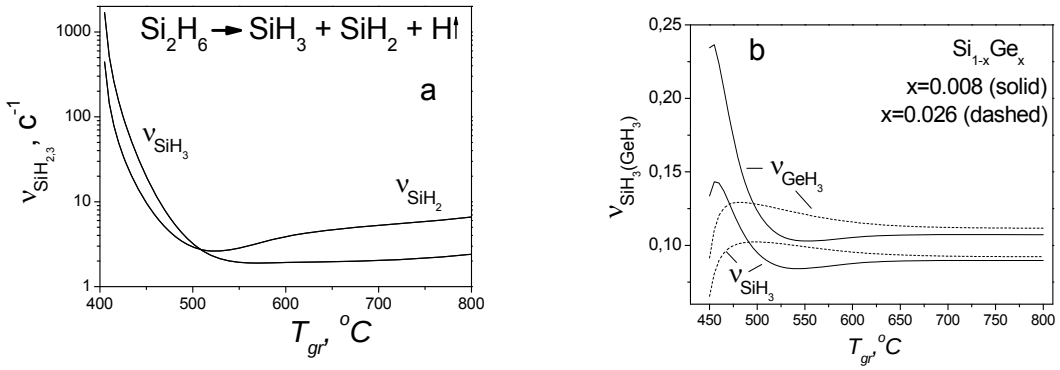

Fig. 1. Temperature dependences of the decomposition rates of the Si_2H_6 molecule fragments $\nu_{SiH2,3}$ on the Si surface for $\theta_{SiH3}/\theta_{SiH2}$ = 3 at disilane disintegration (a) and SiH_4, GeH_4 fragments from gas mixture at $Si_{1-x}Ge_x$ layer growth(b) by UHVCVD method.

Keywords: single crystals, cobalt, alkali metal, scanning tunneling microscopy

1 Introduction

In Fischer – Tropsch synthesis (FTS) [1], natural gas, biomass or coal are converted to liquid fuels via synthesis gas. With respect to Co based catalysts, issues such as the nature of the active site(s), factors controlling the selectivity (C_{5+}, olefin/paraffin), support and promotor effects, and deactivation remain under dicussion. Despite the many investigations applying supported Co catalysts, relativively few model system investigations exist in the literature compared to e.g. precious metals, partly related to difficulties in working with (clean) Co single crystals having a hcp→fcc phase transition at ~420ºC. Investigations of γ-Al_2O_3-supported Co–Re powder catalysts with alkali impurity loadings up to 1000 ppm reported a decrease in catalyst activity during FTS, while the H_2 chemisorption properties [2] and the H_2 and CO differential heats of adsorption [3] remained unaffected. In this project, we investigate the deposition of submonolayer amounts of alkali metals on Co surfaces, and their effect on restructuring and FTS relevant adsorbates.

2 Experimental/methodology

Scanning Tunneling Microscopy (STM) and Low Energy Electron Diffraction (LEED) has been utilized to investigate the adsorption of alkali metals (AM), CO and hydrocarbons on cobalt single crystal surfaces. The AM was deposited from a SAES Getter source at a current of 6.5 A. All measurements were performed at room temperature (RT) and under ultra high vacuum (UHV) conditions. Complementary Density Functional Theory (DFT) investigations of the relevant Co surfaces have been carried out with the Vienna Ab initio Simulation Package (VASP) [4], which utilizes pseudo-potentials and plane wave basis sets.

3 Results and discussion

Figure 1a) and b) compares the clean surface of Co(11-20) with the (n x1) CO-reconstructed surface obtained at saturation level (~6 L). STM images of this surface restructuring was previously reported by Venvik et al.[5], who concluded that migration of Co was involved to give a (3x1) structure in well ordered areas. This provides a starting point for investigating the effect of catalyst poisons and promotors on the surface structure. Figure 1 c) shows the Co(11-20) surface after deposition of submonolayer amounts of K. The LEED images obtained after deposition of K showed a (1x1) structure. Changes to the step edges have been observed during the adsorption of FTS relevant adsorbates on the alkali-precovered surface. It is therefore conjectured that K may be decorating the step edges, as was observed for adsorption of K on the Ni(100)(2×2)p4g-N surface [6]. Results from adsorption experiments on alkali-precovered Co will be presented and discussed along with relevant comparison to modelling investigations.

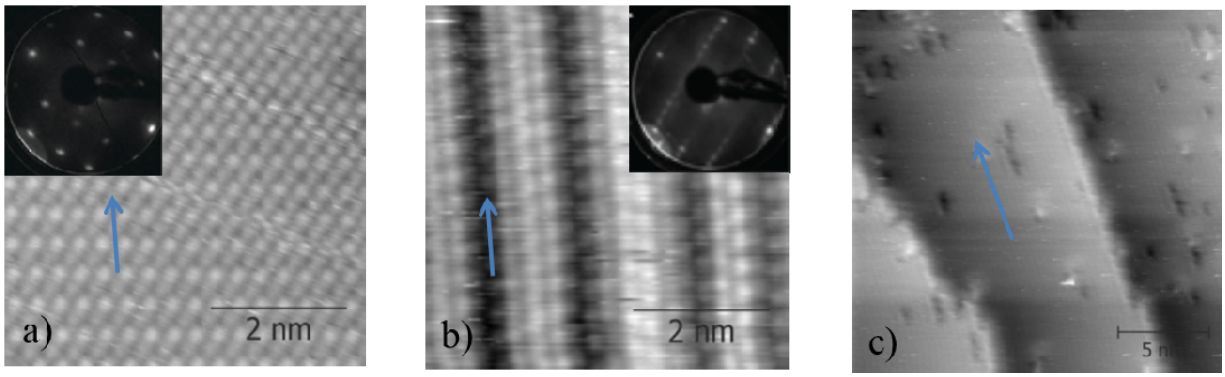

Fig.1. 53x50 Å^2 STM image of the a) clean and b) CO-reconstructed (~6.5 L) Co(11-20) surface with corresponding LEED patterns, and c) 200x200 Å^2 STM image of the Co(11-20) surface after evaporating submonolayer amounts of K from a SAES Getter Source. The [0001]-direction is indicated.

4 Conclusions

Investigations with STM have been carried out on cobalt single crystal surfaces. The preliminary results indicate that submonolayer amounts of deposited K affect the adsorption phenomena occuring during exposure to FTS relevant adsorbates. Further research is required to establish precisely the distribution of K on the single crystal surfaces.

Synthesis of Zeolites from Fly Ashes for Potential Applicationin Environmental Problems

Arroyave M.J., Arboleda E.J.*, Echavarría I.A., Hoyos D.A.

Universidad de Antioquia, Medelín, Colombia

* johana.arboleda@udea.edu.co

Keywords: fly ash, zeolites, alkaline fusion, chromium

1 Introduction

The amount of fly ashes released by factories and thermal power plants has been increasing throughout the world. Several new approaches for disposing this have been taken to reduce the cost of disposal or to minimize environmental impact. Preparation of zeolites from fly ash is one of the approaches which have been receiving a lot of attention as potential replacements for the effective but expensive commercial synthetic materials [1]. One of the most important properties of zeolites are ion exchange capacity that are effective for metal ion adsorption [2]. The properties and chemical composition of fly ashes vary depending on the source and power-plant operation [1,3]. Now, it is particularly important understanding the succession of zeolite formation of different types of fly ashes to provide useful information for the selection of raw fly ashes to synthesize zeolites. Finally we center attention in the environmental significance, of the chromium adsorption onto surface of zeolites synthetized through fly ashes of different sources.

2 Experimental/methodology

Zeolites were prepared by alkaline fusion followed by hydrothermal synthesis. The raw materials were three fly ash from Colombian industry. The fusion process began with mixing fly ash with NaOH powder (fly ash/NaOH 0.8333 in weight) and treating the resulting mixture in air at 700 °C for 3 h at a heating rate of 1 °C/min. After fusion, the powder was dissolved in distilled water (fused fly ash/H_2O 0.2046 g/ml) and sodium aluminate ($NaAlO_2$), followed by aging with stirring for 24 hours at room temperature. The crystallization of the gel was carried out at 100 °C at two different temperatures (24 and 7 hours). Batch processes for chromium adsorption were performed by shaking different amounts of each zeolite (0.01-0.5 g) and 100 mL of chromium solutions with different concentrations. Materials characterization by X-ray diffraction in Panalytical Empyiria 2012 served for identifying phases. Chemical composition were obtained by X-ray fluorescence analysis in Axios MAX (PANalytical). Additionally the materials were characterized by SEM, Surface areas, and thermal analysis. Chromate analyses were determined by atomic absorption spectrophotometry using the Thermo Scintific iCE 3000.

3 Results and discussion

The XRD patterns of the raw fly ashes (Figure 1) consisted mainly of quartz (SiO_2), mullite ($Al_6Si_2O_{13}$) and hematite (Fe_2O_3) as crystalline phases. However diffractogram show evidence ofamorphous phase in the 2θ range of 20-35°. Table 1 shows the elemental composition of fly ashes used in this study which can be classified as Class F according to ASTM C618. The raw fly ashes has 70% SiO_2+ Al_2O_3+Fe_2O_3, with a SiO_2/Al_2O_3 between ratio = 1.47, and low contents of major impurities, such as Fe, Ca and S.

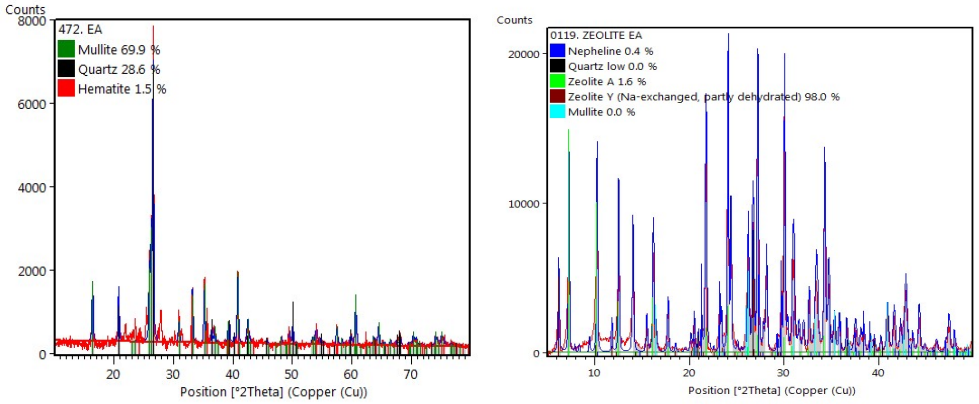

Figure 1. XRD patterns (right:fly ash (EA), left: quantitative refinement of EA/Zeolite Y)

All samples were characterized by X-ray powder diffraction to identify the structure phase and determine the effect of the crystallinity of the structure. Its comparison of peak positions of XRD spectra with reference from PDF4 DATABASE indicating the presence of LTA or FAU phases. As a representative, the X-ray diffraction (XRD) pattern of Slag from food industry (EA) (Figure 1), clearly show XRD pattern of zeolite A without the formation of faujasite. On the other hand, when the fused fly ash solutions were mix with sodium aluminate, faujasite was formed. Furthermore, it was observed that the adsorption percentage of Chromium onto the zeolites synthesized from Colombian fly ashes increased rapidly with increasing adsorbent concentration, as expected.

Table 2 Chemical Compositions and Mean Particle Size of Untreated Fly Ashes

	Slag from food industry (EA)	**Residue from manganese extraction (JMn)**	**Fly ash from textile industry (CTBI)**
SiO_2	46.97	46.78	44.78
Al_2O_3	31.90	15.62	33.63
Fe_2O_3	4.51	14.98	7.16
Na_2O	1.07	---	0.56
K_2O	1.79	2.74	1.41
Other*	13.7	19.82	12.463

* Others include Ti, Mg, P, and S oxides

4 Conclusions

The performed investigations show that a general fusion method can convert several fly ashes with wide variations in composition into zeolite FAU and LTA. Furthermore, the zeolites synthetized were found to successfully remove chromium ions from single aqueous solution.

Spin Probes for Characterization of Active Sites on the Surface of Oxide Catalysts and Prediction of their Catalytic Activity

Volodin A.M.[1*], Bedilo A.F.[1,2]

1 - Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia
2 - Novosibirsk Institute of Technology, Moscow State University of Design and Technology, Novosibirsk, Russia

* volodin@catalysis.ru

Keywords: spin probes, EPR, electron-donor sites, electron-acceptor sites, oxygen, radicals

1 Introduction

Obtaining information on the nature of active sites of heterogeneous catalysts for prediction of their catalytic activity is one of the main goals of physical methods used for investigation of catalysts. Active sites of oxide catalysts are located on their surface, usually are not paramagnetic and in most cases consist of some surface low-coordinated structures. The concentration of such sites is not high. EPR spectroscopy is one of the few physical methods that can reliably deal with such low concentrations. If the active sites are not paramagnetic, their investigation by EPR requires the use of some spin probes forming paramagnetic species after adsorption.

In this communication we shall present the results of the studies carried out at Boreskov Institute of Catalysis SB RAS on application of spin probes for characterization of diamagnetic surface active sites of oxide catalysts. The main goal of these studies is to develop spin probe techniques for determination and characterization of surface active sites that account for catalytic activity of oxide catalysts.

2 Experimental/methodology

To determine a correlation between the concentration of active sites detected by the spin probe method and the catalytic activity, it is necessary to study many samples. Therefore, it is particularly desirable to develop express techniques that do not require "in situ" experiments or vacuum treatment of the samples. In this study we used donor molecules with different ionization potentials (chlorobenzene, toluene, anthracene, perylene) for characterization of electron-acceptor sites with different strengths. Acceptor molecules with different electron affinities (nitrobenzene, 1,3,5-trinitrobenzene) were used for characterization of electron-donor sites. Lewis acid sites were studied using adsorption of stable nitroxyl radicals TEMPO and TEMPONE from toluene solutions. Before the experiments, the catalyst samples were dehydrated in air in quartz EPR tubes at 200-700 °C. Then, they were cooled to room temperature and filled with a solution of the used spin probe. The maximum concentration of the formed radical species corresponded to the concentration of the detected active sites on the surface of the studied catalyst. Some experiments were carried out in an EPR "in situ" installation with adsorption of reagents from the gas phase. Detailed description of the used express techniques and some of their applications were reported in our earlier publications [1-5].

3 Results and discussion

1. It is demonstrated that radical cations formed after adsorption of aromatic molecules with different ionization potentials can be used to determine the concentrations of active sites on the surface of acid catalysts. Using a spin probe with high ionization potential (chlorobenzene), it is possible to detect active sites of sulfated zirconia accounting for isomerization and cracking of light

alkanes [1]. Spin probes with lower ionization potentials (e.g. anthracene) can be used for characterization of active sites on Al_2O_3 accounting for alcohol dehydration [2].

2. Intrinsic electron-donor sites of Al_2O_3 support have been shown to participate in stabilization of atomically dispersed ionic forms of supported Pd. These are the sites accounting for high activity of Pd/Al_2O_3 catalysts in CO oxidation. The activity of such catalysts can be predicted by determining the concentration of electron-donor sites of the surface of such catalysts by measuring the concentration of radical anions formed after adsorption of 1,3,5-trinitrobenzene [5].

3. For characterization of electron-donor and electron-acceptor sites during catalytic and solid-state reactions we developed a novel procedure when the reactions were carried out directly in tubes suitable for EPR measurements. The obtained results indicate that such sites are indeed present during the catalytic reactions and can be measured quantitatively. A good correlation was observed between the rate of the CF_2Cl_2 destructive sorption on nanocrystalline MgO and the concentration of weak electron-acceptor sites characterized using anthracene as a spin probe [4].

4. The concentration of strong Lewis acid sites on the surface of acid catalysts was efficiently measured by titration using adsorption of TEMPONE nitroxyl radical from toluene solution.

5. NO is another spin probe successfully applied by us using "in situ" experiments under vacuum. This paramagnetic molecule proved to be a convenient spin probe for characterization of Lewis acid sites on the surface of oxides where it can be adsorbed at liquid nitrogen temperatures. It was also used for revealing Fe(II) ions, which have even spin and are not observed by EPR, by forming readily observable complexes with S = 3/2 [6].

6. EPR silent oxygen radical anions O^- on the surface of MgO and CaO were revealed using the formation of complexes with molecular oxygen, which are reliably detected by EPR [6]. Characterization of oxygen radical anions is of great interest due to their possible role in photocatalytsis and selective oxidation reactions. It was recently demonstrated by quantum chemical calculations that EPR silent oxygen radical anions might be present under catalytic conditions on the surface of VO_x/TiO_2 catalysts widely used for selective oxidation of various organic substrates [7].

4 Conclusions

The obtained results demonstrate that the spin probe method has great potantial for identification of the active sites of various oxide catalysts. It is shown that in many cases such information can be obtained under relatively simple experimental conditions.

Keywords: Phillips catalyst, Cr-doped porous silica, glass, ethylene polymerization

1 Introduction

The Phillips catalyst is a highly versatile Cr/SiO_2 system accounting for the production of several types of polyethylenes [1]. It is still the subject of an intense industrial and academic research, both from an experimental [2] and theoretical point of view [3]. The determination of the structure of the active sites of the real catalysts remains difficult, although constitutive knowledge about Cr/SiO_2 system has been accumulated on simplified model systems. The sol-gel methods allowing to obtain optically transparent monoliths displaying a high surface area. Both properties facilitate the spectroscopic investigation of the structure and the catalytic activity of metal centres in transmittance geometry in whole UV-Vis-NIR and Mid-IR regions.

Prior to ethylene polymerization, the Phillips-type catalysts have to be "activated" by calcination in air at elevated temperature. During this step Cr ions in the oxidized state (+6) react with the hydroxyl groups at the silica surface and remain anchored in the form of chromates or, less probably, dichromates and polychromates. Simultaneously, molecular water is released through the condensation of surface hydroxyl groups and the formation of strained siloxane bridges; the dehydroxylation process increases with the rise of temperature. A clear relationship between silica hydroxylation degree, properties of the Cr sites, and catalytic activity, is still missing. In the present work we report an experimental study of catalytic activity of the Cr/SiO_2 model systems with different Cr content and the dehydroxylation state of the silica support. The experimental results were then used for validating theoretical models of the Cr/SiO_2 catalyst based on a cluster approach.

2 Experimental/methodology

Tetraethyl orthosilicate (TEOS) was added to a mixture of ethanol and distilled water in molar ratio of 1:4:20, respectively, under stirring at room temperature (RT) [4]. The pH was adjusted to ~1-2 by addition of diluted nitric acid. A proper amount of CrO_3 in water was added to get a set of samples with Cr loading in the 0.01-0.5 wt% range. The mixtures in sealed plastic vessels were kept at 50 °C for 2-3 days until occurrence of gelation. The treatment was followed with a week of aging at 80 °C and that of drying, when vessels were pin-holed and the temperature was gradually rising up to 120 °C. The dry xerogels were calcined at 600 °C for 1 h in air.

The activation procedure consisted of a few successive steps: thermal activation under dynamic vacuum at chosen temperature (550, 650 or 750 °C) for 1 h; oxidation in pure O_2 (100 mbar) for 1 h time of contact with subsequent cooling to 350 °C in the presence of oxygen and evacuation. This allows to prepare three $Cr(VI)/SiO_2$ samples; in order to prepare the corresponding $Cr(II)/SiO_2$ systems, the samples are further treated in presence of CO at 350 °C for 1 h time of contact and evacuation. Then samples are cooled down to RT under dynamic vacuum.

The produced samples were characterized by BET analysis, X-Ray Powder Diffraction, UV-Vis-NIR, FTIR and Raman spectroscopies. The DFT calculations were performed by adopting a cluster approach and Gaussian 09 software.

3 Results and discussion

Fig.1 presents some experimental results (a-d) together with clusters of $Cr_A(II)$ and $Cr_B(II)$ sites adopted to model $Cr(II)/SiO_2$ systems in their highly dehydroxylated form (e) [5].

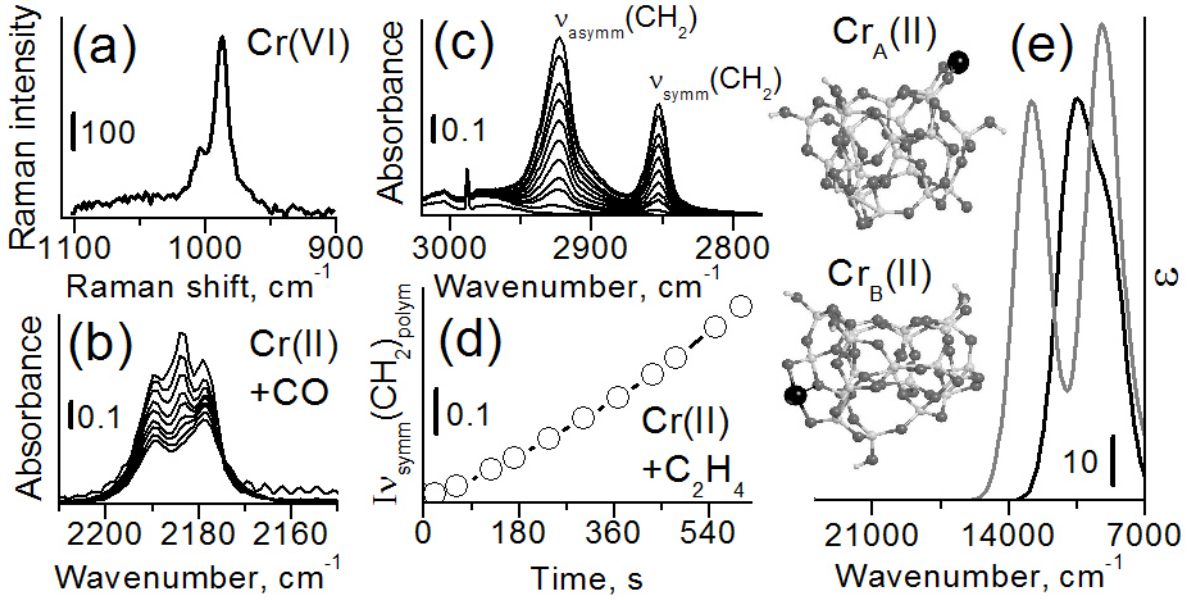

Fig. 1. Experimental results on Cr 0.1 wt% activated at 650 °C: (a) Raman spectrum (325 nm laser line) in air, (b) CO (100 mbar) adsorption on $Cr(II)/SiO_2$ at RT, (c) FTIR of polymerization of C_2H_4 (100 mbar) at RT, (d) the kinetics of C_2H_4 polymerization followed at 2853 cm^{-1}, and graphical representation of $Cr_A(II)$ and $Cr_B(II)$ clusters and computed UV-Vis spectra for both models (e).

4 Conclusions

The Cr-doped silica mesoporous monoliths with high surface area have been synthesised by one-pot sol-gel method. They were employed as a model of Phillips catalyst for fundamental studies on the structure and activity of Cr catalytic centres. Despite extremely low Cr loading, the FTIR of CO probes revealed the families of surface Cr sites, already described for more concentrated Cr/SiO_2 systems. These species readily react at RT with ethylene condensed into the pores, causing a fast growth of polyethylene. A systematic investigation of the hydroxylation state of the surface on the $Cr(II)/SiO_2$ sample as a function of the activation temperature in the 550–750 °C interval was performed in terms of distribution of fully isolated and weakly interacting hydroxyl groups. Experimental observations allowed for development of cluster models of Cr_A and Cr_B sites, which satisfactory reproduce the main experimental data.

* de.chen@ntnu.no

Keywords: rational design, doped, CuCl2/γ- Al_2O_3 catalyst, oxychlorination, UV/Vis spectroscopy, *in situ* spectroscopy

1 Introduction

Oxychlorination of ethylene is the most important route to produce 1, 2-dichloroethane (EDC), which is a key step for poly-vinyl chloride (PVC) [1]. In commercial ethylene oxychlorination reactors, gaseous ethylene, HCl and air react with $CuCl_2/\gamma$-Al_2O_3 catalyst at a temperature range of 217 ^{0}C-257 ^{0}C and a pressure 5-6 atm.

The $CuCl_2/\gamma$-Al_2O_3 catalyst is effective in the oxychlorination of ethylene because $CuCl_2$ can catalyze the conversion of HCl to chlorine. In the literature [2], it has been shown that by feeding the three reactants separately, the oxychlorination reaction is catalyzed by a highly dispersed $CuCl_2$ phase and thereby follows a three step redox mechanism:

Step 1. Reduction of $CuCl_2$ to CuCl.
Step 2. Oxidation of CuCl to form an oxy-chloride.
Step 3. Hydrochlorination of the oxy-chloride using HCl to form $CuCl_2$ and H_2O.

In-situ spectroscopy is an approach to monitor online the physicochemical phenomena of the catalyst material in a reactor [3]. The results from such in-situ study at industrial relevant conditions provide detailed insight into the working principles of the catalytic material. So that it would then be possible to improve the existing catalyst formulations or design completely new catalysts, which are more active and/or selective. In the past [4], an operando XANES and EXAFS have been performed to monitor the Cu^{II} to Cu^{I} transformation in the ethylene oxychlorination environment on the $CuCl_2/\gamma$-Al_2O_3. It has been found that the rate determining step of the overall process (1) is the CuCl oxidation (3). It is noted that the XANES and EXAFS are performed in transition mode, i.e., the catalyst layer is very thin and the space velocity is very high. Therefore, it is difficult for the detailed kinetic study. Hence, we developed an operando set-up to study kinetics of the reaction including catalyst active component involved by combined UV/Vis- and mass spectroscopy, where the reaction conditions and flow can be well controlled in the normal fixed bed reactor.

2 Experimental/methodology

A strategy of combined transient and steady-state kinetic study was employed. The transient kinetic study was performed for individual reaction steps such as the reduction, oxidation and hydrochlorination steps in the catalytic cycle of oxychlorination process. The UV-Vis spectroscopic technique in the reactor focuses on the same spot of a catalyst in a reactor under true reaction conditions and is capable of delivering sub second time resolution. However, in the overall reaction study, the UV-Vis focuses on the same spot of catalysts in the reactor first until the process reached steady-state to get the time resolved kinetic data. After that the whole

catalyst bed of the reactor is scanned by UV-Vis spectroscopy to measure the active Cu^{II} along the reactor axis.

3 Results and discussion

First experiments have been performed by using $CuCl_2/\gamma\text{-}Al_2O_3$ catalyst for individual steps of the oxychlorination process. The change of Cu state from Cu^{II} to Cu^{I} has been studied by the use of UV-Vis spectroscopy, whereas the reaction rate, conversion has been calculated by Mass spectroscopy. It has been found that the rate determining step of the overall process is the CuCl oxidation step. Results obtained from oxychlorination of ethylene on $CuCl_2/\ \gamma\text{-}Al_2O_3$ catalyst, showed a lower reaction rate on the oxidation step (step2) than the reduction step (step1), which leads to deactivation of catalyst due to the excess amount of intermediate (CuCl). Therefore, CeO_2 is used as promoter to enhance the catalytic performance of the reaction by reducing the reaction rate at the reduction step (step1) in one hand and increasing the oxidation rate on the other hand. Various weight percentages of Ceria (1, 3 and 5 wt %) doped with $CuCl_2/\ \gamma\text{-}Al_2O_3$ is been used in several cycles.

4 Conclusions

UV-VIS and Mass Spectroscopies, combined with laboratory techniques made it possible to have a good understanding in kinetic behaviour of the active phase and effects of CeO_2 as promoter for the catalyst. Results show that even low concentrations of ceria in $CuCl_2/\gamma\text{-}Al_2O_3$ can highly enhance catalytic performance of the catalyst however high concentration of CeO_2 has negative impacts on activity of the catalyst.

Keywords: metal dusting, Ni alloys, self-organized catalysts, carbon, fibers, dichloroethane, precursor

1 Introduction

Metal dusting (MD) of bulk metals and alloys (based on Ni, Co or Fe) is well known as catastrophic form of corrosion, which leads to disintegration of initial fabrics into a powdery mixture of graphitic carbon and metal dust. MD occurs in strongly carburizing atmosphere (CO, CO_2, hydrocarbons) at intermediate temperatures of 400-800°C. In the same time, MD process is now considered to be low-cost and efficient route to produce such valuable products as carbon nanomaterials (CNM) including nanotubes and nanofibers [1]. During the process, Fe or Ni nanoparticles which catalyse the growth of CNM, are produced spontaneously from the bulk metal precursors (steel, nichrome, etc.).

In this research we have implemented an earlier developed approach for catalyst preparation which was based on the phenomenon of MD of the standardized bulk Ni-M alloys used as precursors [2]. Being exposed to aggressive reaction medium containing chlorinated hydrocarbons and H_2, the bulk Ni and its alloys undergo very fast disintegration under action of MD resulting in emergence of equivalent active particles catalyzing the growth of nanostructured carbon filaments. Thus prepared self-organized catalytic system was fond to be characterized by very high activity in decomposition of 1,2-dichloroethane (superior to that known for analogous supported catalysts), extreme resistance to deactivation and huge productivity towards carbon nanomaterial exceeding 500 g/g_{Ni} [3].

In the presented study, the bimetallic alloys Ni-M (M=Co, Cu, Fe, Cr, Mo; x=0.01÷0.5) have been synthesized by various methods to be further explored as precursors for preparation of self-organized catalysts active in production of carbon nanomaterials.

2 Experimental/methodology

First series of $Ni_{1-x}M_x$ precursor alloys was synthesized by the coprecipitation technique. The resulted samples of mixed Ni-M hydroxocarbonates were reduced in H_2 flow at 800°C for 30 min to obtain the metallic $Ni_{1-x}M_x$ alloys. Second series of bimetallic Ni-M samples was prepared via mechanochemical activation of the corresponding metallic powders in planetary ball mill AGO-2 at various activation time (τ=0.2÷15 min). Carbon material (Sibunit, S_{BET} = 350 m^2/g) in amount of 5 wt. % was used as a loosening agent.

All Ni-M samples prepared have been tested in quartz flow reactor equipped with McBain balances to study the kinetics of MD in $C_2H_4Cl_2/H_2/Ar$ reaction mix. Reaction temperature was varied in the range of 550-675°C. Physicochemical characterizations of resulted self-organized catalysts as well as the morphology and texture of carbonaceous product were analyzed using microscopy (SEM, TEM), EDX and adsorption method (BET).

3 Results and discussion

XRD patterns revealed that single-phase Ni-M samples were obtained in each case. Shift of the reflexes compared to the position of Ni reflexes (inset) proved the alloys formation (Fig.1).

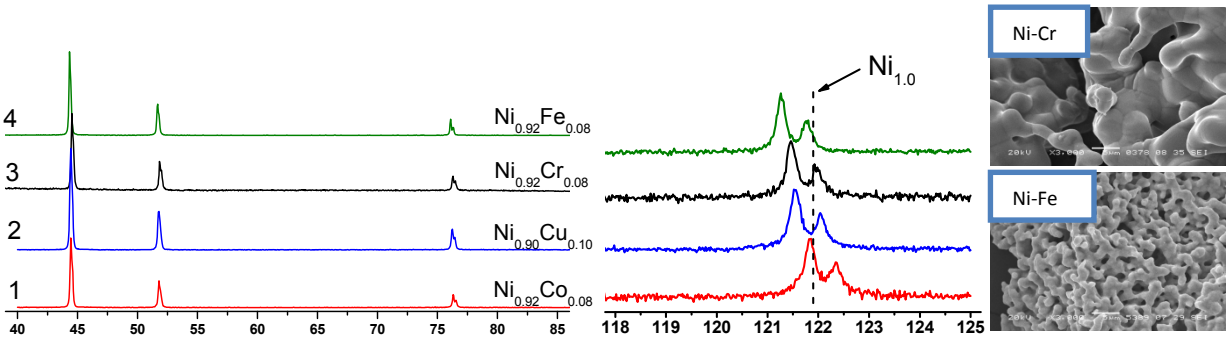

Fig.1. XRD patterns and SEM images for $Ni_{1-x}M_x$ precursor alloys prepared by coprecipitation method. All samples were reduced in H_2 at 800°C.

Results of kinetic studies showed that process of MD of synthesized Ni-M samples is characterized by rather short induction period (less than 30 min) which makes their preliminary activation not necessary. Ni-Mo precursor was found to give the most active catalyst while the best stabilizing effect was elucidated for the addition of Cr. Regardless to initial concentration of Cr added, the resulted disperse Ni particles contained only 0.4-0.6 at. % of chromium.

Disintegration of starting alloys in reaction mixture results in formation of the active metallic sites catalyzing the multi-directional growth of carbon fibers (Fig.2). The grown fibers were found to have submicron diameter and segmented morphology as prevailing. Due to poorly packed and defective structure, the obtained carbon product is characterized with sufficiently high surface area (up to 400 m^2/g) and porosity (0.5-0.8 cm^3/g).

The effect of M and its concentration in Ni-M precursor upon catalytic activity and structural peculiarities of CNM product being formed will be discussed in details.

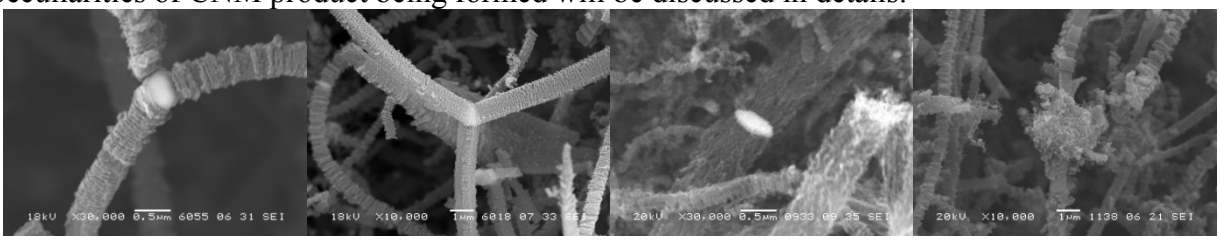

Fig.2. SEM images of active Ni-M particles resulted from disintegration of corresponding alloyed Ni-M precursors (*from left to right*: Ni-Cr, Ni-Fe, Ni-Cu, Ni-Mo). Reaction mix: $C_2H_4Cl_2/H_2/Ar$, 600°C.

4 Conclusions

Metal dusting of Ni-based alloys in aggressive reaction medium can be considered as a new platform for rather simple and effective method to prepare self-organizing catalysts for synthesis of nanostructured carbon materials. Suggested approach is expected to give the great opportunities for purposeful design of catalytic systems with desired properties and unlimited operating durability.

Characterization of the Catalysts with Atomically Dispersed Pd and Rh on Alumina

Vedyagin A.A., Volodin A.M., Stoyanovskii V.O., Kenzhin R.M.

Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

Keywords: noble metal, cations, UV–vis, EPR, luminescence, ethane, hydrogenolysis

1 Introduction

Recent experimental studies have demonstrated that atomically dispersed or sub-nanometer sized ionic clusters of precious metals show the highest activity in a number of oxidation reactions. The nature of oxide support is believed to play the defining role in stabilization of such species in active state. Concentration of intrinsic centers on a surface of γ-Al_2O_3 that are capable to stabilize the supported precious metals in atomic and cluster forms is not that great and usually does not exceed 0.5 wt. % by metal. In the case of Pd and Rh containing catalytic systems there are two main processes known to be responsible for catalyst deactivation. The first one refers to the sintering of dispersed Pd while another process is related to the bulk diffusion of Rh ions into support. The present study aims in a developing of spectroscopic optical, EPR and catalytic (ethane hydrogenolysis) methods for characterization of Pd and Rh state on alumina-based catalysts containing ultra-low concentrations (as low as 0.02 wt. %) of the supported metals.

2 Experimental/methodology

Incipient wetness impregnation was used for the synthesis of Pd and Rh containing catalysts. H_2PdCl_4 (Merk), $RhCl_3 \cdot 4H_2O$ (Merck) and γ-Al_2O_3 (Condea, SSA = 205 m^2/g) were used as the starting materials. After impregnation, the samples were dried and then calcined in air at 630 °C for 12 h [1, 2]. Different concentrations of H_2PdCl_4 and $RhCl_3 \cdot 4H_2O$ in the impregnation solutions were used to obtain the 0.01–0.5 wt. % loadings of the supported metal. The thermal aging of the samples was carried out in air at 830 °C (12 h) and 1000 °C (12 h). In this study, a spin probe technique was used for quantitative and qualitative analysis of the electron-donor sites on the alumina surface. The surface concentrations of Rh and Pd were determined using ethane hydrogenolysis as a test reaction [1, 2].

3 Results and discussion

Deposition of palladium on intrinsic sites on alumina surface which are capable to stabilize Pd in isolated and cluster ionic leads to selective modification of the alumina electron-donor sites. These sites are responsible for appearance and stabilization of TNB radical anions, which could be detected by EPR thereby characterizing the sites. The data presented in Fig.1 show that Pd deposition on Al_2O_3 results in a substantial increase in the concentration of radical anions registered by EPR after TNB adsorption. This increase is readily detectable even at low concentration of deposited palladium (0.06 wt. %, Fig.1).

The diffuse reflectance spectra are known to be sensitive for the Rh state changes during the thermal treatment. Surface Rh^{3+}complexes and Rh^{3+}:γ-Al_2O_3 have d-d bands at 326 and 424 nm, and charge transfer band with the edge at 250 nm. As rhodium leaves the surface, the band becomes narrower without changing its position. Charge transfer bands towards shorter wavelengths as well as d-d shifts were observed in case of bulk Rh^{3+} ions in α-Al_2O_3 indicating a significant increase in magnitude of crystal field for Rh^{3+} in corundum.

Luminescence was observed for Rh^{3+} ($4d^6$) ions occupying low-spin octahedral positions in α-Al_2O_3 only among other transition phases of alumina [1]. The excitation spectrum Rh^{3+}:α-Al_2O_3 consists of two well-resolved bands at 390 and 320 nm corresponding to allowed transitions $^1A_{1g} \rightarrow {}^1T_{1g}$, $^1T_{2g}$ and charge transfer band with the edge at 215 nm (Fig. 2.) Analysis of the concentration of corundum phase in samples with 0.01–0.5 wt. % loadings of Rh after calcination at 1000 °C has suggested a promoting effect of Rh in the formation α-Al_2O_3.

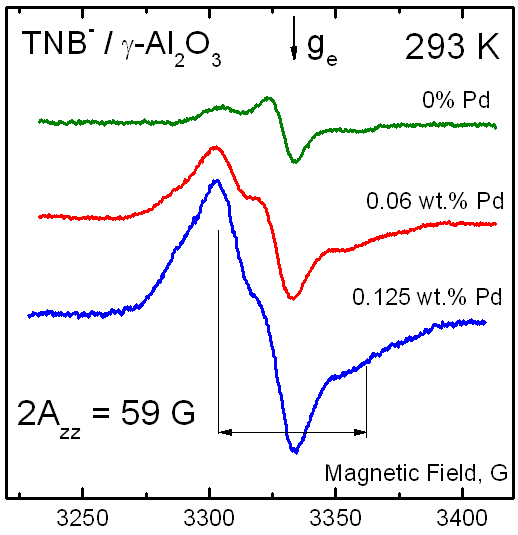

Fig. 1. EPR spectra observed after TNB adsorption on samples with Pd concentrations 0-0.125 wt. %.

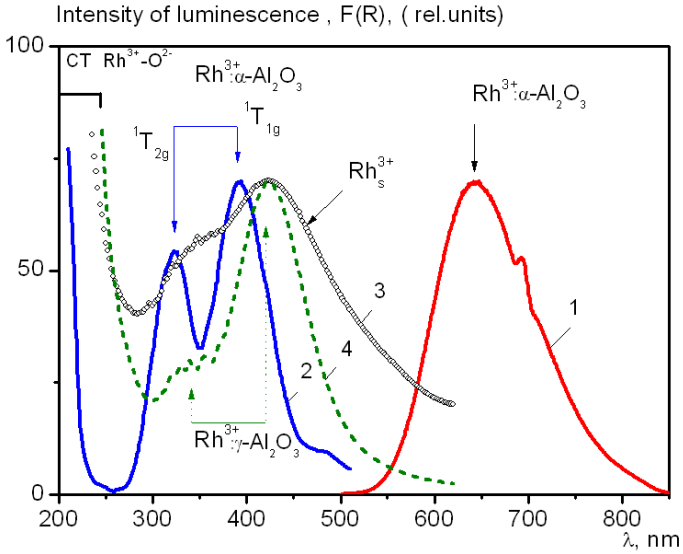

Fig. 2. Luminescence (1) and excitation (2) spectra of Rh^{3+}:α-Al_2O_3. Amplitude normalized diffuse reflectance UV-VIS spectra of Rh/Al_2O after calcination at 600 (3) and 800 °C (4).

The activity of the both Pd and Rh catalysts in ethane hydrogenation correlates with the specific surface area of metal that is proportional to its surface concentration. It was shown that after thermal aging at 830 °C only 9.9% of Rh initial concentration left on the surface. Further treatment at 1000°C resulted in a slight decrease in the concentration down to 8.5% of the initial level.

4 Conclusions

The original highly sensitive spectroscopic optical, EPR and catalytic techniques for characterization of catalysts with atomically dispersed Pd and Rh on alumina will be discussed in details. The methods developed allowed us to investigate such systems with ultra-low concentrations (0.02–0.03 wt. %) of supported metal. In addition to mentioned, these approaches can be successfully applied to study the Pd and Rh state in binary Rh–Pd/Al_2O_3 catalysts [3, 4].

Keywords: metal-organic frameworks, palladium nanoparticles, semihydrogenation, diphenylacetylene

1 Introduction

Selective semihydrogenation of an acetylenic function is a demanding task. Not only does the stereoselectivity (E/Z ratio) need to be controlled, but the hydrogenation of the resulting olefin to alkane must be suppressed as well. During the last decade the metal-organic framewoks (MOFs) received a considerable attention as metal carriers for heterogeneous catalysis, which enable fine tuning the activity and selectivity of the resulted heterogeneous systems [1]. In this study we explored the catalytic performance the novel catalysts on the basis of Pd nanoparticles encapsulated in microporous metal-organic framework MIL-53(Al) in the hydrogenation of diphenylacetylene (DPA) in a liquid phase as the model substrate. Al^{3+}-derived microporous phenylenecarboxylate frameworks, i.e. MIL-53 (Al(OH)bdc, bdc = benzene-1,4-dicarboxylate) was utilized for Pd deposition. MIL-53 (Al) was chosen as a support because of its exceptional thermal stability: the framework crystalline structure remains intact at temperature as high as 450°C [2]. In addition, the aromatic moiety of the framework pore surface facilitates the encapsulation of metal NPs inside the pores. An important task of this research was the elucidation of the impact of the preparation procedure of Pd NP nanocomposites on their catalytic performance. The synthesized palladium-containing catalysts were characterized by a combination of the physico-chemical methods: SEM, DRIFT, selective CO chemosorption, and volumetric N_2 adsorption. The dispersion and location of Pd nanoparticles were examined by XRD, TEM, and XPS.

2 Experimental

Preparation of the Pd@MIL nanocomposites includes the synthesis of metal organic supports and introducing Pd followed by reduction.

MIL-53 Support Preparation. The samples were prepared by hydrothermal reaction between the nitrate salt of the metal ion ($Al(NO_3)_3 \times 9H_2O$) and terephthalic acid (1,4-benzenedicarboxylic acid, H_2bdc) in a Teflon-lined stainless steel Parr autoclave at 220°C for 3 days. To remove the solvent/H_2bdc molecules from MIL-53 pores, further activation treatments of samples were performed by calcinations according to procedure 1 (72 h, 330°C) or procedure 2 (3 h, 450°C) in air.

Catalyst Preparation. Pd (1 wt. %) was deposited by mixing 0.5 g of the parent samples with a $Pd(acac)_2$ solution in absolute chloroform (5.0 mg in 0.30 mL). The 1%Pd@MIL-53 samples were prepared by heating under vacuum at 423 K (4 h). Before reaction the catalyst was additionally activated at 150°C or 300°C in flowing 5%H_2 + Ar.

Characterization of MIL-53 materials.

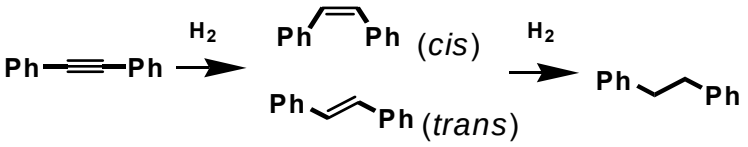
The samples were characterized by a number of physicochemical methods: XRD, SEM, and volumetric N_2 adsorption/desorption. The composition and surface areas of the synthesized MOF supports are given in Table. N_2 adsorption data were obtained at -196°C. The powder XRD pattern were measured in a transmission mode using a Huber G670 Guinier camera diffractometer (CuK_α radiation) at 22°C. Scanning electron microscopy (SEM) studies were performed using a LEO 1455 VP with an XR microanalyzer (Carl Zeiss).

Catalytic tests. The catalysts were tested in the liquid-phase hydrogenation of diphenylacetylene (DPA) at 5 bar of H_2 pressure, room temperature (25°C), using *n*-hexane as a solvent. Substrate/Pd ratio was ~ 4000. Typically, the catalyst (2.5 mg), substrate (170 mg), and solvent (6 ml) were placed into a stainless autoclave, purged by He and pressured with H_2. Stirring was switched on (700 rpm) to start the reaction. H_2 consumption was calculated on the basis of H_2 pressure drop, measured by electronic pressure sensor. The reaction was periodically stopped and the reaction mixture was analyzed by NMR.

3 Results and discussion

XRD and SEM investigation confirmed the retention of crystalline structure of MIL-53(Al) framework upon the Pd NPs introducing and during the reaction. XRD revealed also the significant effect of the introduction procedure of the Pd nanoparticles in the network topology for several samples. Textural properties of microporous metal-organic framework were strongly modified by palladium insertion, leading to significant changes in N_2 sorption properties. TEM and XRD study revealed the average diameter of immobilized Pd nanoparticles of 2-5 nm. Dispersion and location of Pd nanoparticles affected strongly both by MIL-53(Al) activation conditions and reduction procedure of palladium-containing catalyst.

The semihydrogenation of diphenylacetylene proceeds according to consecutive route over Pd/MIL-53(Al) samples (Scheme 1): DPA hydrogenation followed by stilbene hydrogenation. The catalysts demonstrate high activity in this reaction (Table 1).



Scheme 1.

Selectivity in alkene (stylbene) formation exceeds 90% at dipehylacetylene conversion as high as 95%. The catalysts also show high stereoselectivity (E/Z ratio) toward formation of cis-isomer and favorable stability (Table 1).

Table 1. TONs and selectivity parameters in DPA hydrogenation in *n*-C_6H_{14} over Pd/MIL-53(Al) nanocomposites. P_{H2} = 5 bar, T_{react} = 25°C, [DPA]/Pd ~ 4000.

* Metal-organic framework activation procedure (Experimental part).
** Selectivity to alkene and cis-isomer at DPA conversion of 95%.

4 Conclusions

Effective catalysts for selective hydrogenation of DPA to *cis*-stilbene has been developed using the phenylenecarboxyate framework MIL-53(Al) as a host matrix for Pd nanoparticles immobilization. It was found that Pd@MIL-53(Al) catalysts showed favorable activity and selectivity in semihydrogenation even after mild reduction at 150°C. Selectivity of diphenylacetylene transformation into *cis*-stilbene exceeds 94%. Our study revealed a strong impact of parent framework activation conditions on the catalytic performance of Pd@MIL-53(Al) nanocomposites.

Effect of the Synthesis Route on NOx Storage over Ceria/Zirconia Based-Mixed Oxides in LNT Applications

Say Z., Samast Z.A., Ozensoy E.*

Department of Chemistry, Bilkent University, Ankara, Turkey

* ozensoy@fen.bilkent.edu.tr

Keywords: DeNOx, CeO_2, ZrO_2, TPD, LNT, Pt

1 Introduction

CeO_2 can be used as apromoter and/or as a support materialin Three-Way Catalysis (TWC) and Lean NOx Trap (LNT) systems. The primary function of ceria-based stems from theirfavorable redox properties as well thier high oxygen storage and transport capacity [1-3]. ZrO_2can be used together with CeO_2in order to modify surface properties of heterogeneous catalysts that may enhance thermal stability, change surface acidity and improve metal particle dispersion [4,5]. Moreover, ZrO_2 is a promising additive due to its onboard H_2 generation ability via steam reforming reactions [6]. Inthe current study, structural evolution of ternary ($CeO_2/ZrO_2/Al_2O_3$) mixed oxides was followed as a function of temperature by means of XRD, Raman and BET surface area analysis. Moreover, NOx adsorption capabilities of these materials were investigated by means ofin-situ FTIR and TPD techniques [7].

2 Experimental/methodology

Pt/Ce/Al, Pt/Zr/Al, Pt/Ce/Zr/Al and Pt/(Ce-Zr)/Al mixed oxides were synthesized by incipient wetness impregnation method as described in our former reports[2,3]. While subsequent wetness impregnation was used for Pt/Ce/Al, Pt/Zr/Al and Pt/Ce/Zr/Al systems; Pt/(Ce-Zr)/Al catalyst was synthesized via co-impregnation.

3 Results and Discussion

The effect of the synthesis protocol on NO oxidation and relative NO_x adsorption capacity as well as nitrate/nitrite decomposition pathways were studiedvia TPD analysis (Figure 1). Thermal stability of nitrates on Pt/Zr/Al was found to be much higher than that of Pt/Ce/Al, however Pt/(Ce-Zr)/Al revealed the highest NO_x adsorption capacity among all of the investigated materials including the conventional Pt/20BaO/Al benchmark catalyst(Table 1). In other wrords,simultaneous impregnation of CeO_2 and ZrO_2 led to the formation of a mixed oxide(Pt/(Ce-Zr)/Al)that had a superior NOx adsorption ability as compared to the systems where subsequent impregnation was used (*i.e.*Pt/Ce/Zr/Al).Furthermore, CO adsorption experiments via in-situ FTIR spectroscopy(data not shown)indicated a higher dispersion of Pt particles over Pt/(Ce-Zr)/Al as compared to that of Pt/Ce/Zr/Al.It is also worth mentioning that nitrate/nitrite decomposition on Pt/(Ce-Zr)/Al resulted in much higher quantities of N_2 and N_2O compared to that of the other currently investigated catalysts, indicating a greater capability of NO_x reduction. These results indicate that mixed-oxide catalytic systems prepared via co-impregnation method reveal superior catalytic properties as they exhibit higher NO_x storage capability, better Pt dispersion as well as enhanced NO_x reduction ability.

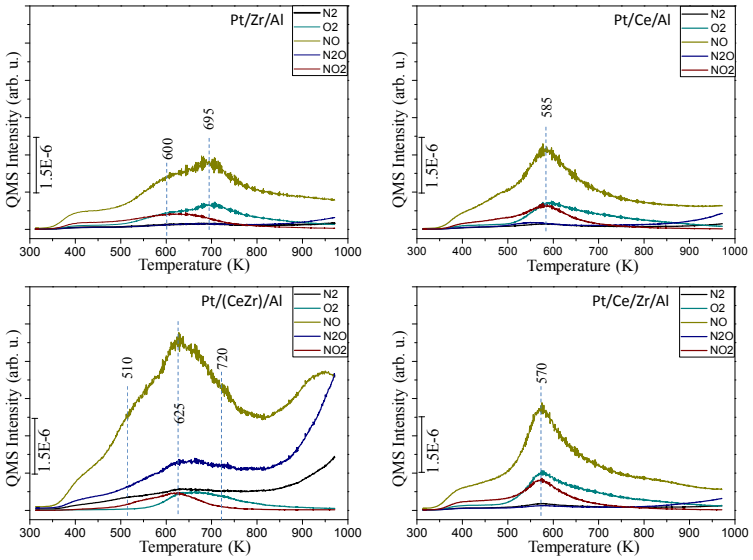

Figure 1. TPD profiles obtained from synthesized materials after adsorption and saturation with NO_2(g) at 323 K for 10 min.

Materials	S_{BET} (m^2/g)	Total integrated areas under NOx-related desorption features in TPD (arb. units)	Total integrated areas under NOx-related desorption features in TPD (arb. units)

Table 1.BET specific surface area values of the investigated catalysts; total integrated areas under NO_x-related desorption features in TPD; and normalized version of these latter values per specific surface area (detailed calculations can be found in Ref.[3]).

4 Conclusions

It is a great challenge to modify surface characteristics of materials in order to achieve superior NOx storage performance. In this study, we investigated the effect of the synthesis route of theternary (CeO_2/ZrO_2/Al_2O_3) mixed oxides on the LNT catalytic properties. The catalyst synthesized viasimultaneous impregnation(i.e. Pt/(CeZr)/Al)revealed superior characteristics with a promising potential in LNT applications.

Keywords: alkylate, alkylation of izobytane, zeolite, dekationation, dealyuminizing, cationic exchange

1 Introduction

Alkylate is one of the most important components of synthetic motor fuel and represents the mix of isoparaffin hydrocarbons with octane number more than 90-94 which is almost not containing aromatic and unsaturated hydrocarbons and possessing stability and detonation firmness in comparison with other components of gasolines. Alkylation of isobutane belongs to the acid catalyzed processes and is traditionally carried out in the presence of the concentrated H_2SO_4 and HF acids. However in connection with strengthening of economic and ecological requirements to industrial processes intensive development of new types of heterogeneous catalysts of alkylation of isobutane which the most perspective are zeolites are conducted now. The gasoline received with application the zeolites of catalysts doesn't contain such polluting impurity compounds as sulfur, nitrogen, oxygen, and also the resinous substances and unsaturated hydrocarbons which are present when cracking oil fractions.

2 Experimental/methodology

Increase of activity of zeolites NaY is conducted, increasing values of the module silicate SiO_2/Al_2O_3 by a dealyuminizing, and changing of molecular sieve, acid and main properties by method by ionic exchange for cations NH_4^+, or 2nd and 3rd valent metals. For optimization technology of synthesis, increase stability and activity, and also decrease in processes of coke production as the promoting additives are chosen: **Cs^+, La^{3+}, Ca^{2+}, Ce^{3+}, Ni^{2+}, Zr^{4+}.** The HCaLa-USY catalyst in a polycationic form on the basis of NaY with the entered ions $Ca^{2+}$and La^{3+} received by methods:

1) 3-stages dekationation of NaY → NH_4Y (fraction of 100-200 microns at mechanical hashing subjected to influence during 1 h in 1,5 M solution $(NH_4)_2SO_4$ with the subsequent washing at 70 °C during 1ch. Further granules filtered and dried at t = 120 °C 4 h).

2) dealyuminizing NH_4Y → H-USY by the method of consecutive deaminization (removal of molecules of NH_3) and thermosteam processing (TSO) at t = 550 °C

3) 2-stages cationic exchange with consecutive replacement of part of the acid centers for Ca^{2+} ions and La^{3+} in 0.75M $CaCl_2$ and $La(NO_3)_3$ solutions respectively at t = 60 °C, washing (t = 120 °C, 4 h), a filtration and TSO: ***H-USY →HCa-USY→HCaLa-USY***

3 Results and discussion

Dealyuminizing and dekationation of ultrastable NaY to H-USY led to decrease in Sud with 898 to 727 m2/g, and also with noticeable change of integrated function of Gammet H0I 11,3→7,7, respectively. About change of a ratio of the silicate module Si/Al illustrating shift of

an intensive strip ~1000 cm-1, characteristic for zeolites, and Si-O-Al relating to antisymmetric valent fluctuations follow from the analysis of IR spectrums. Upon transition from NaY→H-USY there is a decrease in amount of atoms of Al in an elementary lattice of NaY with 55 to 37, raising Si/Al practically in twice with 1,5→2,7. Broadening of a structural and sensitive strip ~ 1000 cm-1 and change of its integrated intensity from 77% (NaY) to 87 (samp. HCaLa-USY), in comparison with an intensive narrow strip of HY-Al-Zr (118%), indicates a rupture of communications and growth of concentration of defects in structures of zeolite.

Table 1. Characteristics of the synthesized samples on the basis of high-silica zeolites

Sample	V_Σ	Vmakro	Vmezo	H_{oI}	Sud	$P_\square$	x,
	cm^3/g				m^2/g	MPas	%
Series on the NaY in polycationic form (NaY + % promotor,2)							
HCaLa-USY	0,56	0,40	0,16	7,3	510	0,6	9,0
HCaLa-USY-Ni	0,52	0,39	0,13	7,1	500/13**	0,8	6.5
HCaCe-USY	0,49	0,33	0,16	7,2	490	0,7	11,0
HCaCe-USY-Ni	0,42	0,33	0,12	7,4	480/13**	0,7	10.5
Series on the NaY + PB + % promotor Me							
HY-Al-Zr	0,49	0,21	0,28	5,8	144	1,1	98,6
HY-Al- Ce	0,41	0,32	0,20	7.6	141	1,0	34.5
HY-Al-Cs	0,39	0,16	0,28	7.8	150	1,3	23,0

Impregnation by ions of Ca2+-La3+, Ca2+-Ce3+ doesn't influence on the acid properties of the H-USY, but conducts to some growth of extent of conversion with 3,5 to 9,5%, thus all samples in the polycationic form are characterized by close VΣ values = 0,42 - 0,56 cm3/g with prevalence of Vmakro 0,33-0,40 cm3/g, with an obvious tendency to coking up - falling of Sud with 480-500 to 13 m2/g. Change of Si/Al in samples of HY and HCaLa-USY with 2,7 to 7,3 speaks about high degree of ionic exchange, and also ability of cations to settle down in zeolite cavities, impregnation of Ni2+ not considerably affects Si/Al values, acidity and activity.

Use as a binding psevdoboehmit PB (10-30% of mas.) increased durability (P□) it is model more than by 1,5 times (tab. samp. HY-Al-Me). In the studied samples there is a reorganization of porous structure due to growth of volume of mesoporous Vmezo=0,25-0,28 and reduction of Vmakro=0,16-0,32 cm3/g. Sample HY-Al-Cs different low x=23%, is characterized by the developed Vmakro, and neutral range of H0I = 7.8 that apparently is connected with features of an arrangement cations of Cs+ mainly in the centers of six-membered rings of three-dimensional structure. Lower Si/Al value in a sample of HY-Al-Zr (4,6) with amount atoms of Al in a zeolite 30 lattice that in comparison with samples in a polycationic form (Si/Al =7,3, number of atoms Al =10) is connected with additional introduction cations of Al in the form of PB in structure of the catalyst, influencing H0I = 5,8 and activity.

4 Conclusions

Thus, introduction of a certain type of a cation (monocationic form of the catalyst), and also a combination introduction of two and more cations (polycationic form), operating availability of porous structure (a dekationation, a dealyuminizing), it is capable to influence formation of the active centers the zeolitecontaining catalysts, the acid and main characteristics, and activity, modeling the direction and selectivity of process. It is established that conversion of isobutane on the HY-Al-Zr catalyst, makes 98,5% thus the maintenance of C5-C8 fractions in alkylate = 82,7% of masses that testifies to prospects of further researches.

Keywords: carbon nanotube growth, bimetallic catalyst, *in situ* methods, activation

1 Introduction

Multi-walled carbon nanotubes (MWCNTs) are known as one of the most perspective components for numerical composite materials due to their remarkable mechanical, chemical, and electronic properties [1]. Properties of MWCNTs significantly depend on their structure (defectiveness, diameter distribution, morphology of agglomerates, concentration of impurities etc.) which in turn depends on the type of catalyst (nature and dispersion of active metals, nature of support and promoters) and on reaction conditions used during nanotube production. It was found that bimetallic catalysts are more effective than monometallic. In the present paper, we study the formation of the active component of various bimetallic catalysts (Fe-Co, Co-Mn, Fe-Mo, Co-Mo) during MWCNT growth using *in situ* synchrotron radiation X-ray diffraction analysis (SRXRD) and *in situ* XPS in combination with *ex situ* and *in situ* high speed HRTEM, solid-state ^{59}Co NMR, and gas chromatography. HRTEM, Raman data, thermal dependence of conductivity and magnetoresistance measurements were used to characterize relationship between MWCNT defectiveness and catalyst composition.

2 Experimental/methodology

Bimetallic oxide catalysts containing Fe-Co, Co-Mn, Fe-Mo, Co-Mo were produced via polymerized complex route based on the Pechini-type method [2,3], which provides the production of highly dispersed oxide systems containing homogeneously distributed metal ions of active components and support. MWCNTs were synthesized in a flow integral reactor via ethylene decomposition on the catalyst surface at 600-680ºC (C_2H_4 : Ar mixture 1:1, 15–60 min). Active metal particles were generated *in situ* on the surface of oxide matrix during catalyst reduction by ethylene.

Catalyst structural changes and MWCNT morphology were monitored by HRTEM and SEM. *In situ* SRXRD measurements at 20–700ºC were carried out with XRK-900 reactor chamber (Anton Paar, Austria) equipped with fast, parallax-free one-coordinate X-ray detector OD-3M-350 in Siberian Synchrotron and Terahertz Radiation Centre. *In-situ* XPS spectra were obtained by a SPECS X-ray photoelectron spectrometer with PHOIBOS-150-MCD-9 analyzer at 600-700 ºC in 5-10^{-6} Torr C_2H_4. ^{59}Co NMR experiments were performed on Bruker Avance II NMR spectrometer outside of magnet using high power broadband probe. The Raman spectra of MWCNT powders have been measured with a Jobin Yvon S-3000 spectrometer (Ar–Kr laser, 514.5 nm) in microscopic configuration with the spectral resolution of 2 cm^{-1}.

3 Results and discussion

According to the XRD data, catalyst active components (alloyed metal particles) are solid or at least contains crystalline core during CNT growth. At the same time alloy particles smaller

than 5-7 nm are roentgen-amorphous in the conditions of the reaction. Sintering rate of active metal particles during catalyst activation is an important factor, which determines the diameter distribution of growing MWCNTs.

For the first time we have obtained data confirming a stepwise formation of bimetallic alloy. It was found that cobalt particles are formed at the first stage of catalyst reduction (Fe-Co catalysts). These primary particles promote (via spillover of activated hydrogen) the reduction of Fe species with the subsequent formation of the alloy. Fig.1A shows in situ XPS data demonstrating different rates of reduction of components of bimetallic Fe-Co/Al_2O_3 catalyst.

Using comparative studies of MWCNTs with HRTEM, Raman data, thermal dependence of conductivity and magnetoresistance measurements it was shown that each type of catalyst promotes formation of MWCNTs with specific properties. Fig. 1B demonstrates almost a linear dependence of a ratio of intensities of 2D (two-phonon scattering) and D (disorder-induced) bands (I_{2D}/I_D) on the mean diameter of MWCNTs produced with two different types of catalysts. It should be mentioned that each type of catalyst provides the linear dependence with its own specific slope. The difference in slope can be explained in terms of differences in kinetics and energy parameters of the main steps of MWCNT growth for different type catalysts. The graphene fragments have been proposed to form a mosaic structure of nanotubewalls .

The obtained data can be used to provide the process kinetic model development and optimize the synthesis conditions to produce MWCNT with controlled properties.

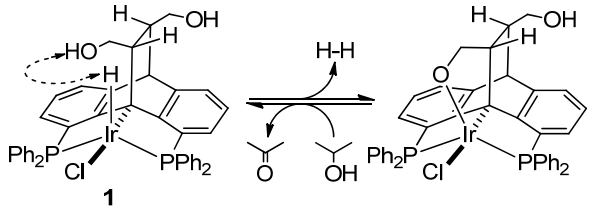
Keywords: iridium hydride, structure, reaction, mechanism, molecular, spectroscopy, DFT

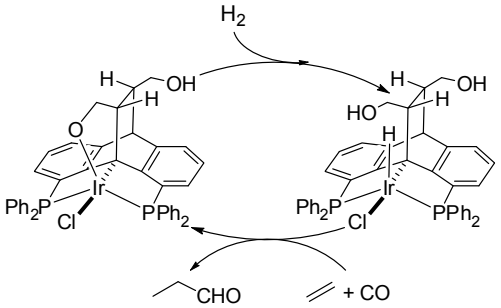
1 Introduction

A variety of recently developed catalysts operate via different ligand-metal cooperating mechanisms and new "non-innocent" ligands and their complexes keep appearing in the literature [1-3]. Reversible switching between different coordination modes found in these compounds opened new practical reactivity patterns in non-oxidative (i.e. alternative to the conventional oxidative addition/reductive elimination sequence) activation and formation of polar and non-polar bonds. At that, many such systems contain stereochemically rigid pincer ligands and keep their geometry during the catalytic runs.

The dibenzobarrelene-based $PC_{sp3}P$ pincer iridium complex **1** is catalytically active in acceptorless dehydrogenation of alcohols (Scheme 1). The intramolecular interaction of hydride with the dangling CH_2OH group that leads to facile hydrogen release was hypothesized as the origin of its high catalytic activity [4]. Indeed, the role of proton-hydride interactions is well recognized in chemistry of transition metal hydrides [5-7]. Herein we present the recent results on the intra- and intermolecular interactions involving hydride ligand and hydroxymethyl groups of **1** and their role in the complex structure and reactivity.



Scheme 1.



Scheme 2.

2 Experimental/methodology

Calculations were performed with the Gaussian09 package at the DFT/M06 level without any ligand simplification and symmetry restrictions. Effective core potentials (ECP) and its associated SDD basis set supplemented with f-polarization functions (SDD(f)) were applied to the Ir atom. The first coordination sphere of Ir (P, H, Cl and C1 atoms), OH and CO groups and all atoms of reactants (C_2H_4, and CO) were described with 6-31++G(d,p) basis set, the rest of atoms - with a 6-31G basis set. The nature of all of the stationary points on the potential energy surface was confirmed by vibrational analysis.

All manipulations were performed under an argon atmosphere using standard Schlenk tech-

nique. NMR investigations were carried out on Bruker AVANCE 600 NMR spectrometers supplied with a specially designed low temperature dual probe-head (SEI, 5 mm tube size). The IR spectra of solutions were measured on Nicolet 6700 FTIR spectrometer in CaF_2 cells using home modified cryostat Carl Zeiss Jena for variable temperature measurements.

3 Results and discussion

The structure of complex **1** differs from that of many other catalysts with "non-innocent" or bifunctional ligands: the hydroxymethyl group is formally far away from the metal. The results of variable temperature IR and NMR (^1H, ^{31}P) analysis of **1** and its analogue – COOEt substituted complex **2** in different media (dichloromethane, toluene, DMSO, and mixed solvents) in combination with the quantum chemical (DFT/M06; AIM) calculations imply flexibility of the dibenzobarrelene-based scaffold [8] unprecedented for conventional pincer ligands. Both the complex **1** and its counterpart **2** prefer facial configuration of the PCP ligand with P-Ir-P angle of ca. 100º. Such geometries are dictated by stabilizing Ir···O interaction and differ by the mutual arrangement of the H and Cl ligands. The complexes show dynamic equilibrium between two most stable *fac*-isomers, which can be transformed into the meridional ones in the presence of coordinating additives (CH_3CN, DMSO or CO, but not Et_3N), some of which have been used as auxiliary base in catalytic alcohols dehydrogenation [4].

A series of stoichiometric and catalytic experiments showed complex **1** is capable of promoting olefin hydroformylation via the metal-ligand cooperating mechanism (Scheme 2) [9]. DFT optimization of some proposed intermediates have been carried out for both hydrogenation and hydroformylation reactions. The mechanism of the H_2 activation and C-H bond formation involves unprecedented intramolecular cooperation between the structurally remote functionality and the metal center. Interestingly the most probable catalytic cycle for hydroformylation/hydrogenation operates via *fac*-form. Model IR studies of *i*PrOH dehydrogenation show higher activity of *fac*-isomer relative to *mer*-one which is further facilitated by addition of Et_3N.

4 Conclusions

The hemilabile CH_2OH group of **1** does not only stabilize active species through the reversible coordination to iridium (Ir···O interaction) but its presence is crucial for catalytic activity. The catalytic reaction mechanism involves intramolecular CH_2OH – Ir cooperation and proceeds without the change of the metal oxidation state.

Manifestation of Resonance Dipole-Dipole Interactions in Spectra of Adsorbed Strongly Absorbing Molecules

Keywords: adsorption, IR, spectroscopy, dynamic interaction, SF6, CF4, NF3

1 Introduction

Lateral interactions, studied in detail by IR spectroscopy for CO adsorbed on metals and oxides , affect greatly the adsorption and catalytic properties of solid surfaces. The method of isotopic dilution enables us to distinguish two kinds of interactions: static effect and the dynamic interaction, referred also as resonance dipole-dipole interaction (RDDI). The former affects the strength of surface sites, while the latter modifies the positions, shapes and widths of absorption bands in the adsorbed molecule spectra, thus distorting the information about surface active sites and the geometry of adsorbed layer. It accounts also for the surface vibrational energy transfer and, thus, plays an important role in catalytic and photocatalytic reactions.

The RDDI manifests itself in vibrational spectra of molecular systems when molecules have large derivative of the dipole moment, i.e. high absorbance. This should be taken into account when the spectra of strongly absorbing molecules are investigated. The aim of this study was to find out the manifestations of the RDDI in spectra of SF_6, CF_4 and NF_3 molecules adsorbed on the surface of amorphous or crystalline oxide adsorbents.

A previous study has shown that the position and band shapes depend critically on the mutual transition dipole moment orientation in the laboratory frame. For the flat oxide surfaces the structure of studied systems can be considered as a 2D adsorbed layer in XY plane perpendicular to Z axis. For SF_6 and CF_4 two collective modes arise in the ν_3 region with the in-plane and perpendicular to the surface orientations of dynamic dipoles. The latter should have a higher frequency and is more sensitive to the influence of the surface.

In adsorbents with channel- like pores the confined molecules form chains that can be considered as 1D (1-dimentional) linear structures. Such model can be used to describe adsorption in silicalite-1, pure siliceous zeolite with ZSM-5 structure. For SF_6 chains the calculated spectrum in the region of ν_3 mode has also a doublet of two components, but with the separation about twice smaller as compared with the spectra of flat layers of the same molecules.

2 Results and discussion

Figure 1 shows the experimental spectra of SF_6 adsorbed on pressed powder samples: ZnO, MgF_2 and CaO, where of 2D adsorbed layers should be formed, as well as on silicalite-1, where 1D chains could be anticipated. For comparison, spectra of solid film of SF_6 on cell windows is also presented. The latter can be considered as a 3D system of interacting molecules.

The spectra of three systems with 2D layers can be considered as a superposition of a couple of two components 44- 62 cm^{-1} apart with one more band at about 944 cm^{-1}. The latter is more intense in the spectra run at higher temperatures and lower coverages, is close to the position of ν_3 band of gaseous SF_6 (949 cm^{-1}) and can be attributed to not interacting single molecules ("2D gas"). Such a band in the spectrum of silicalite-1 appears at 937 cm^{-1}. Its intensity decreases on lowering the temperature, while sharp bands of interacting molecules grow at 949, 929 and 927 cm^{-1} (fig.1 b). Thus, the band becomes split by 20-22 cm^{-1}, the low-

frequency component itself consists of two peaks about 2 cm^{-1} apart.

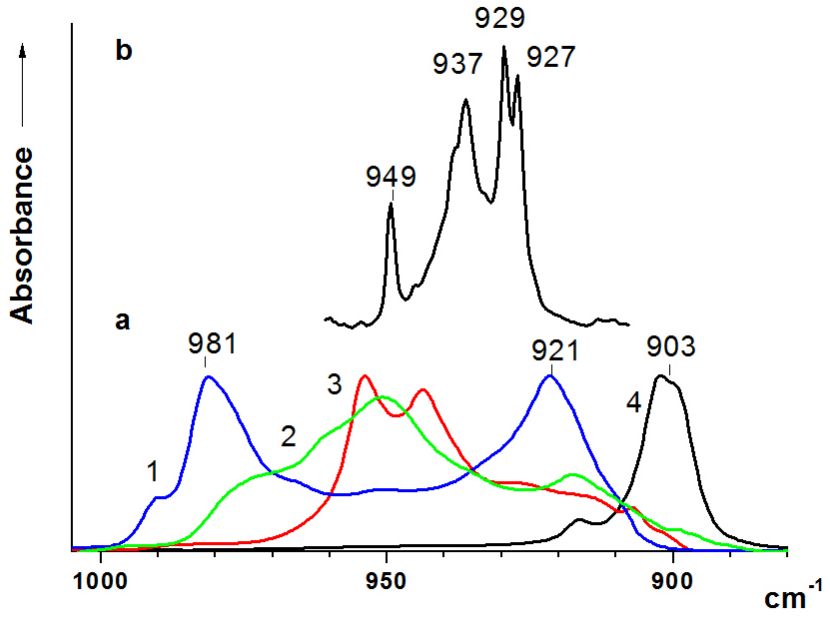

Fig. 1. The region of ν_3 vibration in FTIR spectra of SF_6 adsorbed on: (a) ZnO (1), MgF_2 (2), CaO (3), a solid film on the cell windows (4) and (b) silicalite-1. The spectra were registered with the resolution of 4 cm^{-1} (a) and 1 cm^{-1} (b) at 77K. The presented spectra correspond to maximum surface coverage.

The spectra do not depend seriously on the pretreatment conditions. Two components almost at the same positions were observed for ZnO pretreated at 723 or 773 K, although in the latter case the spectra of adsorbed CO do not reveal the presence of Lewis sites, rather abundant after treatment at lower temperature [5].

Analogous spectra were obtained for ν_3 band of CF_4 adsorbed on ZnO and zeolites. NF_3 molecule has two highly intense IR bands of ν_1 and ν_3 vibrations near 1100 and 900 cm^{-1} [6]. Both the bands of molecules adsorbed on ZnO were found to be distorted by RDD interaction. The observed spectra were consistent with the model, where the molecular axes are perpendicular to the surface.

Thus, this is the RDDI and not the specific adsorption interaction that accounts for the observed bandshape. Moreover, different splitting values for 2D systems and comparison of the observed and calculated spectra enable us to conclude that the intermolecular distances in the adsorbed layers or chains are sensitive to the lattice parameters of the adsorbents, and thus, the adsorbates form rather commensurate layers, than the close packed structures at the surfaces. The bandshape in the IR spectra of adsorbed molecules bears information on the geometry of catalyst surfaces.

Keywords: platinum, surface, oxide, CO oxidation, NO oxidation, operando, STM

1 Introduction

To understand catalytic reactions on surfaces, we need both chemical and structural information on an atomic level of the interface between catalyst and reactants. The surface structure present under reaction conditions is dictated by thermodynamics and the high chemical potential of the gas phase cannot be ignored. Although a high chemical potential can also be achieved by cooling the system to lower temperatures, this will not automatically result in an identical structure. This limitation is most pronounced when atomic mobility is needed to reconstruct the catalytic surface atoms.

Recent developments in instrumentation allow the use of several surface-sensitive techniques at high temperatures and at or near high-pressure conditions. Most of these recently developed tools, such as scanning tunneling microscopy (STM) and surface X-ray diffraction (SXRD), have been used to study CO oxidation over noble metal catalysts [1]. After studying this model catalytic reaction, the focus has shifted towards more complex reactions, such as the oxidation and reduction of NO [2,3], which is of major importance in pollution control.

2 Experimental/methodology

STM is essentially pressure insensitive. We have constructed a complete experimental setup, which integrates a small (0.5 mL) reactor flow cell within an STM. In this microscope, the specimen surface is pressed on an elastomer ring and acts as the top wall of the reactor. The reactor cell with the microscope is housed inside an ultrahigh vacuum system. The vacuum environment allows for traditional surface science preparation and characterization. This reactorSTM enables us to image surfaces and nanoparticle ensembles with high resolution during chemical reactions at high pressures (6 bar) and elevated temperatures (600 K) [4].

3 Results and discussion

Platinum finds its main application as a car catalyst to control the emission of exhaust gases. When the catalyst operates in excess oxygen, platinum catalyzes the oxidation of CO, NO and residual hydrocarbons. Despite platinum's wide use for catalytic oxidation, the active surface phase under oxygen-rich reaction conditions is still highly debated. Traditionally, it was believed that the bare metallic surface was the most reactive. But the recent development of new operando surface science tools has enabled the identification of phase transitions to states of higher activity for CO oxidation. Models, introduced to explain this, range from the formation of a hyperactive oxygen-covered surface to the presence of surfaces oxides or even the growth of a bulk oxide.

For the Pt(111) surface, the facet lowest in energy, it is also not clear what the relevant structure is under oxygen-rich reaction conditions. Both a surface oxide and bulk α-PtO_2 have been found to be stable in different experiments. With the high-pressure, high-temperature reactorSTM, we have studied the oxidation of Pt(111) and have found a stable surface oxide that

assembles in a 'spoke wheel' superstructure at 1 bar O_2 at 430 K as shown in Fig 1A and Fig 1B. Fig 1C shows a proposed structural model of the surface oxide on Pt(111). This surface oxide was also studied during NO oxidation and CO oxidation under reaction conditions.

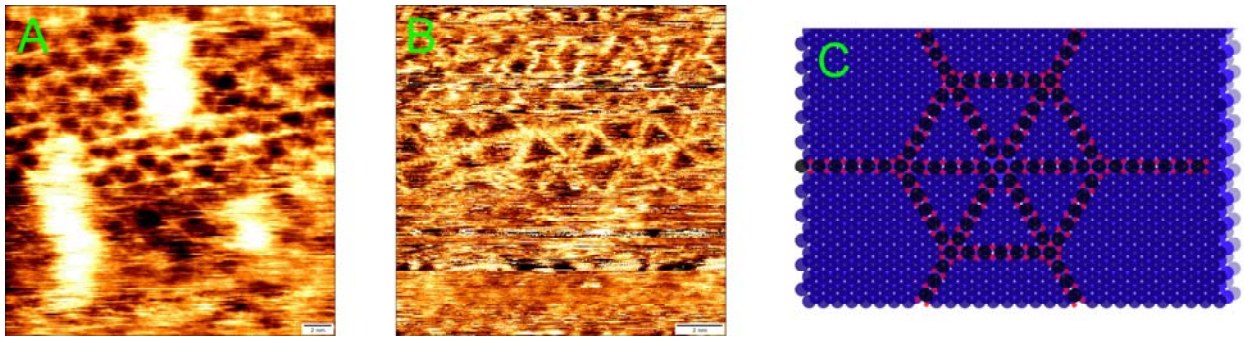

Fig. 1. Two STM images of the surface oxide on Pt(111) under 1.0 bar O_2 and 0.2 bar Ar at 420 K, 24 nm × 24 nm (A) and 15 nm × 15 nm (B). The proposed model, (C), consist of linear change of oxidized Pt rows. O atoms are depicted in red and oxidized Pt atoms in black. The remaining Pt atoms are visualized in blue.

4 Conclusions

We report the formation of surface oxide on Pt(111) that has not been observed previously. This surface oxide forms at high O_2 pressure and at elevated temperature (1.0 bar, 420-520 K). This surface oxide was studied under both NO and CO oxidation and it is believed to be the active phase in these reactions.

Keywords: methane deep oxidation, manganese catalyst, flameless, combustion

1 Introduction

Gaseous hydrocarbons (methane, ethane, and propane) have special significance among the organic fuels. They are mainly used in the form of household and motor fuel or burned in the composition of waste gas in the "torch". Each year, approximately 403 million m^3 of dilute gases (0.5 - 1.0 % CH_4) of coal mines in Kazakhstan is released into the atmosphere without processing. In this case, a potential source of energy is lost and ozone layer of the Earth is destroyed. In this regard, the problem of their efficient processing and optimal use for various technological purposes (production of heat and electricity, as well as organic synthesis) is relevant.

Catalytic oxidation of CH_4 to CO_2 to produce heat is a promising way of utilization of mine, ventilation and burnt in flares methane. Calculating the cost of heat in Gcal produced during deep methane combustion in a pilot plant showed that at the concentration of CH_4 0.6-0.85% it is 0.5-0.6 USD which is below the cost of coal-fired boiler heat. Catalytic combustion is different from thermal combustion, as occurs on the surface of solid catalysts without flame selectively to CO_2 at significantly lower temperatures which avoids the formation of nitrogen oxides and other harmful substances. Unfortunately, most of the known oxide and mixed catalysts other than hexa-aluminate lose activity in the case of overheating (up to 1473K) at methane combustion in heat generators, gas turbines due to their interaction with carriers. Therefore, the development of catalysts complete combustion of CH_4, aimed at improving the thermal stability of oxide contacts due to modification of carriers through the synthesis of perovskites and hexaaluminates is particularly relevant. Development of active polyoxide Mn catalysts and the study of their thermal stability for deep oxidation of lean mixtures of methane to CO_2 for use in catalytic heat generators is the aim of this work.

2 Experimental/methodology

New approaches to the synthesis of thermally stable multicomponent oxide catalysts were used for the development of catalysts for combustion of methane and propane-butane in heat generators. The rare earth elements (REE - La, Ce) and alkaline earth elements (AEE - Ba, Sr) were entered into the composition of supported polyoxide catalysts based on 3d metals (Ni, Cu, Cr, Mn) for the formation of perovskite-like structures and spinels on the surface. The granulated θ-Al_2O_3 (S = 100 m^2/g) modified with cerium, which forms resistant surface $CeAlO_3$ perovskite up to 1373 K was used as a carrier. The oxide catalysts have been promoted with platinum and palladium (0.05 %) to improve the activity and thermal stability.

Catalysts were prepared by capillary impregnation of alumina by mixed aqueous solution of nitrates by incipient wetness, followed by drying at 453-473 K (4-5 h) and calcination at 873 K (1-1.5 h) in air. Activity of catalysts was determined at oxidation of methane by air in flow installation at 673-973 K. Investigation of deep oxidation of CH_4 (0.5-4 %) on catalysts was

carried out by varying the space velocity from 10×10^3 h^{-1} to 20×10^3 h^{-1} and the O_2 concentration from 2 % to 20 %.

3 Results and discussion

It was carried out oxidation of 0.5 % CH_4 in air at GHSV =10×10^3 h^{-1} on the synthesized catalysts after heating at 873 K and 1473 K. Initial contacts allow to obtain 85-99 % conversion at 973 K after heating of catalysts at 873 K for 1 h. Catalysts heated at 873 K for 1 h can be arranged in series according to the degree of oxidation at 973 K: AP-56 (100 %), NiCuCr + Pd (99 %), NiCuCr + Pt (96 %), MnREEAEE/2 % Ce/θ-Al_2O_3 (92 %), NiCuCr/2 % Ce/θ-Al_2O_3 (91 %), MnREEAEE + Pd (90 %), MnREEAEE + Pt (85 %). Contact based on Ni-Cu-Cr/2 % Ce/θ-Al_2O_3 is the most effective catalyst for oxidation of methane at 973 K. This catalyst is similar to the known industrial Pt contact AP-56 (0.56 % Pt). Synthesized contacts were heated in air at 873 K for 1 h, then sequentially at 1073 K, 1273 K, 1373 K and 1473 K for 5 h at each temperature due to the fact that catalysts may be subjected to significant overheating (1473 K) and lose activity during combustion of CH_4.

Heating at high temperatures affects in different ways on the degree of oxidation of CH_4 on different catalysts. Heating of catalysts at 1473 K resulted in a significant decrease in the surface of catalysts. High temperature heating had no negative effect on the degree of oxidation of CH_4 on MnREEAEE catalysts up to 1373 K. Slight decrease in the degree of conversion of CH_4 (not more than 10 %) was observed only in the case of heating at 1473 K in contrast to Pt/Al_2O_3 (AP-56) catalyst the efficiency of which dramatically decreased after 1373 K. As a result, α_{CH4} reached 60 % at 973 K and only 10 % - at 773 K. The activity of MnREEAEE catalyst decreased slightly for the initial and heated samples at 973 K (not more than 2-7 %). A sharp decrease in the degree of conversion of methane occurred after heating starting from 1373 K and especially at 1473 K for Ni-Cu-Cr catalyst. It reached 63 % at 973 K and decreased to "zero" at 773 K. Specific oxidation rate of methane remains constant for MnREEAEE catalyst even as result of heating at 1373-1473 K in contrast to Ni-Cu-Cr catalyst.

It has been shown that MnREEAEE/2 % Ce/θ-Al_2O_3 catalyst is the most thermally stable up to 1473 K in comparative studies of oxide catalysts for the combustion of methane to CO_2. It provided 88-92 % methane oxidation at 973 K and a GHSV of 10×10^3 h^{-1}. The results indicate the greater thermal stability (up to 1473 K) of the Mn-containing contacts with the addition of Ce, La, Ba, and Sr at combustion of methane. It was found that part of oxides form perovskite according to research carried out by ESDR, TPD.

4 Conclusions

It was established that MnREEAEE catalyst supported on 2 % Ce/θ-Al_2O_3 has a higher thermal stability (up to 1473 K) and specific activity in the reaction of deep oxidation of methane, compared to known catalysts (IC-40 and Ni-Cu-Cr/2 % Ce/θ-Al_2O_3) which are used for purification of gases from organic substances and combustion of CH_4. The results indicate the real possibility of practical use of thermally stable up to 1473 K MnREEAEE/2 % Ce/θ-Al_2O_3 catalyst for utilization of lean mixtures of CH_4 in catalytic heat generators. The developed catalyst does not concede to known analogues both in activity and thermal stability, where perovskites and manganese hexaaluminates were used.

Keywords: grafted catalyst, thermostability, cyclohexanol dehydrogenation

1 Introduction

The dehydrogenation of cyclohexanol to cyclohexanone is a necessary stage for obtaining the monomer in the caprolactam production. The process is carried out at low temperature Cu-containing catalysts.

Better selectivity of H3–11 catalyst made by foreign company BASF [1] reaches 99.5% at the experiment temperature of 240 – 250 °C, but its activity does not exceed 50% and is very sensitive to the possible overheating. On exposure to elevated temperatures the copper particles easily migrates along the support surface, sintered to agglomerates, which leads to a reduction of the active surface. The best of native K-CO catalysts [2] are more active, but less selective (97 - 98%) than the H3-11catalyst.

In the Mendeleev University together with LLC "NIAP-Katalizator" there is developed the technology of catalyst dehydrogenation of MAK-K cyclohexanol with grafted nano-structured active component on the surface of silica support.

The technology was tested at the factory. The pilot batch of MAK-K catalyst was prepared.

2 The methods of experiment

The samples of MAK-K catalyst prepared by depositing the active component (AC) from an aqueous solution of ammonium carbonate complex of copper on the carrier under the conditions of intense heat and mass transfer. As the catalyst carrier was used the white carbon powder and active aluminium hydroxide in the form of boehmite, in a weight ratio of 3:1. The finished catalyst contains 20-22 wt. % of CuO and represents the light turquois cylindrical granules with the diameter of 4.5-5.5 mm and a length of 5-12 mm. Measurement of the activity and selectivity of catalyst samples were carried out in a multi-flow type setting at 220 - 250 °C, atmospheric pressure and volumetric feed rate of 1.0 h^{-1}, mounted at JSC "Grodno Azot". Thermostability of catalyst was estimated by the reduction degree of activity after overheating under reaction mixture at volumetric flow rate of 0.5 h^{-1} and a temperature of 350 °C during 16 hours. The total duration of catalyst test sample was 64 hours. Analysis of the reaction mixture was performed by chromatography.

The specific surface area (S_{BET}) was measured by chromatographic method via thermal desorption of nitrogen. The average size of nanostructured crystallite AC ($d_{cr,}$) calculated according to the X-ray phase analysis [3] and by the formula [4]. The mechanical strength (σ) of the samples was estimated by the value of destructive effort on the corn of catalyst.

3 Results and discussion

Selectivity, activity, textural properties and the mechanical strength of MAK–K and H3–11 catalyst samples are shown in the table 1.

Table 1. Characteristics of MAK–K and H3–11 catalysts

Catalyst	Selectivity, %	Activity, %	σ, kg/corn	S_{BET}, m^2/g	d_{cr}, nm
H3–11	99,5 (100 *)	50,0 (29,8*)	75 (10*)	125 (80*)	13 (28*)
MAK–K	99,1 (100 *)	56,6 (48,1*)	30 (36*)	220 (215*)	3,5 (4*)

* values of the catalysts after overheating

It can be seen that both catalysts have approximately equal initial selectivity, high value of which maintained after their thermostability experiment. H3-11 catalyst activity reduces from 50.6% to 29.8% (a change of 41 rel.%) after overheating at 350 °C. Under the same experiment conditions the MAK–K catalyst activity reduces by 15 rel.% from 56.6% to 48.1%. According to the petrography and electron microscopy analyses the particle morphology of AC in the MAK-K remain unchanged in the form of nanoscale clusters associated or included in the structure of the silica. On the contrary, in the H3−11 catalyst the irreversible changes happen associated with reduction of S_{BET} and aggregation of the AC nanoparticles. Their high mobility and lightweight surface migration are due to the weak interaction of the copper component with crystalline silica carrier. According to IR-spectrometry at synthesis MAK catalyst changes the surface properties of the silica component of the carrier due to the enrichment of its hydroxyl group associated with aluminum. As a result, there is a chemical interaction and binding of AC with carrier to form the grafted phase in the stable nanostructured state. The initial strength of the H3−11 catalyst is larger than the strength of MAK−K catalyst, but after overheating and the resulting effects of polymorphic transformation of the carrier is sharply reduces. Mechanical strenght of MAK-K, on the contrary, increase by 15-20% due to the formation of layers of crystallized phase consisting AC (intergrain hardening effect) around the periphery of the grains of the amorphous carrier.

4 Conclusions

The technology of Cu-containing MAK−K catalyst based on the combined aluminum-silica carrier was developed, that provides a uniform distribution of the active component in a stable nano-structured state.

A selectivity of MAK−K corresponds a selectivity of better industrial H3−11catalyst, and its activity and thermostability significantly higher.

Hydrogenation of Benzene in the Presence of Nickel Nanocatalysts Immobilized on Chitosan

Taghiyev D., Zeynalov N.*

Institute of Catalysis and Inorganic Chemistry named after academician M.Nagiyev of NAS of Azerbaijan, Baku, Azerbaijan

* zeynalovnizami3@gmail.com

Keywords: nickel nanoparticles immobilization, chitosan, hydrogenation of benzene, carrier, cyclohexane

1 Introduction

Hydrogenation of aromatic compounds is one of the most important processes both in modern petrochemical industry and thin organic synthesis. In this regard, an essential object is to develop highly-active and selective hydrogenation catalysts providing appropriate results even under low loads and permitting us to regenerate and recycle them. The systems based on nanoparticles of metals are perspective in this respect.

Materials containing metal particles of nanometer size show unique physical-chemical properties and in recent years they have been the object of intensive researches. The use of them as catalysts is of particular interest, because in such systems the share of surface atoms in relation to total number of atoms in a particle is very great and by varying the sizes of nanoparticles we can manage their catalytic properties. Zerovalent complexes and nanoparticles of nickel are more commonly known as effective and selective catalysts of many organic reactions. The basic problem is aggregative instability of metal nanoparticles and their tendency to coarsening. Thus, nanoparticles are fixed on carriers (oxides of metals, zeolites, carbon and et.) or stabilized by adding ligands, including polymers of various types. In the majority of cases it is necessary to find a balance between interaction of nanoparticles with carrier and stabilization of their sizes.

2 Results and discussion

The purpose of our researches is to use chitosan matrix for the synthesis of nickel nanoparticles and evaluation of its catalytic properties in hydrogenation of benzene. To produce nanocomposites of chitosan-metal we used a chemical method which consists of the reduction of metals to the zero state from solutions of their salts with polymer matrix. Because of its specific and high sorption properties; possibilities of developing active surface in the reaction, chitosan is a convenient matrix for chemical reduction of metals in it. It is possible to perform reduction processes with high rate, to produce a considerable amount of reduced metals, to regulate the arrangement (on chitosan or in its volume) and sizes of formed metal particles. N,N´-methylene-bis-acrylamide was used as a cross-linking agent. The stage of depositing metal was performed in the water due to a good solubility of nickel salts in it and ability to swelling of polymers containing amine groups. It was established that because of regular structure of a carrier we can obtain immobilized nanoparticles with narrow size distribution.

We determined the reduction conditions of ion Ni (II) from the solutions of its salts to Ni(0) by using sodium borohydride and hydrazine as a reduction agent in non-soluble chitosan matrix. It was shown that when reducing $NaBH_4$, nickel particles with 12-15 nm radius were formed, but when using hydrazine it is found to be 26 nm. Sizes of particles were determined by X-ray phase analysis.

One of the main requirements to efficiency of catalysts is a high swelling capacity in

reaction media which contributes to the distribution of active centers throughout all the volume. The catalyst obtained by us swells well in reaction medium, during hydrogenation not only its surface but also all its volume operates.

Synthesized nickel nanoparticles were filtered and washed out with water (from unreacted salts of metal and non-complexing polymers) and dried under vacuum at room temperature. Before using the catalyst was activated by gaseous hydrogen. Regeneration of the catalyst must be always carried out in conditions higher than the reaction temperature. Reaction products were analyzed by gas-liquid chromatography method.

Hydrogenation of benzene with chitosan-nickel nanocatalyst was performed at room temperature and atmospheric pressure. The obtained polymer-immobilized nickel nanoparticles show high activity in hydrogenation reaction of benzene and maintain it in repeated cycles. Catalytic properties of nanocomposites depend on producing conditions which impact on the size of the formed nickel nanoparticles.

Cross-linking agent largely determines the sizes of cavities and pores of the material, and therefore, the size of particles and possible diffusion limitations, occurring during the reaction.

We have studied the influence of cross-linking degree on the size and character of distribution of nickel nanoparticles, as well as activity and selectivity of synthesized materials in hydrogenation of benzene in detail.

It is shown that the catalysts based on matrix with high cross-linking degree also showed high activity in hydrogenation of benzene. The selectivity by end product (cyclohexane) turned to be a few per cent more than for analogues with low cross-linking degree.

The influence of the reaction time on selectivity in hydrogenation of benzene with catalyst chitosan-nickel was investigated. It is shown that at an early stage of hydrogenation reaction of benzene (1-1.5 h.) the mixture containing cyclohexadiene, cyclohexene, cyclohexane and benzene was obtained. Then the first two products are partially converted to cyclohexane with overall conversion of benzene to 35-40%. It was found out that up to 50.2% of cyclohexane is produced in the presence of chitosan-nickel nanocatalyst during hydrogenation of benzene for 5 h.

3 Conclusion

The use of nanostructured systems based on cross-linked chitosan carrier permits us to synthesize catalysts of hydrogenation of benzene based on nickel nanoparticles. Variation of cross-linking degree of a carrier permits us to regulate the size of nanoparticles, their activity in hydrogenation of benzene and to influence on substrate selectivity of the process. The studied nanocomposites keep catalytic activity when carrying out repeated cycles of the reactions on them and the fact that they are in immobilized form enables to detect them easily from reaction medium and reuse.

Key Magnetic Intermediates in Rhenium-Based Olefins Metathesis Catalytic Systems

Abbasov Y.[1], Ismailov E.[1*], Tagiyev D.[2]

1 - Institute of petrochemical Processes, Physical and Physical-Chemical Investigations department, Baku, Azerbaijan

2 - Institute of Catalysis and Inorganic Chemistry, Department of Heterogeneous Catalysis, Baku, Azerbaijan

* etibar.ismailov@gmail.com

Keywords: magnetic intermediates, rhenium complexes, metathesis of olefins

1 Introduction

In the last 20 years metathesis has become one of the most powerful method for construction of chemical carbon-carbon bond and is used in chemistry of organic, mono- and polymer materials [1-3]. Three types of metathesis - cross metathesis in which two different alkenes undergo an intermolecular transformation to produce a new olefinic product; ring opening metathesis polymerization, a procedure that involves the opening of cyclic alkenes to give polymeric compounds. ring closing metathesis, which enables the formation of cyclic compounds [4,5]. Although the molecular structures of the active sites in different systems are characterized for a lot olefin metathesis catalytic systems, there is no information about the nature of these sites during catalyst activation and olefin metathesis. The absence of direct characterization during catalyst activation and olefin metathesis prevents accessing fundamental information about the reaction intermediates and reaction mechanism. The absence of direct observation measurements of the catalytic active sites and reaction intermediates during olefin metathesis is one of the primary reasons for the lack of scientific progress in this important field of catalysis.

In this report the results of studies of magnetic intermediates and reactions with their participation in rhenium-based catalytic systems of olefin metathesis are given. Three of the most active metals used in classical olefin metathesis are molybdenum, tungsten and rhenium. However, none of the known compounds of these metals showed activity in the metathesis reaction in the absence of a co-catalyst or activator.

2 Experimental/methodology

It is shown that electron paramagnetic resonance (EPR) technique allow to identify complexes of rhenium with nonzero spin and get sufficient information about the nature of rhenium intermediates and reactions with their participation in catalytic systems of the above processes. Rhenium complexes with nonzero electron spin are identified in olefin metathesis catalyst systems based on complexes of mono-, bi-, hexa -nuclear compounds of different valence of rhenium: $Re(CO)_5X$**;**$Re_2X_4(CH3COO)_4 \cdot 2H_2O$, $[DMFAH]_2Re_6X_{14}$, where (X=Cl, Br).

Figure 1 shows a characteristic paramagnetic rhenium complexes registered in the systems for olefins metathesis based on rhenium complexes and aluminiumorganic compounds.

EPR signals with magnetic resonance parameters (MRP): g_o =2.070, A_o (^{185,187}Re) =321 G at 300K and $g_{\parallel}$=2.135, $g_{\perp}$=2.067, $<g_o>$ =2.098, $A_{\parallel}$ (^{185,187}Re) =469 G, $A_{\perp}$ (^{185,187}Re) =271 G, $<A$ (^{185,187}Re)$>$ =337 G at 77K are registered for the products of the reaction of $Re(CO)_5Br$ with $(C_2H_5)_3Al$ in n- heptane solution. These values of MRP belong to low spin complexes of rhenium with total spin S=1/2 and square-pyramidal structure of a local environment. Results of this work show that in all cases the interaction of rhenium complexes with aluminiumorganic

compounds in solution leads to stable at room temperature paramagnetic complexes with total spin S=1/2 and highly covalent Re-C bond. The formation of paramagnetic rhenium complexes with $Re=CH_2$ bond and total electron spin S = 1/2 is established. The presented spectra are the first direct observation of paramagnetic rhenium intermediates in the catalytic systems for olefin metathesis.

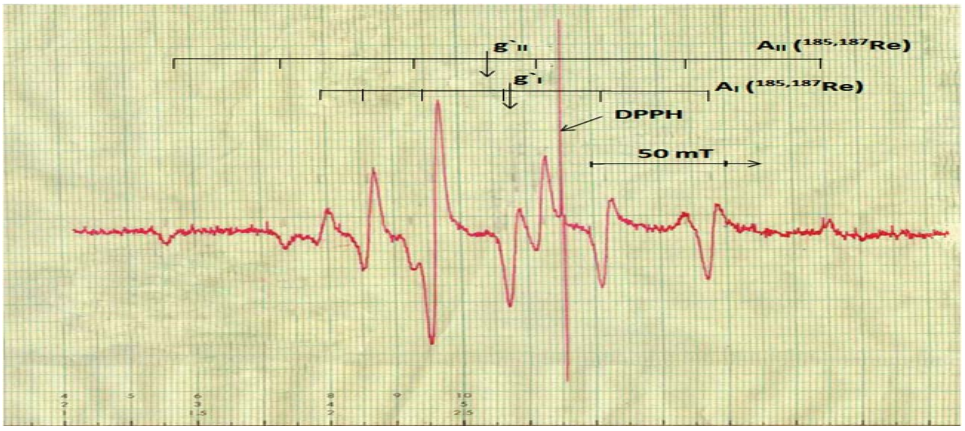

Fig. 1. EPR spectrum at 77K of the $Re(CO)_5Br+Et_2AlCl$ in n-heptane solution after 10 min interaction at room temperature.

3 Conclusions

It is shown that the used electron paramagnetic resonance (EPR) technique allows to identify complexes of rhenium with nonzero spin, to establish the structure of rhenium intermediates and study the reactions with their participation in catalytic systems for olefins metathesis. Rhenium complexes with nonzero electron spin are identified in olefin metathesis catalyst systems based on complexes of mono-, bi-, hexa -nuclear compounds of different valence of rhenium. The formation of paramagnetic rhenium complexes with an electron spin S = 1/2 and paramagnetic complexes with $Re=CH_2$ bond is established. We can also note that in this report the first direct observation of paramagnetic rhenium intermediates in olefin metathesis systems is given. The reactions of intermediates with C_2-C_4 olefins are studied and catalytic cycle involving these intermediates in the metathesis of olefins in these catalyst systems are discussed. The results have methodological value also: the detected signals in the EPR spectra of paramagnetic complexes of rhenium in the Ziegler type catalyst systems consisting of mono-, (bi-, hexa-) nuclear rhenium complexes of different valence and aluminum organic compounds was used to identify paramagnetic rhenium complexes in other systems. Used approaches apparently also render a possibility to understand the nature of rhenium based catalysts activity in olefin metathesis and open for broad and successful future use of rhenium catalysts for this purpose.

Keywords: dibenzothiophene hydrogenolysis, hydrotreating catalyst

1 Introduction

Ni-MoW/Al_2O_3 catalysts, applied for oil fractions hydrotreating, have high hydrogenation, but haven't enough hydrodesulfurization (HDS) activities. Introduction a low concentration of ZnO into hydrotreating catalysts lead to increase in HDS activity [**1, 2**]. This method of modification by transition metal additives is very perspective, like it should be concluded from rare scientific works [**3**]. The growth of HDS up to 20 wt. % of ZnO in work [**3**] in opposite to [**1**] was shown. So, the optimal amount of ZnO, increased HDS, wasn't found. The effect of modification wasn't explained.

2 Experimental/methodology

γ-Al_2O_3 carrier was synthesized from AlOOH (TH-60, «Sasol»). Pore structure was determined by adsorption of nitrogen at 77K (S_{BET} = 205 m^2/g, V =0,682 cm^3/g, $R_{eff.}$ = 48 Å). A line of Ni-MoW/Al_2O_3 catalysts was synthesized by means of wetness impregnation method from aqua solution of Ni, Mo and W compounds ($Ni(NO_3)_2 \cdot 6H_2O$, $H_3PMo_{12}O_{40} \cdot 17H_2O$, $H_3PW_{12}O_{40} \cdot 29H_2O$). Introduction of ZnO was carried out with different methods (**Table 1**). Catalysts were sulphided before catalytic tests. The HR TEM images of active phase were recorded for samples 1-4 after sulphidation. Catalytic activity was determined in a bench-scale flow reactor unit in the hydrogenolysis of dibenzothiophene under the next conditions: hydrogen pressure of 3.00 ± 0.04 MPa, model mixture volume feed of 10.0 ± 0.2 cm^3/h, hydrogen feed of 40 cm^3/min, temperature of 250 ± 1 ^0C. 0.300 ± 0.005 g catalyst with particle size 0.50-0.25 mm was loaded in reactor. Model mixture contained dibenzthiophene (DBT) and isooctane. Every catalytic test was carried out twice. Relative deviation of parallel tests was ± 0,8 %. Hydrogenated products were analyzed by means of gas-liquid chromatography. Identification of products was carried out by combined gas chromatography mass-spectrometry method.

3 Results and discussion

Three lines of Ni-MoW/Al_2O_3 catalysts were synthesized. Samples № 2-4 and № 5-7 had a different order of component introduction. Carriers of samples № 2-4 were prepared by means of Al_2O_3 impregnation with aqua solution of $(CH_3COO)_2Zn \cdot 2H_2O$, than dried (120°C) and calcined at 500°C for 1 hour. Modified ZnO-Al_2O_3 carrier was impregnated with aqua solution of Ni, Mo and W compounds and than dried. Al_2O_3 carriers of catalysts № 5-7 were impregnated with aqua solution of Ni, Mo and W compounds, dried, impregnated with aqua solution of $(CH_3COO)_2Zn \cdot 2H_2O$ and dried again. Catalysts № 8-10 were impregnated with aqua solution of Ni, Mo, W and Zn compounds and dried. Comparison sample was Ni-MoW/Al_2O_3 catalyst without ZnO (№1).

Catalysts have approximately the same loads of NiO, MoO_3, WO_3 and different amounts of ZnO (**Table 1**). Results of catalytic test are presented in **Fig. 1**.

ZnO modification of Al_2O_3 surface changes the morphology of NiMoW(S)/Al_2O_3 catalysts sulfide phases. The increase of sulfide phase slab length from 4,1 to 4,6 and 4,3 nm and number

of layers from 1,5 to 1,9 and 1,7 was found for NiMoW/ZnO-Al_2O_3 catalysts, modified with 0,5 and 1 % ZnO, respectively.

Table 1. Properties of synthesized catalysts

№	Catalyst	Content, wt. %				Synthesis method
		NiO	MoO_3	WO_3	ZnO	
1	NiMoW/Al_2O_3	5,9	13,7	6,0	-	1. Impregnation of γ-Al_2O_3 by solution of Ni, Mo and W compounds.
2	NiMoW/ZnO-Al_2O_3	5,1	14,1	6,0	0,5	1. Impregnation of γ-Al_2O_3 by solution of $(CH_3COO)_2Zn$, drying and calcination. 2. Impregnation of Al_2O_3-ZnO by solution of Ni, Mo and W compounds.
3		5,0	13,4	6,0	1,0	
4		5,4	13,3	6,0	3,0	
5	Zn/NiMoW/Al_2O_3	5,1	13,6	6,0	0,5	1. Impregnation of γ-Al_2O_3 by solution of Ni, Mo and W compounds, drying. 2. Impregnation of NiMoW/Al_2O_3 by solution of $(CH_3COO)_2Zn$, drying.
6		5,8	13,9	6,0	1,0	
7		5,7	13,8	6,0	3,0	
8	NiMoWZn/Al_2O_3	5,7	13,7	6,0	0,4	1. Impregnation of γ-Al_2O_3 by solution of Ni, Mo, W, Zn compounds, drying.
9		5,3	14,2	6,0	0,8	
10		5,8	14,6	6,0	2,4	

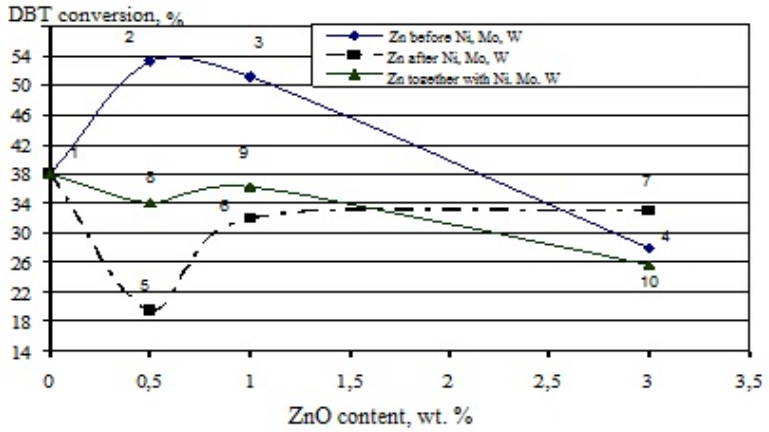

Fig. 1 Relationships between DBT conversions, amounts of ZnO and introduction method (numbers on the curves correspond to samples numbers in Table 1)

The number of multilayer slabs has a linear correlation with DBT HDS activity. Too high dispersion of sulfide phase particles isn't good for DBT HDS activity.

4 Conclusions

Modification of Al_2O_3 with ZnO in amounts of 0.5-1.0 wt. %, followed by introduction of active phase precursors, increases DBT HDS activity from 38 to 54%. Impregnation of dried NiMoW/Al_2O_3 catalysts with solution of $Zn(CH_3COO)_2$ decreases the activity (the minimum of activity in this case was found for NiMoW/Al_2O_3 modified with 0.5 wt.% of ZnO). Parallel introduction of Zn, Ni, Mo and W decreases the catalysts activities in all cases.

Hydrotreating of Vacuum Gas Oil on NiMo/P-γ-Al_2O_3 Catalysts

Maximov N.M.*, Tomina N.N., Solmanov P.S., Pimerzin A.A.

Samara State Technical University, Samara, Russian Federation

Keywords: hydrotreating, vacuum gas oil, phosphorus

1 Introduction

Analysis of works in period of 2009-2014 years showed, that the most frequently method of hydrotreating catalysts modification was introduction of phosphorus on carrier surface. These catalysts have mild acidity (good resistance to deactivation by coking) and high hydrogenation activity in hydrogenation reactions for aromatic hydrocarbons and heterorganic compounds. So, investigations in the field of hydrotreating catalysts, modified by phosphorus, are actual ones.

2 Experimental/methodology

Modification of hydrotreating catalysts carrier was carried out with phosphoric acid water solution by wetness impregnation method (P_2O_5 content 0,5, 1, 2 and 5 wt. %), followed by draying and calcination. Modified carrier was impregnated with water solution of active phase precursors (Mo, Ni(Co)) on the second stage of synthesis.

NH_3 TPD analysis of synthesized catalysts was carried out with TPDRO 1100 analyzer. NH_3 adsorption was performed in flow of NH_3/N_2 (1:1 vol.) for 30 minutes. Temperature range of desorption was 25-1000°C. The catalytic activity of the samples was determined in a bench-scale flow reactor unit in the hydrotreating process of vacuum gas oil.

3 Results and discussion

Catalyst, contained 2 wt. % P_2O_5, showed the maximum of activity in hydrodesulphurization (HDS) reactions (1,0 order kinetic model) and sample with 5 wt. % P_2O_5 demonstrated the highest hydrogenation degree (HYD) in reactions of polycyclic aromatic hydrocarbons (PAH) and olefins (**Fig. 1-3**). The situations of minimum were different for HDS and HYD curves.

P_2O_5 introduction at 0.5 wt. % reduces a number of acidic centers, desorbed NH_3 in temperature range of 550-820 °C (**Fig. 4**). P_2O_5 introduction at 5.0 wt. % increases total acidity in the range of 550-820 °C (**Fig. 4**).

Authors **[1]** showed that the usage of carbon carriers for hydrotreating catalysts synthesis had significant limitations. A large number of strong Lewis centers on synthesized catalysts, adsorbed polycyclic aromatic hydrocarbons more intensive than sulfur-organic compounds. It's well known that the adsorption of sulfur-, nitrogen-organic and polycyclic aromatic compounds are competitive reactions, so the catalyst had a low HDS activity.

HDS reactions, when carrier has a low number of strong adsorption centers, passes in a low degree, but inhibits in less degree by nitrogen-organic and polycyclic aromatic compounds. This is the source of the first minimum of activity in HDS (**Fig. 1**). The introduction of larger amount of P_2O_5 result in increase of strong adsorption centers number, which get an optimum for HDS activity at 2.0 wt. % of P_2O_5.

Further increasing of P_2O_5 amount causes a lot of strongest centers, which fast and irreversible adsorb polycyclic aromatic hydrocarbons. In this way, HDS reactions are effectively inhibited on catalysts with amount of P_2O_5 more than 2 wt. % (the second minimum of activity in HDS (**Fig. 1**).

The curves of hydrogenation of polycyclic aromatic hydrocarbons and olefins have one

minimum, which corresponds to minimum of catalysts acidity (**Fig. 2-4**).

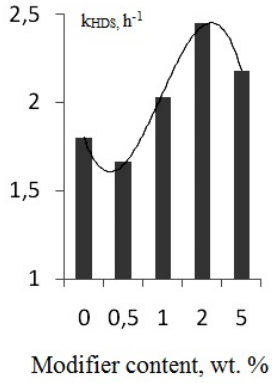

Fig. 1. Relationship between k_{HDS} and P_2O_5 content for NiMo/P-γ-Al_2O_3 catalysts

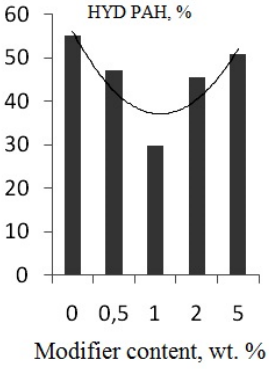

Fig. 2. Relationship between HYD PAH and P_2O_5 content for NiMo/P-γ-Al_2O_3 catalysts

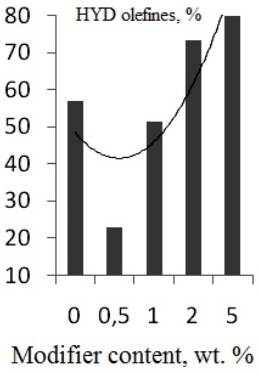

Fig. 3. Relationship between HYD olefines and P_2O_5 content for NiMo/P-γ-Al_2O_3 catalysts

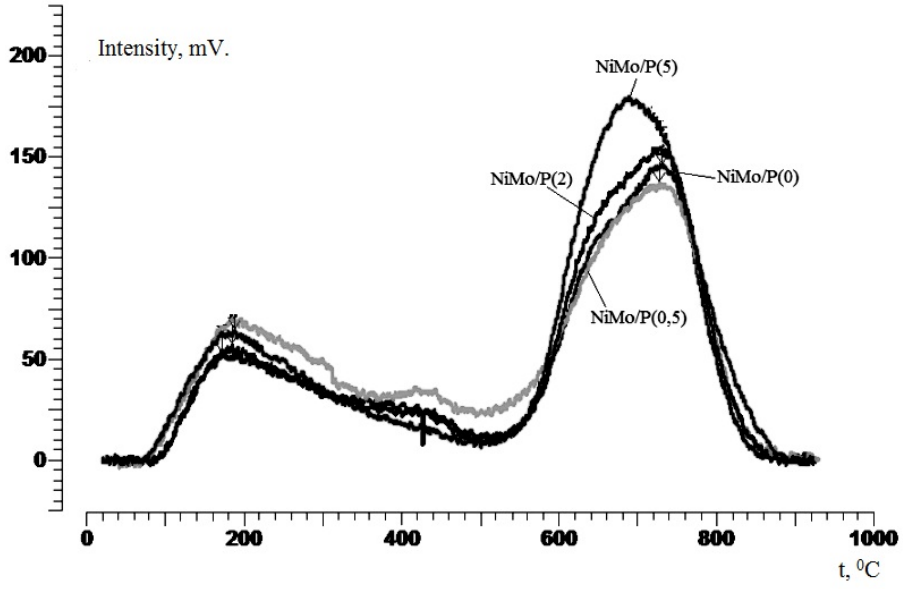

Fig. 4. NH_3 TPD curves for NiMo/P catalysts

4 Conclusions

The optimum amount of P_2O_5 for modification of vacuum gas oil hydrotreating catalyst was found. The relationships between HDS, HYD PAH, HYD olefins and P_2O_5 content for NiMo/P-γ-Al_2O_3 catalysts were determinated. The maximum of HDS activity was found for catalyst, contained 2.0 wt. % of P_2O_5.

Keywords: SAXS, masking liquids, supported catalysts, functional materials

1 Introduction

Determination of particle sizes is an important and complicated problem in heterogeneous catalysis. At present, TEM, XRD and CO chemisorption are conventionally used for solving this problem. The Small Angle X-ray Scattering (SAXS) potentially has great advantages compared to these traditional methods. First of all, unlike transmission electron microscopy, SAXS yields information about particle sizes from a macroscopic amount of sample. Second, unlike XRD, SAXS allows for obtaining a particle size distribution instead of an average value of particle sizes. Also SAXS can be applied for study of amorphous and soft samples. However, SAXS is rarely used for determination of particle sizes in heterogeneous catalysts. The reason of low interest is the problem of distinguishing a weak scattering signal originating from supported metal particles from the huge background scattering signal of a porous support. One of the ways for effective separation these signals is a using of liquids with high density for masking support scattering (Fig. 1) [1].

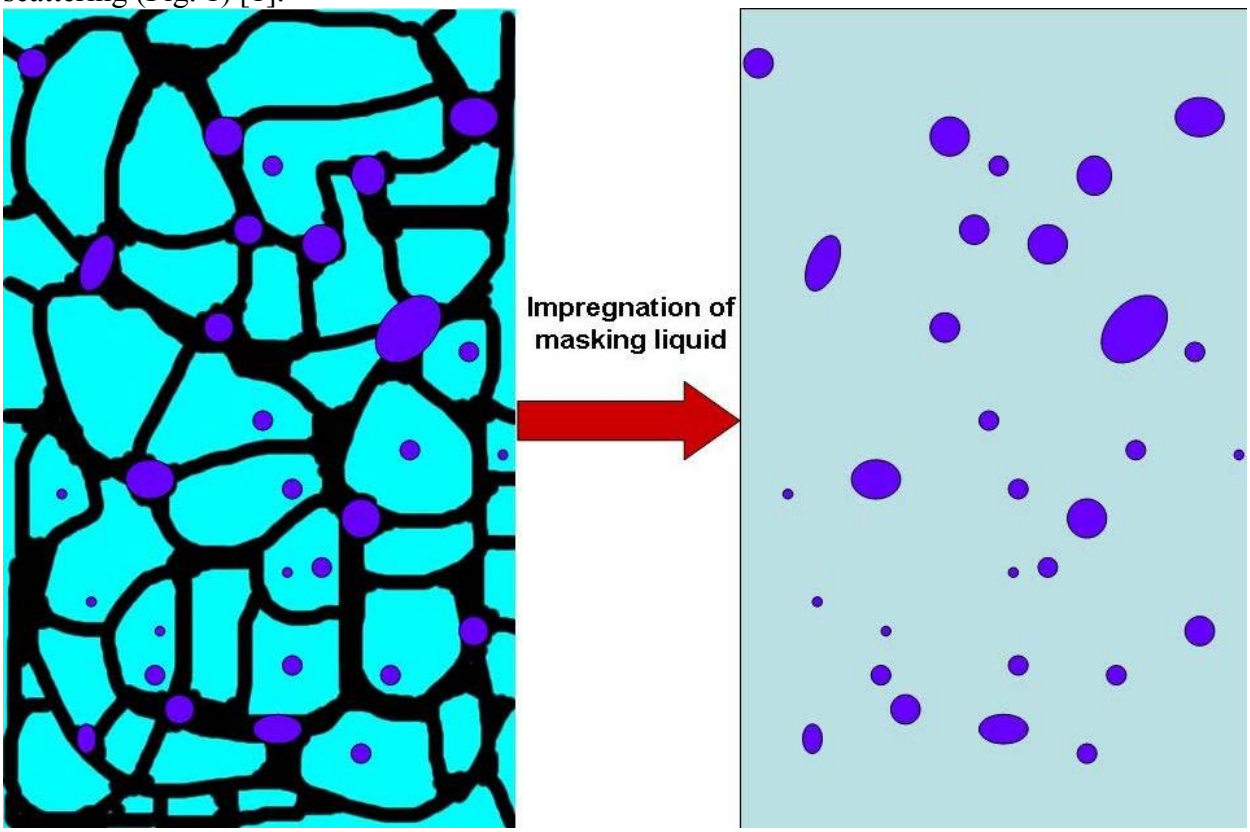

Fig. 1. Principal scheme of parasitic scattering background removal from support pores and particles.

The main barrier for application this concept is extremely high absorbance of X-ray radiation for typical high dense liquids (such as $CHBr_3$ or CH_2I_2). Despite on the opposite requirement to the masking liquids we design high-density liquid mixtures with relatively low X-ray absorbance. The main compounds of these mixtures are fluorocarbons which has good compromise properties between high density and low absorbance. Using this technique it is possible to mask parasitic scattering signal from any phases with density less 2.8 g/cm^3.

2 Experimental

The S3 MICRO (HECUS) small angle diffractometer (Cu Kα, 50W) with a point collimation of primary beam was used for measuring scattering patterns of all samples. The scattering vector magnitude $h = 4\pi*\sin(\theta)/\lambda$ (where 2θ is the scattering angle, and $\lambda = 1.541$ Å is the radiation wavelength) was used as the scattering coordinate. The scattering intensity was measured in the range of the scattering vector magnitudes $0.01 < h < 0.6$ Å^{-1}. A powder sample was placed in a quartz or glass capillary with 1.5 mm diameter. Then, a masking liquid was added using a special syringe with a thin needle. In all cases, the quantity of the masking liquid exceeded the pore volume in the sample. Calculation of the particle size distributions from scattering data were based on the GNOM program from the ATSAS package [2].

3 Results and discussion

In presentation will be discussed prospects and restrictions of new technique, examples of their application to study some catalysts and porous composites. Application of masking liquids for SAXS study of supported catalysts has been revealed advantage of this method versus TEM and XRD. Using this method we can get particle sizes distribution in the wide size range and analyze bulk inactive metal particles more effectively comparing to TEM and XRD. Also in presentation will be shown results of study amorphous carbon-mineral composites. These composites have been prepared from renewable resources (such as rice husk and sapropels). It has been found that shape of silica-contained template particles their behavior depends on the nature of initial precursor. In the case of composites prepared from rice husk has been found that inorganic template have a small particles with smooth shapes near to spheres. Increasing of the temperature treatment are increasing sizes of template particles. In the case of composites prepared from sapropels mineral template have large particles with fractal shape which partially destroyed after heat treatment.

SAXS with using this technique became a highly effective method for study different types of supported catalysts or porous composites. The main limitation in current version is a medium level of material density which could be effectively masking. Nevertheless even current density range which we plan to expand contains a lot of type's different materials and catalysts.

Silica Poisoning Effect on HDT Catalysts Processing Light Coker Naphtha

Pérez-Romo P.*, Aguilar-Barrera C., Navarrete-Bolaños J., Fripiat J.

Instituto Mexicano del Petróleo, México, México

* pperezr@imp.mx

Keywords: silica poisoning, HDT alumina catalyst, silicon compounds, deactivation

1 Introduction

Delayed coking process is a thermal cracking process that upgrades crude oil vacuum distillation bottoms into gas and liquid products such as gas oil and naphthas, leaving behind a solid concentrated carbon material known as petroleum coke. Delayed coking units use silicon polymers (antifoaming) that are added to the coker drums in order to suppress foaming that is generated by the light gases that are produced. As a consequence of the high temperatures that prevail in DC operation, silicon polymers decompose to form lighter silicon compounds that distill mainly with the naphtha product. Deactivation of industrial HDT catalysts by silicon deposition was studied by Kellbergs et al [1] and found that catalysts have relative short lifetimes because of the accumulation of silicon species on the surface and concluded that the silicone oil in the naphtha feed is transformed into silica gel species.

The aim of the present contribution is to further both the knowledge of the silicon deposition mechanism under different concentrations and the interaction of silicon with the alumina support of a commercial HDT catalyst.

2 Experimental/methodology

Samples of fresh and industrially spent $NiMo/Al_2O_3$ HDT commercial catalyst were used.

Linear polydimethylsilane (PDMS) $(CH_3)_3SiO[SiO(CH_3)_2]_nSi(OCH_3)_3$, which is currently used as an antifoaming product in delayed coker operations, was dissolved into the coker naphtha feed with different concentrations. This stream was treated at 427°C and 1 kg/cm^2 in a stainless steel, ¾" O.D., reactor that was heated by automatic temperature control.

In order to produce the Si-doped catalysts, a reactor test unit was used. The reactor was packed with 13.9 g of fresh NiMo HDT commercial catalyst, which was dehydrated in N_2 stream at 150°C for 2 h, then sulfided at 315°C by dimethyl-disulfide diluted in a straight run naphtha stream to reach the sulfide phase. Three catalysts were treated (labeled as DNA, DNB and DNC) with the Si-doped naphtha at 240, 260 and 280°C and 55 kg/cm^2.

3 Results and discussion

Table 1. Silicon content in feedstock and in the final catalyst.

Sample	Si in thefeed (ppm)	Theoretical Si (%)	Si deposited on the catalysts (%)
DNA	383	6.9	3.5
DNB	223	4.0	3.2
DNC	98	1.8	1.6

The silicon content in the naphtha and Si-doped HDT catalysts was analyzed by atomic absorption and the results are shown in Table 1. Theoretical Silicon, defined as the % silicon that

should be deposited on the catalyst assuming a complete removal of silicon from the stream, was calculated from the silicon content in the feedstock, the naphtha flux and the time on stream. Silicon deposited on the catalyst was lower than theoretical silicon in different amounts, as shown in Table 1. The difference between them was wider as the silicon concentration in the feed was higher too (Table 1). This suggests that the Si deposition on the catalyst is controlled by the accessibility and availability of active sites on the catalyst surface.

In DNA and DNB samples (Figure 1), the peak attributed to dialkyl silicon species at -22 ppm is clearly observed, whereas the peak assigned to monoalkyl and inorganic silicon compounds are detected in all the Si-doped catalysts. The highest content was found for Q species, followed by T species, while dialkyl structures were found in minor content in all samples. The DNA and DNB samples showed a similar content and distribution of Si species in spite of the different content of silicon in naphtha with which was doped. It is important to note that in these two catalysts, the amount of T and Q species was comparable while in DNC, the proportion of them was increased from species type D to T and finally to Q. The results of the species distribution in the deactivated industrial catalyst suggest that silicon species in the coker naphtha are adsorbed and converted on the surface of HDT catalyst, releasing CH groups from dialkyl to monoalkylsilylated structures. The next steps in the transformation are the formation of silanol species and, finally, the siloxanes groups. In this case, the conversion is constant and the accumulation is observed at the end of the path. It is important to note that this behavior is valid when a few ppm of silicon are put in contact with the catalyst. When higher concentrations of silicon are used, rapid saturation is observed. An accumulation process was detected, which begins with species T and excess of silicon cannot be retained. It is a suggested explanation for the distribution of T and Q species and for the total amount found in the DNA and DNB catalysts.

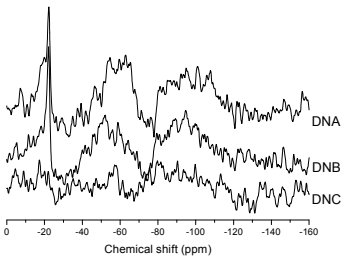

Fig. 1. 29Si MAS NMR spectra of samples doped with different silicon contents.

4 Conclusions

Because of its affinity for silica, the alumina surface is extremely sensitive to the poisoning of the catalyst. On the alumina surface there is a finite available amount of active sites that could be retaining silicon compounds from antifoam additives. The adsorption reaction rate is controlled by the transformation of D into T silicon species. The amount of deposited silicon plays a major role in the catalytic activity for hydrodenitrogenation and hydrogenation reactions)

Keywords: Ru colloidal NPs, synthesis, effect of reduction temperature, PVP/Ru ratio, reducing agent, metal content, microwave assistance

1 Introduction

Nowadays nanosized metal nanoparticles (NPs) attract a lot of attention due to their unique chemical and physical properties. Among different applications of metal NPs a special attention is focused on catalysis. In particular, a colloidal method based on immobilization of colloidal metal NPs over different types of supports is an effective alternative approach to the synthesis of supported metal catalysts with well-defined particles. A precise control over size and shape of NPs at the nanometer scale by varying the synthesis conditions is expected to allow prediction of their catalytic performance as well as to give possibility to tune material properties with high accuracy and reproducibility. The purpose of the current work is to explore regularities of ruthenium NPs formation via polyol reduction and to determine key parameters for the synthesis of Ru NPs with a controllable particle size allowing further preparation of heterogeneous catalysts for different catalytic application, e.g. aqueous phase reforming (APR) of bioderived sugar and sugar alcohols. The influence of different synthesis parameters, such as reduction conditions, the ratio between Ru and stabilizing agent (PVP), and the Ru concentration on the particle size was studied.

2 Experimental

A series of colloidal Ru NPs were synthesized by the polyol method using $RuCl_3 \cdot nH_2O$ and ethylene glycol (EG) as a metal precursor and a reducing agent, respectively [1]. As a general procedure, $RuCl_3 \times nH_2O$ and PVP (mol Ru/mol monomers PVP = 1/1 – 1/50) were dissolved in EG under stirring followed by heating up to a predetermined temperature (170÷198°C) in a sand bath or in the microwave oven. In the case of $NaBH_4$ reduction was performed by addition of the stoichiometric amount of $NaBH_4$ under efficient magnetic stirring.The Ru NPs formation as well as their stability after immobilization over mesoporous Sibunit, carbon nanofibers of platelet structure and TiC carbide-derived carbon under reaction conditions simulating APR were monitored by physical methods, including UV-Vis, XRD, TEM, XPS.

3 Results and discussion

In order to develop an approach to the synthesis of Ru NPs with a controllable particle size the regularities of PVP-stabilized Ru NPs formation from $RuCl_3$ through the polyol method were studied (Fig. 1). The effect of the PVP/Ru, Ru concentration, reduction temperature and

the reducing mode on the mean diameter and size distribution of Ru-NPs was investigated. The particle size prepared by the current polyol technique does not depend strongly on the Ru/PVP ratio and reduction temperature varied in the range 1/1-1/50 and 170-198ºC, respectively, while an increase in the metal concentration in the solution favoured NPs growth. The hundred-fold increase in $RuCl_3$ concentration in the solution was shown to result in a particle size growth from 1.7 to 2.6 nm. A relatively simple method was developed for the synthesis of Ru NPs under microwave irradiation providing small Ru NPs with a narrow size distribution (Fig.2). The synthesis of Ru colloids with Ru/PVP ratio 1/5 under microwaves was found to afford the particle size of about 2.1 nm, which is similar to the one obtained under reflux conditions. However, the method developed under such microwave assistance is rather simple and leads to a fast formation of small Ru NPs with a narrow size distribution due to faster attainment under microwave of the required reduction temperature (Fig. 2a). Faster reduction by $NaBH_4$ at an ambient temperature was found to result in formation of smaller NPs of ca 1.8 nm compared to that reduced by EG (Fig. 2b). According to UV-Vis and XPS data the Ru NPs were found to be in the metallic state independent on the PVP/Ru ratio, the reducing agent and the heating mode. Highly concentrated Ru colloids with a controllable NPs size were immobilized over different carbon supports.

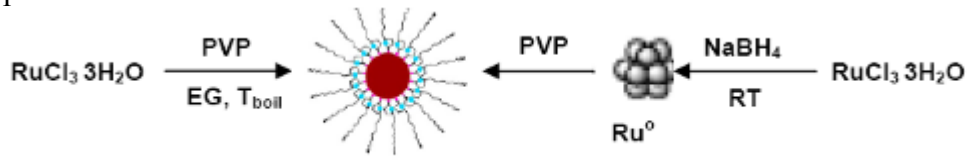

Fig. 1. Different approaches of PVP-stabilized ruthenium nanoparticle synthesis.

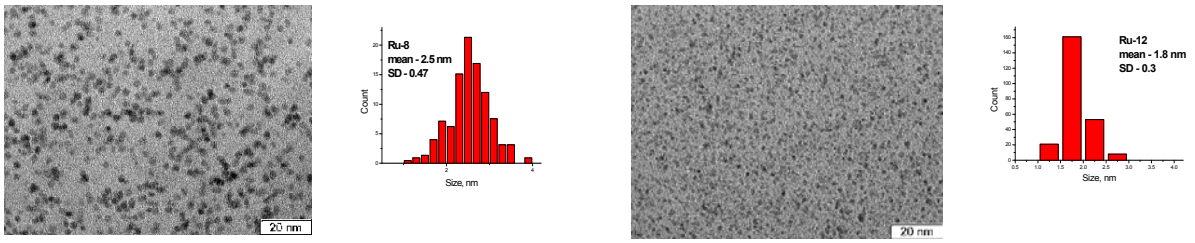

a **b**

Fig. 2. TEM images (left) and the corresponding particle size distribution (right) of PVP-stabilized Ru NPs reduced by a) EG under microwave irradiation b) by $NaBH_4$.

4 Conclusions

Different strategies to prepare Ru NPs of different size with narrow particle size distribution were applied. Stable Ru NPs with mean diameters 1.7÷2.8 nm and a narrow distribution were prepared by reduction of $RuCl_3$ with EG as well as PVP as a stabiliser in the temperature range 170 ÷198^{o}C. As an effective alternative approach Ru NPs synthesis using microwave assistance along with $NaBH_4$ reduction at room temperature was developed. The effect of heating conditions, Ru/PVP ratio, reducing agent and initial Ru precursor concentrations on the particle size was studied.

Sulfated Perfluoropolymer on Carbon Nanofibers Composites: Preparation, Acidity and Catalytic Activity in the Gas-Phase Benzene Nitration

Keywords: gas-phase nitration, sulfated perfluoropolymer, polymer-carbon composite, nitrobenzene

1 Introduction

In industry the aromatics nitration is carried out in the liquid phase with a mixture containing nitric and sulfuric acids [1]. The sulfuric acid medium has two functions: it acts as a homogeneous nitration catalyst and at the same time as a dehydrating agent. A major problem of this technology is associated with diluting of the nitration mixture by water formed as one of the reaction products [2]. Another disadvantage of homogeneous benzene nitration is related to contamination of nitrobenzene (NB) with a high concentration of nitrophenols (NPs, more than 2000 ppm) formed as by-products [3]. Heterogeneous catalytic nitration processes could be regarded as an alternative to the industrial homogeneous nitration technique.

In this study we developed synthetic methods for Nafion deposition on carbon nanofibers and studied the catalytic properties in the gas-phase benzene nitration, durability and acidity of the obtained materials. Our main goal was to achieve higher nitrobenzene selectivity to meet the market demand (total NPs content < 400 ppm).

2 Experimental/methodology

Carbon nanofibers (CNF-*x*, where *x* is the CNF specific surface area) were selected as a catalyst support due to the highly-defective structure of their graphite layers, which is convenient for synthesis of a durable Nf/CNF composite. CNF were prepared by decomposition of methane (or propane-butane mixture) on supported Ni-Cu/Al_2O_3 catalyst at 500-700° [4]. The sulfated perfluoropolymer was deposited on the surface of the support either by wet mixing (wm) or by wet impregnation (wi) methods [5].

Gas-phase benzene nitration reaction was carried out in accordance with proved technique using nitric acid water azeotropic solution as a nitrating agent (160°-170°C, feeds: Benzene/ HNO_3/N_2 = 1/0.42/21.3 (molar ratios)) [5]. The yield of NB was determined by GC (Crystall-2000M, HP-5, TCD); concentration of NPs by HPLC (Agilent-1200, the column SE-30, UVD). Catalytic activity of samples was represented by calculation of the STY_{NB} parameter, by $mg_{NB}/g_{cat}/h$.

The pore volume, average pore diameter and specific surface area of the samples were measured by low-temperature nitrogen adsorption (Micrometrics ASAP-2400). Chemical analyses of the materials were carried out by AAS. Pyridine adsorption experiments were carried out by saturating Nf/CNF in solution containing the already known concentration of pyridine in THF. GC was used to quantify the amount of pyridine adsorbed on the catalyst.

3 Results and discussion

The most active and stable catalysts were synthesized by the wet impregnation method. The best results were obtained for the catalyst containing 20 wt.% Nafion prepared by multi-step wet impregnation (ms, STY_{NB} = 327 mg_{NB} g_{cat}^{-1} h^{-1}, benzene (nitric acid) conversion were 36.2 (38%)). Its good performance can be explained by a combination of high surface area with high concentration of acid sites.

Total amount of the Nf/CNF acid groups were estimated via sulfur element analysis, because each sulfonic group constitutes a potential acid site (0.164 mmol/g for 20% Nf/CNF). Elemental analysis data are well consistent with the polymer loadings used in the catalyst preparation. The experiment on the pyridine adsorption reveal that 0.181 mmol/g are adsorbed on 20% Nf/CNF and 0.021 mmol/g on the ion-exchanged Na^+-20% Nf/CNF form. The accessibility of the H_3O^+-Nf/CNF acid sites (in swelling form) was estimated by EPR [6]. Radical cations are formed by anthracene adsorption on the H_3O^+-Nf/CNF sites. We observed an increase in the concentration of cation radicals when the amount of deposited Nafion was increased. No acceptor sites were found on the CNF support or on dry Nafion. Overall, a good correlation was observed between the concentration of the acceptor sites on the surface of the composites measured by EPR and their catalytic activity in the gas-phase nitration of benzene.

Table 1. Catalytic properties of H_2SO_4/SiO_2, Nafion/SiO_2 and Nafion/CNF composites in gas-phase benzene nitration.

#	Sample, preparation method	S, m^2/g	N^I, 10^{16} g^{-1}	STY_{NB}, mg_{NB} g_{cat}^{-1} h^{-1}		Nitrophenol content, ppm[4]
				5 h	12 h	
1	Nf-H (pure)	0.02	0	340	trace	252
2	10% H_2SO_4/SBA-15	770	25	375	211	377
3	20% Nf/CNF-318, wm	121		293	130	181
4	10% Nf/CNF-318, wi	234	16	280	111	203
5	20% Nf/CNF-318, wi	169	40	327	320	291
6	50% Nf/CNF-318, wi	60		270	265	243

[1]Concentration of radical cations generated from anthracene adsorbed from 0.04 M benzene solution on the samples activated at 120°C for 16 h followed by heat treatment at 80°C for 32 h.

4 Conclusions

In summary, the best catalyst exhibits 99.9% selectivity to nitrobenzene with concentration of by-products (mainly nitrophenols) less than 300 ppm. The prepared Nf/CNF catalysts containing supported perfluoropolymer were shown to have sufficiently high catalytic activity and acceptable resistance to the sulfuric acid leaching, which is typical for all known H_2SO_4/Silica catalysts.

Keywords: ceria, hydrogen, peroxide, precipitation method, dry reforming of methane

1 Introduction

Cerium oxide was suggested as a promising candidate for anode component in Solid Oxide Fuel Cells (SOFCs), due to its catalytic activity in reforming and enhanced resistance against coke formation [1-2]. This capability has been attributed to some unique properties, such as oxygen storage capacity, oxygen mobility and ability of cerium to switch easily between oxidized and reduced states ($Ce^{3+} \leftrightarrow Ce^{4+}$). The preparation method affects properties such as the surface area, defects concentration and thermal stability. As an example the addition of H_2O_2 during the preparation steps of ceria nanomaterials led to an improvement of the surface area and redox properties [3].

The present work aims at studying the effect of adding H_2O_2 during the synthesis, alone or with cetyltrimethylammonium bromide (CTAB), a template agent, on morphologic, structural and catalytic properties of ceria. The samples were characterized by powder X-ray diffraction (PXRD), scanning electron microscopy (SEM), isotherms of adsorption-desorption of nitrogen at -196 ^{o}C, thermogravimetric and differential thermal analysis (TG-DTA), Raman spectroscopy, and temperature programmed reduction experiments in CH_4 (TPR-CH_4) or H_2 (TPR-H_2). Catalytic properties in methane dry reforming were investigated in view of the potential use of ceria as SOFC anodes operating on CH_4+CO_2 mixtures such as in biogas.

Experimental

Samples were synthesized using an aqueous solution of $Ce(NO_3)_3 \cdot 6H_2O$ (0.1 mol/L) and adding to it H_2O_2, CTAB, or H_2O_2/CTAB. NH4OH was the added drop-wise ammonium hydroxide until the pH reached the value of 9 to obtain the precipitate (stirring at 60 °C for 1 h). The precipitate was separated by centrifugation, washed in water and ethanol, and dried. Samples were further calcined in air at 500 and 900 °C (5h). The samples were denoted in relation with the additive used: CeO_2; CeO_2_CTAB; CeO_2_H_2O_2; CeO_2_CTAB_H_2O_2.

Dry methane reforming reaction was carried out in a continuous flow system at atmospheric pressure using mixtures containing 0.5% CH_4 - 0.5% CO_2 and 0.25% CH_4 - 0.75% CO_2 in He as balance (stoichiometric and oxidizing conditions, respectively). The total flow rate was equal to 60 mL/min. The conversion was measured within the temperature range of 750 - 900 °C.

Results and discussion

Samples were all active in the conversion of CH_4/CO_2 mixtures, CO and H2 being produced. H_2/CO ratios much lower than unity were obtained. This was explained by the contribution of the reverse water gas shift reaction which becomes predominant above 850 °C in the experimental conditions used. Table 1 shows methane conversion rates at 900°C in stoichiometric and oxidizing conditions. Samples prepared by H_2O_2 addition were found to be

slightly more active, which can be only partly correlated with their higher surface area.

Table 1. Comparison between the surface areas of the CeO_2 powders calcined at 900 °C and the specific methane conversion rates obtained at 900 °C in CH_4/CO_2 reaction mixtures

Sample	CH_4 consumption rate (mmol/h.g)		Surface area (m^2/g)
	Stoichiometric	Oxidizing	
CeO_2	5.6	4.0	5.6
CeO_2_CTAB	5.2	3.4	7.6
CeO_2_H_2O_2	6.8	4.6	13.7
CeO_2_CTAB_H_2O_2	6.7	4.5	20.1

TPO experiments after catalytic testing indicated that no graphitic carbon formed during the reaction on CeO_2_H_2O_2 and CeO_2_CTAB_H_2O_2 while 7.3 and 0.2 µmol C per g of sample was measured on CeO_2 and CeO_2_CTAB, respectively. For all samples bands at 600 and 667 cm^{-1} were observed by Raman (figure 1), being consistent with the presence of Ce^{3+} associated or not with oxygen vacancies in the ceria lattice. With respect to the conventional preparation or CTAB use, the H_2O_2 addition in the synthesis step favors the formation of stable bulk defects (oxygen vacancies) as shown by XRD, and improves bulk reducibility as determined by TPR-H_2. It is also observed that the ultimate OSC measured by TPR-CH_4 is about twice lower than that of CeO_2 and does not change upon successive TPR/TPO cycles. When CTAB is used as additive, the ceria structure suffers modifications upon cycles as for CeO_2. However, while a stable structure is reached for CeO_2 after only one cycle, this evolution is inhibited by the presence of CTAB. The effect is suppressed when CTAB is used with H_2O_2. Physicochemical properties of various samples are discussed and tentatively correlated with catalytic performances.

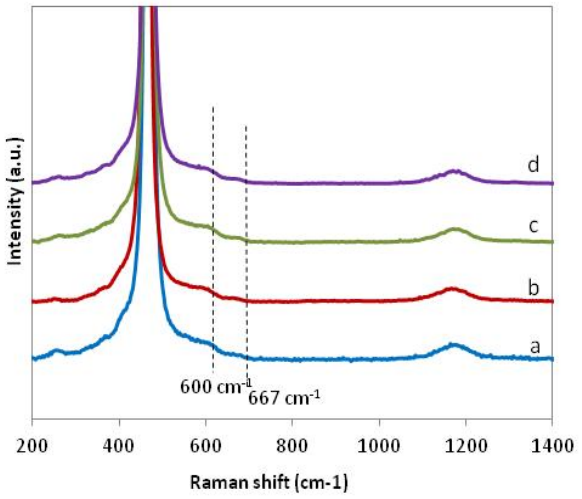

Fig. 1. Raman spectra of CeO_2 samples calcined at 900 °C. (a) CeO_2, (b) CeO_2_CTAB, (c) CeO_2_H_2O_2, (d) CeO_2_CTAB_H_2O_2_.

Conclusions

Compared to materials synthesized conventionally or by using CTAB, the use of H_2O_2 during synthesis mitigates surface loss under high temperatures operation (e.g. 900 °C), improves bulk redox properties when alternating between oxidizing and reducing treatments, and highest catalytic activity and resistance to deposition of graphitic carbon. CeO_2_CTAB_H_2O_2, while not exhibiting improved catalytic properties, presents the highest surface area upon calcination at 900 °C and can find application in catalytic processes where this property is of special importance.

1 Introduction

Development of effective approaches for controlled synthesis of metal nanoparticles (NPs) is of great fundamental and practical interest due to a wide range of applications in different fields, including electronics, optics, magnetic devises and catalysis. In fact, the NPs size and shape strongly affect their chemical and physical properties. In this connection, there are numerous investigations devoted to the synthesis and detail studies of key parameters determining formation of nanostructured materials [1, 2]. A rational control of NPs characteristics can be achieved through regulation of the synthesis conditions. Ni is widely used as an industrial hydrogenation/hydrotreating catalyst while Co exhibits appreciable activities for C–C bond scission, water–gas shift reaction, and Fischer–Tropsch synthesis [3]. Supported Ni and Co metal NPs are anticipated also to be of potential interest as inexpensive catalytic materials for aqueous phase reforming (APR) of bioderived sugar and sugar alcohols resulting in a mixture of hydrogen and alkanes [4]. In the present work it is demonstrated that Ni and Co NPs with controllable sizes can be prepared in bench scale quantities by a facile modified polyol method utilizing sodium borohydride ($NaBH_4$) as a reducing agent and polyvinylalcohol as a capping agent with a high metal/PVP ratio.

2 Experimental

Co and Ni NPs were prepared by the modified polyol method. Solutions of Co or Ni chloride in ethylene glycol with PVP (Ru/PVP = 1:5) were used as initial mixtures. The reduction was performed by a stoichiometric amount of $NaBH_4$ under an efficient magnetic stirring at the temperature varied from 7 to 170°C during 1 h. Ni NPs were synthesized under both Ar and air atmosphere, whereas Co colloids synthesis was performed only under inert atmosphere. Ni and Co colloids as well as NPs immobilized on the carbon supports (mesoporous Sibunit, carbon nanofibers, and TiC carbide-derived carbon) were analyzed by a variety of state of the art physical methods including TEM, XPS, XRF, UV-Vis.

3 Results and discussion

In order to find out the operating parameters of the polyol synthesis determining a controllable formation of Ni and Co NPs the role of the reduction temperature under an inert gas atmosphere was studied. Changes in the reduction temperature were suggested to affect the reduction rate allowing particle size regulation. The reduction temperature was varied from 23 to 170°C for Ni NPs and from 7 to 23ºC for Co NPs. TEM date shown that the average diameter

of Ni NPs size increased from 2.6 to 3.2 nm when the reduction temperature increased from 23 to 140ºC. With respect to Co NPs the temperature increase from 7 to 23ºC resulted in the increase in Co NPs size from 1.8 to 2.6 nm, whereas further change from 23 to 100ºC affected less significantly the metal particles size. The results presented above indicate that the size of the base metal NPs increases with elevation of the synthesis temperature. To investigate the role of gas atmosphere on the formation of Ni NPs the gas-dependent evolution of the NPs size was carried out in air or in Ar at 140ºC. As a result, the size of NPs formed at 140ºC in air was 5.4 nm compared to 3.2 nm formed in Ar. When the temperature was increased to 170 C, the Ni NPs size increased to 9.8 nm. Thus, a tendency of the particle size to increase with an increase in the reduction temperature was observed for base metal colloids synthesized by the modified polyol method. In the case of Ni colloids an oxidative atmosphere promoted formation of larger NPs with a wider particles size distribution compared to those formed in the inert gas atmosphere.

Table 1. Average size of Ni and Co NPs synthesized by a modified polyol method.

Me	Atmosphere	T_{red}, °C	d_n, nm	SD
Ni	Ar	23	2.6	0.6
Ni	Ar	140	3.2	0.9
Ni	air	140	5.4	2.7
Ni	air	170	9.8	6.9
Co	Ar	7	1.8	0.5
Co	Ar	23	2.6	0.6
Co	Ar	100	2.8	0.5

4 Conclusions

A series of Co and Ni NPs with the average particle sizes 1.8÷2.8 and 2.6÷9.8 nm, respectively, were synthesized by the modified polyol method. The influence of reducing temperature and gas atmosphere was studied. Parameters determining formation of Co and Ni NPs by the polyol method with a controlled size were found. Increase of reduction temperature and application of an oxidative atmosphere were found to increase nanoparticles size favouring the NPs growth versus nucleation.

Keywords: dry reforming of methane, spinel, reducibility, $NiFe_2O_4$, $NiAl_2O_4$

1 Introduction

The reforming of methane to syngas using CO2 instead of steam is an attractive route, including from the point of view of sustainability because it uses two greenhouse gases. Compared to noble metals, Ni-catalysts are cheap but very easily deactivated by coking. Ni-based mixed oxides structurally well-defined like perovskites and spinels are being studied because they possibly make solid solutions and allow to vary the composition and thus the catalytic properties. In this study, the textural, structural and catalytic properties of nickel ferrite aluminate samples prepared by coprecipitation method, using nitrates and chlorides salts as precursor, are presented.

2 Experimental/methodology

The catalysts $NiAl_xFe_{2-x}O_4$ (x = 0; 0.5; 1; 1.5; 2) were prepared by coprecipitation route using nitrates and chlorides salts as precursors and sodium hydroxide as precipitating agent. The precursors were calcined at 800 °C. Samples were characterized by B.E.T, XRD, Raman, SEM-EDS and XPS. Their reducibility was investigated by in situ methods (H_2-TPR and H_2-HTXRD), at various temperatures. The catalytic performance in DRM was measured in a fixed bed reactor, at 1 atm, CH_4/CO_2/He/Ar = 20:20:10:50 (total flow 100 mL/min) and 650–800°C range. After experiment, the catalyst was reoxidized under 2% O_2 in He (50 mL/min) at 700 °C for 30 min to quantify the coke deposition.

3 Results and discussion

The surface area as well as the surface Ni/Fe atomic ratio (EDS and XPS), varied according to the Al percentage (Table 1). According to EDS and XPS, the surface Fe/Ni ratio was more or less close to stoichiometry (Fe/Ni = 2). Raman spectroscopy and XRD (Figure 1) patterns showed the presence of the spinel as majority phase in all synthesized oxides [2,3], traces of free NiO are observed in all case excepted $NiFe_2O_4$ case. The catalytic activity in DRM of the spinel samples showed that aluminate spinel is more active (with the CH_4 and CO_2 conversions ~ 90 mol%) than ferrite spinel (whose the CH_4 and CO_2 conversions not exceed 3 and 6 mol% respectively). This could be related to the high reducibility and the high specific surface area observed for aluminate samples. For $NiFe_2O_4$, a significant contribution of reverse water gas shift reaction was observed. At higher reaction temperatures (above 700°C), aluminate spinel

catalysts showed substantial carbon deposition (20%).

Table 1. Textural, structural and surface properties of $NiAl_xFe_{2-x}O_4$ catalysts

Catalyst	S_{BET}	EDS data		XPS data				
(x=)	(m^2/g)	Fe/Ni	Al/Ni	BE[a] Fe	BE[a] Al	BE[a] Ni	Fe/Ni	Al/Ni

00025166028825165926 4

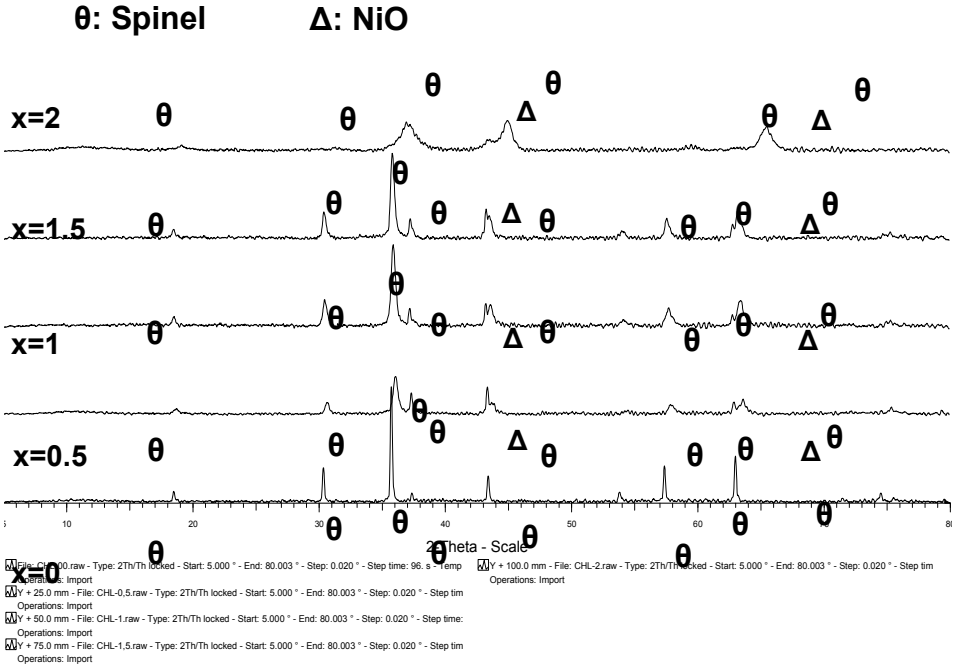

Figure 1. XRD patterns of $NiAl_xFe_{2-x}O_4$ catalysts prepared by coprecipitation method

4 Conclusions

The obtained results show that all aluminate spinel is more active than ferrite spinel in CO_2-reforming of methane. A significant contribution of reverse water gas shift reaction was observed in ferrite spinel case. A good correlation between textural and structural properties and reducibility of catalysts with catalytic performance is observed.

Preparation of Cu Loaded Magnetic Nanoparticle Catalyst and its Catalytic Activity for Degradation of Azo Dyes

Kurtoglu K., Gubbuk I.H.*

Selcuk University Faculty of Sciences Department of Chemistry, Konya, Turkey

* ihilalg@gmail.com

Keywords: dye degradation, magnetic, nanoparticle, methylene blue

1 Introduction

Magnetic separation using magnetically recoverable nanoparticles offers a promising approach that can meet the requirements of high accessibility with improved reusability. Therefore, magnetically separable catalysts have attracted increasing attention in recent years [1]. The development of more efficient and stable catalysts has been an increasingly important goal for chemists and material scientists for both economic and environmental reasons [2].

In this study, Fe3O4@SiO2 - Cu nanoparticles for catalytic reduction of azo dye pollutants are prepared. This nanoparticles exhibit enhanced catalytic reduction efficiency for azo dyes compared with those of pure Cu or Fe3O4 nanoparticles, and can also be rapidly separated from aqueous solution using a magnet. Synthesized magnetic nanoparticles were characterized by different techniques including X-ray diffraction (XRD), Scanning electron microscopy (SEM), Fourier transform infrared (FT-IR) spectroscopy and thermal analysis (TGA). The degradation efficiency was found to depend essentially on initial dye concentration, solution pH and the catalyst loading.

2 Experimental/methodology

All chemicals were analytical reagent grade: copper nitrate (Merck), sodiumborohydride and azo dyes (all from SigmaeAldrich). Water used for the preparation of all solutions was deionised by reverse osmosis. FeCl3 and FeCl2 were purchased from Sigma Aldrich.

The magnetic nanoparticle, Fe3O4, was prepared by a precipitation method. Briefly, 60mL of FeCl2 and FeCl3 aqueous ethanol solution with a concentration ratio of 5:1 was prepared, 1.0 mol/L ammonia solution was added drop by drop with vigorous stirring until pH 10, and a black product was obtained. Then, the black product was crystallized under 50 ◦C water bath for 3 h. Subsequently, separated with magnet, the obtained black magnetite particles were washed with ethanol for 3 times, dried at 50 ◦C for 12 h [3].

Fe3O4 spheres were coated by SiO2 films, by using TEOS as a precursor. The resulting Fe3O4@SiO2 particles were loaded with Cu nanoparticles. The material showed better performance than a conventional Fe3O4 catalyst in catalytic reduction of azo dyes with NaBH4. It can be separated from the reaction mixture by a magnet and be recycled without obvious loss of catalytic activity [4].

Catalytic activity of Fe3O4@SiO2 - Cu was investigated by means of degradation of azo dyes by sodium borohydride in aqueous solutions. Typically, 300 mL of the 1x10-4 mol L-1 dye solution was mixed with 0.010 g of Fe3O4@SiO2 - Cu. Thereafter, 5 mL of the sodium borohydride solution was added to the dispersion and the reaction was monitored by UV-VIS spectrometry. Study of the catalytic activity of Fe3O4@SiO2 - Cu was conducted at the laboratory temperature.

3 Conclusions

We have demonstrated that it can be used as magnetic recoverable nanocatalysts. The magnetic nanocatalyst exhibits an enhanced performance towards the decomposition of organic azo dyes.

In this study, Fe3O4@SiO2‐Cu composites have been synthesized by a chemical method, with Fe3O4 as a substrat, copper nitrate as a metal precursor and TEOS as a stabilizator. These composites accessible and highly dispersed Cu nanoparticles, thus resulting in high catalytic activities in the degradation of azo dyes.

The Photocatalytic Hydrogen Evolution by Alloyed CdTeS Nanocrystals

Aslan E.[1], Baslak C.[1], Hatay Patir I.[1], Kus M.[2], Ersoz M.[1*]

1 - Department of Chemistry, Selcuk University, Konya, Turkey

Keywords: hydrogen, evolution, quantum, dots, photocatalysis

1 Introduction

Energy and environmental issues at a global level are vital topics. Because of its environmental friendliness and high energy capacity, hydrogen has been described as a potential energy carrier. Conversion of sunlight into chemical energy in the form of hydrogen (H_2) is one of the crucial issue of 21st century chemistry. The key issue for approaching this target is to develop highly efficient and cheap catalytic systems. Since the discovery of hydrogen evolution through the photoelectrochemical splitting of water on n-type TiO_2 electrodes [1]. In recent years, photocatalytic water splitting using solar energy has become a promising approach to the production of clean, environmentally friendly and low-cost hydrogen. So far, numerous active semiconductor-based photocatalysts and their composites have been developed for photocatalytic hydrogen production reactions because of their suitable physical and photochemical properties. Among the various semiconductor photocatalysts, the hydrogenase-CdTe hybrid-nanostructures [2, 3] and water-soluble CdTe quantum dots (QDs) [4,5] have recently attracted considerable attention for their high photocatalytic activity under visible-light irradiation. In this study, photocatalytic generation of hydrogen by using 3-mercaptopropionic acid capped CdTe and CdTeS alloy nanocrystals have been investigated under visible-light irradiation in the aqueous solution by using at the pH 4.65 ascorbic acid solution as a sacrificial electron donor and $CoCl_2.6H_2O$ as an artificial catalyst.

2 Experimental/methodology

Synthesis of nanocrystals

In the synthesis, all reactions were carried out in oxygen-free water under nitrogen. The $Cd(MPA)_2$ precursor was prepared by mixing n moles $CdCl_2$. $5/2H_2O$ with 2n moles MPA in 200 ml of water. pH of the solution was adjusted to 12 with 0.1 mol. L^{-1} KOH. The prepared solution of Cd-thiolate complex was loaded in a three-necked flask. It was deaerated by bubbling of nitrogen for 30 min and heated at 100 °C. At the 80 °C of temperature, 10.0 ml of fresh NaHTe aqueous solution prepared from $NaBH_4$ and Te powder (0.2 mmol) and to prepare the sulphur precursor thiourea (0.2 mmol) with 2 ml of fresh NaHTe aqueous solution under nitrogen were used. The precursor solutions were injected into the reaction system under vigorous stirring using two syringes; the solution was then refluxed at 100 °C. Part of the refluxing solution was taken out at regular intervals for further characterizations. The prepared CdTeS QDs were precipitated and washed with 2-propanol more than three times. The QDs were dried overnight at room temperature. CdTe core nanoparticles were synthesized using only Cd and S precursor and MPA capping agent.

Photocatalytic hydrogen evolution

Ascorbic acid (3×10^{-2} M) and $CoCl_2.6H_2O$ (2×10^{-4} M) solution was prepared in the flask and

bubbled with N_2 to remove O_2. Nanocrystals (CdTe and CdTeS) was taken a reaction cell (total volume 135ml) and then, both electron donor solution and nanocrystals were taken in the glove box system. Solution and catalyst was mixed in the glove box. Catalysts are dissolved easily in the sacrificial solution. And then this mixture was stirred vigorously under the visible light source (Solar Light – XPS 300TM) and at room temprature. Then gas sample took periodically in the headspeace, which is above the solution. The gas in the headspace was analyzed using a Shimadzu GC-2010 Plus gas chromatograph (detector, TCD; column temperature, 323 K; column, RESTEK molecular sieve 5A porous layer open tubular capillary column 30 m 0.53 mmID 50 um df; Ar as a carrier gas) to determine the produced hydrogen.

3 Results and discussion

CdTeS alloy nanocrystals exhibits the hydrogen evolution rate of 8 $mmolg^{-1}h^{-1}$, which is about two times higher than that of CdTe. When a sample of CdTe and CdTeS alloy nanocrystals is irradiated in ascorbic acid/Co^{+2} solution for 12 h, they produce a total of 49 $mmolg^{-1}$ and 88 $mmolg^{-1}$ of H_2. Remarkably, the photocatalytic hydrogen evolution on as-prepared nanocrystals proceeds for longer than 12 h without any noticeable decrease in the activity, indicating that catalysts are stable and are not photocorroded in the aqueous medium.

4 Conclusions

In summary, we have successfully developed the 3-mercaptopropionic acid capped CdTe, and CdTeS alloy nanocrystal photocatalysts. The higher photocatalytic activity obtained for CdTeS alloy nanocrystals as compared to the CdTe.

Keywords: lactic acid, 1,2-propanediol, biomass, hydrogenation, Ru catalyst

1 Introduction

1,2-propanediol (PDO) is an attractive commodity chemical, frequently used as a de-icing fluid and anti-freeze, as well as in the production of cosmetics and pharmaceuticals[1]. The production of PDO currently involves the selective oxidation of propene and involves environmentally unfriendly processes. An efficient synthesis of 1,2-propanediol from lactic acid is an area of great interest in modern day green chemistry. Ru-C catalysts are the most widely studied system for this reaction[2-4], but most of the literature is focussed on using commercially available Ru/C materials for characterizing reaction parameters or comparing different promoters. In this study, we report that various different types of carbon can be used for supporting the Ru nanoparticles and they show different activity under moderate reaction conditions and compare the activity with a commercial carbon-supported Ru catalyst. We also show the effect of preparation method on the catalyst, comparing the use of impregnation *vs*. sol immobilisation and investigate the stability of each catalyst.

3 Experimental/methodology

Wet impregnation method: Asolution of the Ru nitrocyl nitrate (5 wt% with respect to activated carbon) was added to the support in order to obtain a paste. The catalyst was dried (110 °C, 16 h) and heated in N_2 (400 °C, 3h, 20 °C/min heating rate).

Sol immobilisation method: Catalysts were prepared starting from a solution of PVA (10 mg) and ruthenium chloride (0.04g) in water (800 ml). Freshly prepared solution of $NaBH_4$ ($RuCl_3/NaBH_4$ = 1/3.3 mole %) was added to generate the sol. After 30 min the activated carbon (1.98g) was added and the solution was acidified to pH 2 with sulphuric acid. The catalyst was then filtered and dried (110 °C, 16 h).

Characterisation: XRD, TPR, TEM, XPS, and EXAFS were all employed to characterise the samples in this study.

Catalyst testing: The reactor was charged with lactic acid (5% in H_2O, 10 g) and catalyst (0.025 g). The autoclave was sealed, pressurised with hydrogen (35 bar) and stirred (1000 rpm) for 2.5-32 hours at 120 ^{O}C. The reaction mixture was analysed by HPLC (Agilent Technologies 1260 Infinity with a Varian MetaCarb 67H capillary column (0.65 x 30 cm) and a refractive index detector). Products were identified by comparison with authentic samples.

4 Results and discussion

The commercial Ru/C catalyst was more active than those prepared supported on different carbons, as shown in Table 1.

Table 1: LA conversion to PDO with Ru supported on different carbons, wet impregnation method of preparation. Reaction conditions*:* 5 wt.% substrate (0.5M ML, 0.6M LA) in water, 120 ^{o}C, 35 bar H_2 pressure, and 2.5 h reaction time

Catalysts (Ru/C)	LA conversion (%)	PDO Selectivity (%)
Commercial catalyst	19	100
Wood derived carbon	13	100
Coconut shell derived carbon	10	100
Activated carbon	9	100
Graphene oxide	2	100
Carbon black	15	100

The BET surface areas of the carbon supports and the Ru/C were determined along with the the pore size distributions of the two most active catalysts. The addition of Ru did not affect the overall surface area and that there are significant variations in surface areas and pore size distributions that do not correlate with observed catalyst activity. XRD patterns for the Ru-catalysts supported on various carbons show that no reflections can be assigned to Ru.

TPR measurements show that the support has an effect the reduction behaviour of ruthenium, which can have an effect on its activity. Graphene oxide supported Ru, for example, has a higher reduction temperature, which explains its poor activity under reaction conditions. The more active catalysts showed a peak around 90 ^{O}C and another Ru species that reduced at around 200 ^{O}C. The activated carbon and the wood derived carbon showed only one reduction peak at 100 ^{O}C.

XPS and EXAFS measurements also point toward well dispersed ruthenium nanoparticles on the surface being the most

5 Conclusions

We have prepared a series of 5wt.% Ru/C catalysts and compared then with a commercial Ru/C catalyst and carried out characterisation to determine the reason for the activity of these catalysts. The commercial catalyst was the most active, followed by the catalyst prepared on VXC72. These carbon supports facilitate a greater dispersion of ruthenium on the surface, upon which the activity relies.

Keywords: oxygen, activation, Au-Ag clusters, propylene epoxidation

1 Introduction

The development of nanostructured catalysts of selective oxidation is of exceptional significance for science and chemical technology. It is generally accepted that gold is inert, however nanostructured gold exhibits high catalytic activity [1,2]. The electronic properties of gold nanoparticles change with doping heteroatoms [3]. In particular, in gold nanoparticles, the replacement of Au atoms by Ag atoms creates $Au^{\delta+}$ sites. It is known that gold and silver nanoparticles have been used as catalysts for propylene edoxidation. However, silver nanoparticles have very poor selectivity for the epoxidation reaction of propylene. In the case of gold catalysts, shape and size of gold nanoparticles have influence on selectivity of this reaction. One of the key questions for this study is how doping of gold clusters with silver will affect the mechanism of the propylene epoxidation. Another key question is how the structure of gold-silver clusters in general and the structure of active centers in particular will affect on oxygen adsorption and activation.

2 Methodology

Geometry optimizations were performed within the spin-polarized approach (PBE functional) [4]. The Priroda program [5] was used for the all-electron calculations within the scalar-relativistic approach, which was based on the full four-component one-electron Dirac equation with separation of the spin-orbit effects. The initial coordinates of the tetrahedral Ag_{20} and Au_{20} clusters were taken from previous studies [6–8]. The true TS structures were determined according to the Berny algorithm [9]. Calculations or the intrinsic reaction coordinate through the single imaginary mode of the TS were performed to validate the TS structures.

3 Results and discussion

In the present work we considered tetrahedral Au_{20} and Ag_{20} clusters, their mono-doped analogs ($Au_{19}Ag$ and $Ag_{19}Au$), as well as core-shell clusters Au_4Ag_{16} and $Au_{16}Ag_4$. After optimizations, all clusters preserved tetrahedral structure. It should be noted, that silver tends to occupy atoms with high coordination number (facet atoms) in $Au_{19}Ag$, while gold tends to occupy atoms with low coordination number (edge, top) in $AuAg_{19}$. We have previously calculated ionization potentials (IP), electron affinity (EA), energy of HOMO-LUMO gap (E_{H-L}), and average atomic binding energy (E_b) [10]. It was shown that values of all these parameters decrease with an increasing number of silver atoms in cluster. Then we considered three type of oxygen adsorption: molecular (O_2^-), peroxide (O_2^{2-}) and dissociative (atomic O). We obtained that pure gold cluster does not interact with molecular oxygen. It must be emphasized that oxygen dissociation on Au_{20} is endothermic process. Upon replacement of gold atoms with silver atoms in clusters oxygen adsorption became exothermic. In $Au_{19}Ag$ O_2 prefers bonding the apex gold atoms than the facet silver atoms [10]. Only molecular or peroxo-like oxygen adsorption can be formed on the core-shell $Au_{16}Ag_4$ cluster. Two sites of oxygen

adsorption were found on the Au_4Ag_{16} cluster: on the silver atoms located on the edges and on the gold atoms placed on the centre of the facets. Molecular and peroxo-like adsorption is more favorable on the edge sites in the Au_4Ag_{16}. We considered O_2 adsorption on the three isomers of $AuAg_{19}$ having gold atom on apex, edge and facet ($AuAg_{19}$_1, $AuAg_{19}$_2, $AuAg_{19}$_3). The heat of adsorption slightly depends on the location of gold atom, and it is close to 31 kJ/mol for all isomers. E_{ad} of oxygen calculated for Ag_{20} are equal to the E_{ad} calculated for $AuAg_{19}$. Oxygen adsorption on the top atoms of Ag20 is the most favorable [10].

4 Conclusions

The model tetrahedral $Au_{20-x}Ag_x$ (x = 0, 1, 4, 16, 19) clusters having different composition are proposed and examined in the reaction with oxygen. The stability and reactivity are predicted by the calculation of IP, EA, E_b and HOMO−LUMO gap. With the increase of the silver content in the bimetallic Au−Ag clusters values of IP, EA, and HOMO−LUMO gap decrease. Silver tends to occupy the facet position in the bimetallic cluster and gold tends to occupy the apex position. Strong correlation between the cluster activity in oxygen activation and the content of silver atoms in cluster is observed. Oxygen activation and dissociation on Au−Ag clusters are more favorable on edge atoms.

1 Introduction

Porous TiO_2 nanopowders are widely used in solar cells, lithium-ion batteries, photocatalysis, nanobiotechnologies and catalysis [1-2]. The porous structure is important for all the listed fields because it determines the specific surface area, the pore system of a material, and in most cases makes it possible to enhance the functional properties of a material. In catalysis, the porous structure of a material is of special importance because the catalytic processes require pores of a certain size and shape to provide an access of reactants to the active component. Features of the porous structure are determined by the particle size, packing and morphology, i.e. by the texture of a material. In this work, the effect of $TiCl_4$ hydrolysis temperature on the textural properties of the resulting nanoscale rutile and on the changes of these properties upon calcination were studied.

2 Experimental

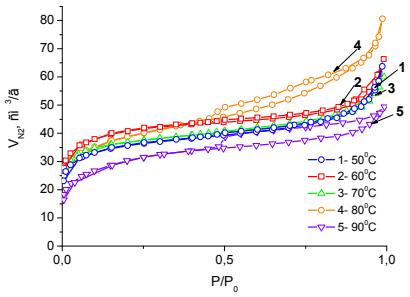
Nanoscale titanium dioxide with the rutile structure was synthesized by thermolysis of titanium tetrachloride in a 0.5 M solution of hydrochloric acid at a temperature of 50, 60, 70, 80, 90°C and a constant ratio $[H_2O]/[Ti] = 39$ in 0.5 M HCl. After the synthesis, the finished product was purified by dialysis against distilled water, dried at 100°C and calcined at 300, 500, 700 and 1000°C.

The textural properties (specific surface area, pore volume and pore size distribution) of the samples synthesized at different temperatures with subsequent calcination were studied by low-temperature nitrogen adsorption on an ASAP-2400 (Micrometrics) instrument and by mercury porosimetry on an AutoPore IV 9500 V1.09 (Micromeritics) device. TEM studies were carried out on a JEM-2010 (JEOL, Japan) electron microscope. SEM studies were performed on a JSM 6460LV (JEOL, Japan) scanning microscope.

3 Results and discussion

As shown by the study of the textural properties of the starting dried rutile powders synthesized at different hydrolysis temperatures, materials with a high specific surface area of 110-140 m^2/g and a pore volume of 0.09-0.12 cm^3/g are produced over the entire temperature range [3]. According to the low-temperature nitrogen adsorption data, the samples synthesized at low temperatures (50-70°C) contain 33-41% of micropores. As the temperature of hydrolysis is raised, the fraction of micropores decreases to 18-21% and, accordingly, the fraction of mesopores increases, which is indicated also by a growing hysteresis loop on the adsorption isotherms (Fig. 1).

Fig. 1. Nitrogen adsorption-desorption isotherms for rutile samples synthesized at different temperatures.



Calcination of the rutile samples is accompanied by a decrease in the specific surface area and pore volume. A decrease in the specific surface area upon calcination up to 300°C is related to the sintering of micropores and the growth of crystallites. Further elevation of the temperature produces even a greater increase in the crystallite sizes, increases the size of mesopores and decreases their volume. Sintering of mesopores and a decrease in their size and volume are observed for the samples calcined at 1000°C. These samples are virtually non-porous. As shown by the BET study, rutile synthesized at 90°C is most stable to sintering.

According to the TEM data, the coherently intergrown rutile crystallites form the filaments that agglomerate into the fan-like structures. Raising the synthesis temperature increases the length of filaments and the density of agglomerates. Upon calcination of the rutile samples, size of the particles increases and their shape changes from filamentary crystals at 100°C to elongated 10-30 nm plates at 300-500°C, and then to 50-70 nm octahedra at 700°C and more than 300 nm octahedra at 1000°C. In addition, elevation of the calcination temperature decreases the number of interparticle boundaries, decreases the number of defects in the samples and increases their crystallinity. The TEM data agree well with the results obtained by the BET study of the calcined samples.

The morphological features of nanorutile powders in dependence on the synthesis and calcination temperatures were revealed by the SEM method. It was shown that a low synthesis temperature (50-70°C) leads to conglomerates of underdeveloped globules consisting of the fan-like agglomerates. As the synthesis temperature is raised to 80°C, the globules start to separate from each other to form the spheres with a better energy compensation; this process is completed at 90°C. The size of conglomerates increases with raising the hydrolysis temperature and remains virtually unchanged during the calcination.

4 Conclusions

The BET, TEM and SEM studies of nanoscale rutile have demonstrated that the particle morphology is characterized by a hierarchical packing: the coherently intergrown crystallites form the filaments that are aggregated into the “open fan” structures, such fan-like aggregates are packed in conglomerates represented by the intergrown or separated globules in dependence on the synthesis temperature. The temperature mode is the key factor that produces changes at different packing levels and determine features of the porous structure of nanoscale rutile.
