2 Experimental/methodology

Cesium salts of tungstophosphoric acid $Cs_xH_{3-x}PW_{12}O_{40}$ (x= 1.5; 2.0; 2.5) were prepared as described in [3]. They were characterized by BET, XRD, TEM, FTIR techniques [3,4]. Gas-phase carbonylation of DMM was studied in a flow reactor at pressures 1 and 10 atm in the temperature interval 80-140°C, at GHSV = 5000-6000 h^{-1} and molar ratio DMM/CO = 4/96 ÷ 4/76. The composition of the inlet and outlet gas mixtures was analyzed by gas chromatographs.

3 Results and discussion

Table 1. Performance of $Cs_xH_{3-x}PW_{12}O_{40}$ in DMM carbonylation to MMAc.

Catalyst	S_{BET} [a] m^2/g	N [b] mmol/g	X_{DMM} [c] %	S_{MMAc} [d] %	W_{MMAc} [e] mmol/(g h)	TOF [f] h^{-1}
$Cs_{1.5}H_{1.5}PW_{12}O_{40}$	57	0.128	58	11	0.2	1.56
$Cs_2H_1PW_{12}O_{40}$	103	0.118	90	12	0.5	4.2
$Cs_{2.5}H_{0.5}PW_{12}O_{40}$	216	0.048	96.5	16	0.92	19

a – BET surface area, b – concentration of BAS, c – DMM conversion, d – MMAc selectivity, e – MMAc productivity, f – rate of MMAc formation per one BAS.

Table 1 compares the catalytic properties of $Cs_xH_{3-x}PW_{12}O_{40}$ for DMM carbonylation to MMAc. The data were obtained at atmospheric pressure, T = 120 °C, molar ratio CO/DMM =

4/96 and GHSV = 5000 h^{-1}. Similarly to [1,2], MMAc, DME and MF were the main reactions products. It is seen that the activity (X_{DMM}, W_{MMAc}, TOF) and selectivity (S_{MMAc}) of $Cs_xH_{3-x}PW_{12}O_{40}$ catalysts in the DMM carbonylation reaction descended in the following order: $Cs_{2.5}H_{0.5}PW_{12}O_{48}$ > $Cs_2H_1PW_{12}O_{48}$ > $Cs_{1.5}H_{1.5}PW_{12}O_{40}$.

The most active catalyst $Cs_{2,5}H_{0,5}PW_{12}O_{40}$ provided ~100% DMM conversion and MMAc productivity ~1 mmol·g^{-1}·h^{-1} with ~16% selectivity.

The effect of pressure in the DMM carbonylation reaction was studied with the use of most active catalyst. Fig. 1 presents the effect of temperature on DMM conversion and product distribution at DMM carbonylation over $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ at pressure of 10 atm.

Obviously, the DMM conversion increases with increasing temperature and exceeds 80% at 120°C. The DME concentration also increases with increasing temperature and reaches 1.7 vol.% at 120°C. The MF concentration remains constant in the temperature interval 90-120°C and amounts to ~0.7 vol.%. Concentration of the target product MMAc increases with increasing temperature and attains maximum value of 1.6 vol.% at 110°C. Under these conditions, the selectivity to MMAc was 54%, MMAc yield and productivity amounted to 40% and 2.4 mmol · g^{-1} · h^{-1}, respectively.

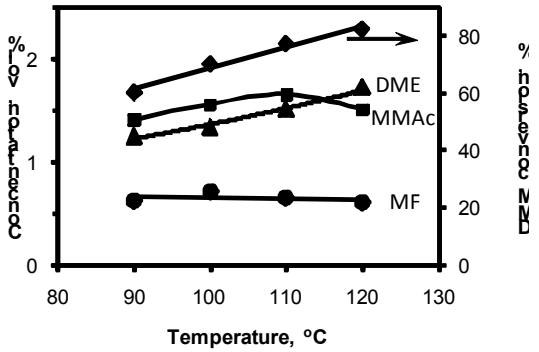

Fig. 1. Effect of temperature on DMM conversion and product distribution at DMM carbonylation over $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ catalyst. Reaction conditions: P = 10 atm, GHSV = 6000 h^{-1}. Inlet composition, vol. %: DMM:CO:Ar = 4:76:20

Based on the data obtained, the nature of the active centers, origin of the observed catalytic activity order and probable mechanism of DMM carbonylation over $Cs_xH_{3-x}PW_{12}O_{40}$ are discussed. Comparative analysis of available DMM carbonylation to MMAc data is presented as well.

4 Conclusions

Catalytic properties of cesium salts of tungstophosphoric acid $Cs_xH_{3-x}PW_{12}O_{40}$ (x= 1.5; 2.0; 2.5) for the gas-phase DMM carbonylation to MMAc were studied for the first time. Among the studied catalysts, $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ showed the best performance. It provided the MMAc yield ~40% at mild conditions: T = 110 °C, P = 10 atm, GHSV = 6000 h^{-1} and DMM/CO = 4/76 mol/mol.

Keywords: rhodium, chiral, ligand, enantioselectivity, hydrogen transfer

1 Introduction

Transfer hydrogenation (TH) catalyzed by transition metal complexes is frequently used for reduction of multiple bonds due to availability of hydrogen donor and simplicity of experiment technique.

In particular, widely known ruthenium catalysts, containing N-(toluensulfonyl)-1,2-diphenyl-diamino-ethane, effective in asymmetric reduction arylketones in 2-propanol or a mixture of formic acid and triethylamine [1,2].

The purpose of this study was the testing of rhodium complex with three structurally similar N,N,N,N-bis-imine ligands in transfer hydrogenation of acetophenone, and establishing the composition and structure of rhodium complex with N,N'- (1R,2R)-cyclohexane-1,2-diyl)bis(1-(pyridin-2-yl)methanimine.

2 Experimental

Elemental analysis was performed on "Euro EA3000-Single", the carrier gas is argon, 120kPa, the temperature of front furnace - 980^{o}C , the chromatograph thermostat temperature - 100^{o}C.

^{1}H and ^{13}C NMR spectra was recorded on impulse spectrometer Bruker DPX250 at 298K in 5 mm ampoules using a broadband sensor BBO5mmZ3074/58.

GC analysis was carried out by Gas Chromatograph-Mass Spectrometers Shimadzu QP2010 Plus in electron impact mode at 70 eV with a subsequent scanning in range m/z 40 to 350; capillary column Equity 5. **Optical rotation** of solutions was determined by automatic digital polarimeter ADP 410 at wave length 589 nm (l = 50 mm, C = 1–5 g/100 ml). Enantiomeric excess of product was determined by Gas Chromatograph GC Agient 7890A, flame-ionization detector and chiral capillary column CYCLODEX-B (length 30 m, internal diameter 0.25 mm).

To clarify the geometry of original rhodium (I) complex with ligand **1** we used DFT B3LYP [3,4] hybrid method. The 6-31G(d) basis set was chosen to describe C, N, O, H atoms and the LanL2DZ basis set was used for Rh. All calculations were performed with Firefly version 8.1 program [5].

3 Results and discussion

Hydride transfer from 2-propanol to acetophenone in the presence system $[Rh(cod)Cl]_2$ + L], where L- bis-aldimine ligands, synthesized by condensation of (*R,R*)-1,2-cyclohexandiamine and pyridin- (**1**), quinolin- (**2**) and thiophencarboxaldehyde (**3**).

Hydrogenation of the ketone in the presence of a catalyst with ligand **1** runs with high reaction rate, for 1-4 hours achieved 100% chemical conversion of acetophenone to 1-

phenylethanol, by-products are not formed. In all cases, we observed the predominant formation of (R)-1-phenylethanol, but catalytic reaction enantioselectivity is only 28%. It is noted that at high reaction rate, leading to the rapid achievement of equilibrium ketone ↔secondary alcohol, there are low yields of predominant enantiomer. Possibly, it could be explained partial racemization of product as a result dehydrogenation reverse reaction of mixture enantiomers.

Enantioselectivity of the catalytic reaction increases in series of ligands: **2** < **3** < **1**, the activity is approximately equal for catalysts with ligands **1** and **2**.

To establish the structure of this complexes we studied interaction of a solution $[Rh(COD)Cl]_2$ in *i*-PrOH with ligand **1**using ^{1}H and ^{13}C NMR spectroscopy method. It was found that there is monodentate coordination of chiral ligand **1** to rhodium atom via nitrogen atom from one of two aldimine bonds. Cyclooctadiene molecule remains in the coordination sphere of rhodium (I) atom.

DFT calculation proves asymmetric coordination of C_2-symmetry ligand **1**.

4 Conclusions

It was found that after hydrogenation of cyclooctadien, Rh(cod)(1)Cl complex transforms into C_2-symmetry five-coordinated hydride rhodium complex, which is active in hydrogen transfer from 2-propanol to ketones.

For acetophenone coordination need to vacate a coordination site near to Rh atom, that involves changing in geometry structure of complex and breaking one or two Rh-N bonds. The last one leads to decrease of enantioface differentiation of prochiral ketone in chirality transfer step. Detailed study of reaction mechanism for optimization process will be discussed in the next researching.

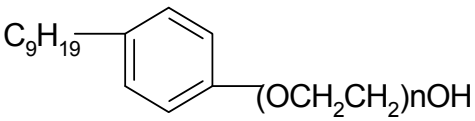
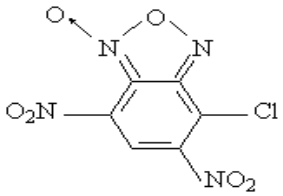
Keywords: kinetic, micelles, liquid crystal, ethoxylated, alkylphenol, 5,7-dichloro-4,6-dinitrobenzophu

1 Introduction

Investigation of the nature of the reactions in liquid crystals is an important problem, which has been poorly studied so far. Knowledge of the laws of chemical processes in the water systems constructed as liquid crystals may shed light on the transformation of the compounds in the human body, because solutions in the human cell are represented in the liquid crystal state [1]. This is especially true for biologically active compounds, such as the 5,7-dichloro-4,6-dinitrobenzophuroxan. Its antifungal activity was shown in the micellar solutions of sodium dodecyl sulfate, cetyltrimethylammonium bromide, p- (1,1,3,3-tetramethylbutyl phenoxy) polyoxyethylene glycol, Tr X-100, cetyl ether, polyoxyethylene (10), regarding *Trichophyton mentagrophyte, Candida albicans* [2]. 5,7-dichloro-4,6-dinitrobenzofuroksan is solubilized in micelles of oxyethylated nonylphenols, NPh 9-n [3]. However, behavior of this substrate in liquid crystals has not been studied so far. In this study we investigated the effect of the hexagonal mesophase formed in water by the ethoxylated alkylphenol (NPh 9-12) on the chemical behavior of substrate:



$C_9H_{19}C_6H_4O(C_2H_4O)_{12}H$,
NPh 9-12



5,7-dichloro-4,6-dinitrobenzophuroxan
DChDNBPh

2 Experimental/methodology

The UV/Vis absorption spectra were measured using Agilent 8453 spectrophotometer. The type of mesophase was determined by means of polarizable microscope Biolam L 212 (LOMO).

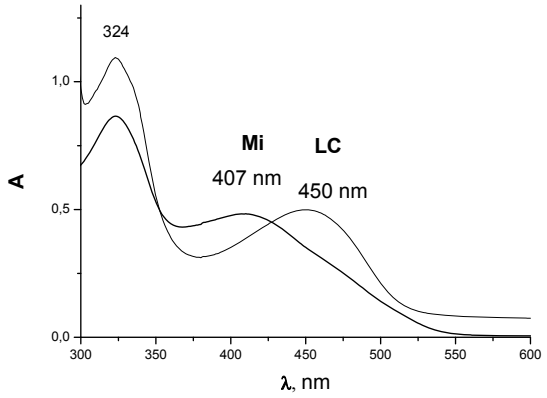
3 Results and discussion

Micelles in system NPh 9-12 + H2O (I) were formed in the concentration of $1.24*10^{-4}$ M [2]. Fig. 1 shows the alteration of DChDNBPh spectra depending on its concentration after 24 hours after preparation. As can be seen from Fig. 1, in system (I) DHDNBFO in the micellar environment has the absorption bands at 323 nm and at 407 nm., which are close to the absorption bands in water (400 nm).

When concentration of the NPh 9-12 in system (I) reaches 30%, hexagonal mesophase is formed (texture is shown in Fig. 3). The hexagonal mesophase, or E-phase, is a hexagonally-

packed cylindrical micelles.

Injection of the DChDNBPh substrate in E-phase stimulates the reaction leading to the shift of the absorption band from 407 nm to 450 nm. This may be caused by the formation of the DChDNBPh- NPh 9-12 σ-complex (see Fig. 2). The reaction rate of the σ-complex formation was computed from the dependence A = f (τ) (Fig. 4), where A is an optical density and τ is the time in seconds. Analysis of the kinetic curve indicates a first-order reaction of DChDNBPh. First order rate constant calculated with the Guggenheim method is equal k = 0,00103 s^{-1}± 2,8967 10-5 s^{-1} , r = 0.9950



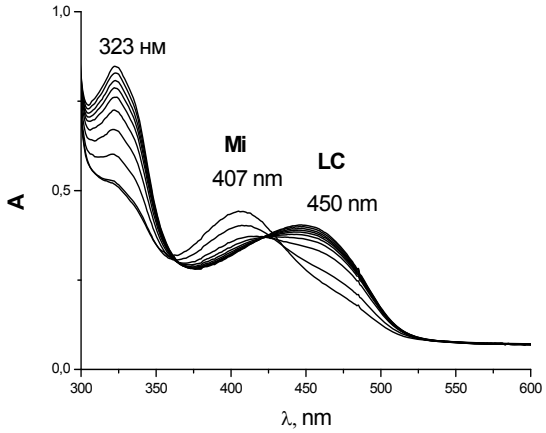


Fig.1. The alteration of UV-spectra of DChDNBPh **Fig.2.** The alteration of UV-spectra with the time in micellar and hexagonal mesophase after 24 hours. for the NPh 9-12 + H_2O + DChDNBPh system, 25 ^{0}C

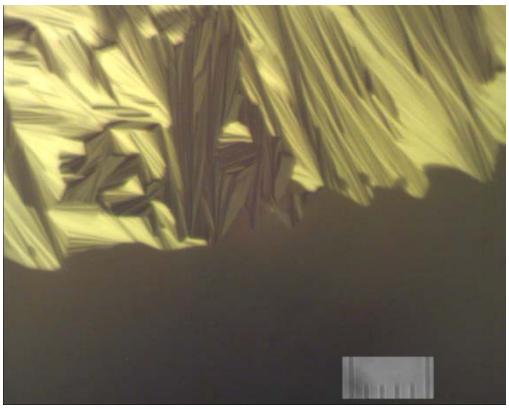

Fig.3. Fanlike texture of hexagonal mesophase NPh 9-12 + H_2O system. Crossed Nicols, x 200

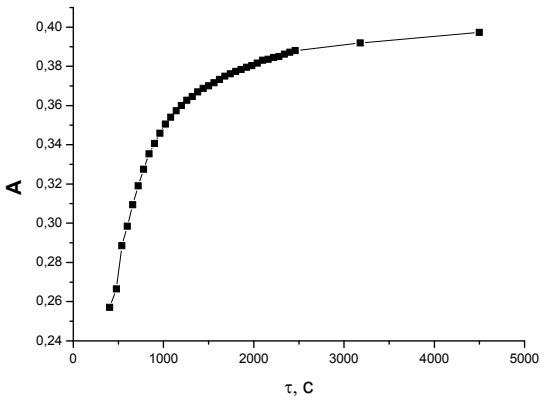

Fig.4. The alteration of optical density with time for absorbtion band at 456 nm in system NPh 9-12+ H_2O + DChDNBPh, 25 ^{0}C

4 Conclusions

Thus, this study for the first time reveals the formation of the σ-complex in the hexagonal mesophase of the NPh 9-12+ H_2O+ DChDNBPh system, whereas this complex has not been observed in the micellar pseudophase.

Oxidation of Heavy Oil in the Presence of Supercritical Water

Baybekova L.R.*, Petrov S.M., Zakieva R.R., Ibragimova D.A., Karalin E.A.

Kazan National Research Technological University, Kazan, Russia

* L_baibekova@mail.ru

Keywords: supercritical water, extra heavy crude oil, conversion, canalytic, crude oil upgrading, bitumen

1 Introduction

Supercritical fluids are now becoming more and more relevant in the processes of oil production and processing, especially in connection with development of unconventional hydrocarbon resources: heavy oil and natural bitumen. Recent academic studies have shown that supercritical solvents give high level of quality control and productivity in the reaction chemistry and the processing of materials that is difficult to provide using conventional techniques and solvents.

The transfer of material into a supercritical state occurs in a closed volume in the critical temperature and pressure, and accordingly, these values determine the critical point of each of these substances. Supercritical fluids are characterized by very low viscosity and high diffusion ability. Both characteristics are extremely important for the petroleum industry and are the basis of the practical use of the substance in the supercritical state.

2 Experimental/methodology

The aim of this work was the conversion of unconventional hydrocarbon resources in light petrochemical products. We studied heavy bituminous oil upgrading, reducing the sulfur content and increasing the yield of valuable distillate fractions.

As the object of the work was selected bituminous oil of Ashalchinskoye field with a density of 0.9715, and a viscosity of 2771 mPas at 20 ° C.

A series of experiments on the oxidation of high-viscosity oil in the presence of water in a supercritical state was performed in a laboratory catalytic reactor made of stainless steel in the temperature range with an upper limit of 380 ° C, the effect of temperature and pressure conditions was 2 hours.

Was produced by the selection of initiating agents. Components additives previously milled in a ball mill until the coarse state, and then were homogenized by a mechanochemical activation apparatus with an ultrasonic frequency of the ultrasonic waves of 22 kHz and the energy density of 5 W / cm² at the installation Ultrasonic Processor UP 400S, Hielscher. Control of nano dispersion was made on the device SORBI-M. Determination of the morphology of the surface of the carbonaceous substance carried in the raster scanning electron microscope. Initiating stabilizing additive in an aqueous medium the anionic surfactant.

3 Results and discussion

The results of experiments on the effects of water in a supercritical state on high-viscosity crude oil upgrading were impressive. The viscosity of the oil after the test decreased by 28% compared to the initial sample. In a converted oil decreased content of resin-asphaltene components and redistribution of high molecular weight paraffins from complex molecules agglomerates.

4 Conclusions

For products of conversion to perform a complex analysis, which allowed trace the

transformation of hydrocarbon components of oil. Based on these studies, we evaluated the effect of various additives in combination with thermobaric effect on the conversion of heavy hydrocarbons into lighter fractions.

Keywords: catalysis, gold copper, bimetallic, selective oxidation, colloid

1 Introduction

A wide range of selective oxidative transformations of high importance in synthesis of fine chemicals and value added chemicals from biomass are promoted by gold using O_2 as oxidant at relatively low temperature and with very high selectivity. Efficiency of gold can be significantly improved or modified combining it with a second metal. We investigated earlier sol derived bimetallic AuAg nanoparticles (NPs) supported on SiO_2 in selective oxidation reactions using glucose and benzyl alcohol model substrates [1,2]. In this work alumina supported AuCu bimetallic systems were studied.

2 Experimental/methodology

Bimetallic AuCu (Au/Cu=1/1 molar ratio) and analogous monometallic aqueous sols were prepared by liquid phase reduction using $NaBH_4$ reducing and polyvinyl alcohol stabilizing agent. AuCu NPs with different structure were formed by co- (Au&Cu) and consecutive reduction of the precursor ions, Cu reduction on Au NPs (Cu→Au) and vice versa (Au→Cu). The nanoparticles were deposited on Degussa alumina support by adsorption, the total metal loadings were 1 mmol/g_{cat}. The samples were studied after calcination (400°C/air/1h) applied for removal of organic contaminations and also after consecutive reductive treatment (350°C/H_2/30min) providing metallic state of the active components. For structural characterization UV-vis spectroscopy, high resolution electron microscopy (HRTEM), X-ray photoelectron spectroscopy (XPS) and CO chemisorption followed by FTIR spectroscopy was applied. The catalyst samples were tested in selective glucose oxidation (0.1 M glucose in water, 35°C, pH: 9.5) and benzyl alcohol oxidation (1.0 M benzyl alcohol in toluene, 80°C) using O_2. The selectivity of gluconic acid formation was 100% for all the catalysts. In benzyl alcohol oxidation beside benzaldehyde only benzyl-benzoate with 4-10 % selectivity (up to around 5-10% conversion) was detected. Initial reaction rates were determined and compared.

3 Results and discussion

Table 1 presents several structural data of the catalysts in as prepared state and after calcination and reduction treatments, their catalytic activity is characterized by initial reaction rates. The particle sizes of the original nanoparticles varied between 1.8-2.8 nm in diameter. According to HRTEM studies in Au&Cu and Cu→Au samples alloyed AuCu (with around Au/Cu≈8/2 atomic ratio) and Au core with less and more Cu-oxide decoration, respectively, were formed, while in Au→Cu alloyed AuCu of less Cu-concentration than in Au&Cu was suggested with Cu-oxide decoration. The presence of some Cu-oxide separated from gold containing particles was also possible. The oxidative and reductive treatments of the supported

samples induced some restructuring of the particles diminishing the differences between them. Due to slight sintering in the bimetallic samples caused by calcination treatment the particle sizes became very similar (only in Cu→Au/Al_2O_3 was somewhat larger), that did not change during reduction. Calcination induced some segregation and oxidation of Cu as deduced from HRTEM (based on lattice parameters) and XPS (as shown by Cu/Au atomic ratios and appearance of Cu^{2+} states) results. Treatment in hydrogen reduced copper and decreased surface Cu/Au ratio that may be due to the dissolution of some copper into the alloyed phase or sintering of that. Au&Cu/Al_2O_3 was the most active among the bimetallic samples in both glucose and benzyl-alcohol oxidation. In the latter reaction all the AuCu/Al_2O_3 samples showed synergetic activity increase compared to the monometallic ones (remember that Au loading in Au/Al_2O_3 was two times higher than in bimetallic catalysts), in glucose oxidation the Cu introduction decreased the activity of Au/Al_2O_3.

Table 1. Metal particle sizes, mean lattice distances of Au(Cu) (111), Cu/Au surface atomic ratios and catalytic activity of the samples after different treatments.

	calcined	n.a.	-	-	0.0	0.0
	reduced	n.a.	-	-	0.0	

4 Conclusions

AuCu/Al_2O_3 (Au/Cu=1/1) catalysts derived from bimetallic colloids prepared by co- or consecutive reduction of precursor ions, presented clear synergetic activity increase in selective oxidation of benzyl alcohol as compared to the monometallic analogous, while in glucose oxidation the Cu addition decreased the activity of Au/Al_2O_3. In both reactions Au&Cu/Al_2O_3 with alloyed core (Au/Cu≈9/1 atomic ratio) and possible less Cu-oxide decoration was the most active bimetallic sample. Presumably, the size of the free extended AuCu alloy surface of increased activity was less optimal for adsorption of glucose than that of benzyl alcohol.

Comparative Analysis of the Thermal Stability of Unmodified and SiO_x-Modiefed Chromia-Alumina Dehydrogenation Catalysts

Bekmukhamedov G.*, Egorova S., Shamsuvaleev B., Boretsky K., Lamberov A.

Kazan (Volga region) Federal University, Kazan, Russia

* giyjaz413@yandex.ru

Keywords: chromia-alumina catalyst, isobutane, dehydrogenation, thermal treatment

1 Introduction

Dehydrogenation of lower paraffins in the fluidized bed of a chromia-alumina catalyst is performed to obtain a C_3-C_5-olefins, which is used in production of synthetic rubber, fibers, films, plastics, high-octane additives. The temperature in the industrial dehydrogenation reactor is 530-580ºC and in the regenerator is 650-680ºC. The oxidative burning of coke on the catalyst surface in the upper region of the regenerator is carried by the combustion of the fuel gas, which results in local overheating of the catalyst. This is accompanied by an irreversible deactivation, which negatively affects the efficiency of the dehydrogenation process. Therefore, an actual task is to improve the thermal stability of chromia-alumina dehydrogenation catalyst.

The aim of this work was a comparative study of changes in the dehydrogenation activity of the unmodified and SiO_x-modified chromia-alumina catalysts under thermal treatment in the range of 900-1100°C.

2 Experimental

Catalysts were synthesized by impregnation of the alumina support with silica sol, aqueous solutions of chromic anhydride and potassium carbonate. The chemical composition of the catalysts is shown in Table 1. Catalyst activation temperature 800°C.

Table 1. Composition of the chromia-alumina catalysts.

Sample	C(Cr_2O_3), wt.%	C(K_2O), wt.%	C(SiO_2), wt.%
Cat-1	9.0	1.0	0
Cat-2	9.0	1.0	2.5
Cat-3	9.0	1.0	4.5
Cat-4	12.5	1.3	0

Catalysts were calcined in a muffle furnace; heating to 900–1100°C was performed at a rate of 4 K/min in an atmosphere of air, and the samples were kept at a specified temperature for 1 h.

The catalysts were studied by X-ray diffraction, low-temperature nitrogen adsorption, electron paramagnetic resonance, UV-Vis- and Raman spectroscopy, temperature-programmed desorption of ammonia.

Catalytic properties in the isobutane dehydrogenation reaction were determined on an automated laboratory unit in a steel flow reactor with a fixed catalyst bed.

3 Results and discussion

During thermal treatment at 900-1100°C the transformation of the catalyst support from γ-Al_2O_3 into mixture of crystalline phases of δ-, θ- and α-Al_2O_3 takes place. It is accompanied by the coalescent pore sintering and the reduction of specific surface area (S_{sp}) of catalysts. At

900°C S_{sp} decreases from 73-77 to 54-60 m^2/g, and in the range of 1000-1100°C S_{sp} decreases to 24-41 m^2/g. As a result the treatment of Cat-1 at 900-1000°C is accompanied by combination of isolated Cr(III) ions into Cr_2O_3 clusters. This leads to increase of the dehydrogenation activity - the isobutane conversion increases from 48.5% to 50.5-51.5% (Table 2).

Table 2. Conversion of isobutane in the dehydrogenation reaction.

Treatment temperature, °C	**Isobutane conversion, %**			
	Cat-1	**Cat-2**	**Cat-3**	**Cat-4**
Initial sample	48.5	53.3	54.5	50.4
900	51.4	52.3	52.1	46.8
1000	50.5	47.9	47.3	41.1
1100	36.3	42.1	43.4	32.4

At 900-1000°C in the SiO_x-modified catalysts Cat-2 and Cat-3 highly ordered Cr_2O_3 structures are formed, which leads to a decrease in the conversion of isobutane from 53.3-54.5 to 47.3-52.3%. During treatment of Cat-4 at 900-1000°C the crystallites of α-Cr_2O_3 are formed, the conversion decreases to a greater extent - from 50.5% to 41.1-46.8%.

Treatment at 1100°C is accompanied by the decrease in dehydrogenation activity of unmodified catalysts Cat-1 and Cat-4 to 32.4-36.3% due to the formation of Cr_2O_3-crystallites and solid solution α-$Al_2O_3 \cdot Cr_2O_3$.

In the modified catalysts Cat-2 and Cat-3 the active component is more stable to treatment at 1100°C compared to the unmodified catalysts due to a decrease in the amount of chromium, which incorporates to the support. In this case the dehydrogenation activity is less reduced, conversion of isobutane decreases to 42.1-43.4%.

Keywords: bimetallic catalysts, selective hydrogenation, palladium, nickel, sulfur resistance

1 Introduction

Gasoline and BTX (Benzene, toluene and xylenes) streams coming from the cracking of petroleum must be purified in order to minimize the concentration of diolefins, responsible of gums formations. The widespread method of purification is the selective hydrogenation of vinyllic bond, keeping the aromatic rings unaltered. These streams can have up to 1000 ppm of sulfur compounds, among them thiophene is one of the most common ones [1,2], being these sulfur compounds the main cause of the loss of activity of metal catalysts in several refinery processes. The objective of this work is to evaluate the influence of the order of impregnation of Pd and Ni in bimetallic catalysts on the activity and sulfur resistance during styrene partial hydrogenation.

2 Experimental Methodology

Catalysts Preparation and Characterization: γ-Al_2O_3 Ketjen CK 300 previously calcined at 823 K (S_{BET}: 180 $m^2\ g^{-1}$) was used as support. Mono and bimetallic Pd-Ni catalysts were prepared by the incipient wetness technique using chloride salts. The bimetallic catalysts were prepared by successive impregnations. Volume and concentration of the impregnating solutions were adjusted to get 1wt % of Pd, 2.4 wt % of Ni on the final catalysts. The systems were characterized by ICP, H_2 chemisorption and XPS. *Catalytic Tests:* styrene to ethylbenzene selective hydrogenation was used as a test reaction. The reaction was performed in a stainless steel, PTFE coated stirred tank reactor, operated in batch mode at 333 K, 2 MPa H_2 pressure and 1200 rpm, using 0.3 g of catalyst and 200 mL of 5% (v/v) styrene in toluene solution. The poisoning tests were done adding 600 ppm of thiophene to the feed. Reactant and products were analyzed by GC.

3 Results and Discussion

The values of mass concentration determined by ICP technique were 1wt% of Pd and 2.4 of Ni. Table 1 shows that the dispersion of monometallic Pd/Al is 3 and 3.6 times higher than that of NiPd and PdNi, respectively. The lower H_2 adsorption on bimetallic could be due to an effect of decoration of Pd particles by Ni species, the latter being not active for H_2 adsorption.

Table 1. Catalysts naming, dispersion (D) and XPS data.

Catalyst	1st imp.	2nd imp.	D(%)	atomic superficial ratios			*Pd 3d5/2 BE (eV)*		*Ni 2p3/2 BE (eV)*	
				Cl/Al	*Pd/Al*	*Ni/Al*	*$Pd^{\delta-}$, Pd^0*	*Pd^{d+}*	*Ni^0*	*NiO*
Pd	Pd		45.1	0.0028	0.0025		334.8 (63%)	336.7 (37%)		
PdNi	Pd	Ni	12.4	0.0108	0.0016	0.015	334.5 (73%)	336.0 (27%)	851.2 (18%)	856.3 (82%)
NiPd	Ni	Pd	15.7	0.0109	0.0021	0.012	334.1 (58%)	335.5 (42%)		856.1

XPS spectra of the catalysts had a peak at 198.5 eV assigned to chloride species that were not eliminated during the thermal treatment stages [3]. On the other hand, bimetallic catalysts had a very low intensity peak for Pd $3d_{5/2}$ in the 334.1-334.5 eV range attributed to $Pd^{\delta-}$, while monometallic Pd had a band at 334.8 assigned to Pd^0 [3]; all the catalysts presented a high intensity peak at 335.5-336.7 eV

assigned to $Pd_x^{\delta+}O_yCl_z$ [4]. When analyzing the BE region of Ni $2p_{3/2}$ spectrum in the bimetallic PdNi two peaks were observed: at 852.1 eV assigned to Ni^0 and at 856.3 eV attributed to electrodeficient species of Ni^{+2}[3]. In the case of NiPd catalyst, only electrodefient Ni species are detected. Bimetallic catalysts had the highest Cl/Al atomic ratios (Table 1). The presence of $Pd^{\delta-}$ species would indicate the formation of a metallic bond or a Pd–Ni alloy.

In all the performed tests the selectivity to ethylbencene was higher than 98%. In Figure 1 are plotted the total conversion of styrene as a function of time-on-stream for all catalysts in absence or presence of poison. It can be seen that PdNi and Pd catalysts display the highest total conversion.

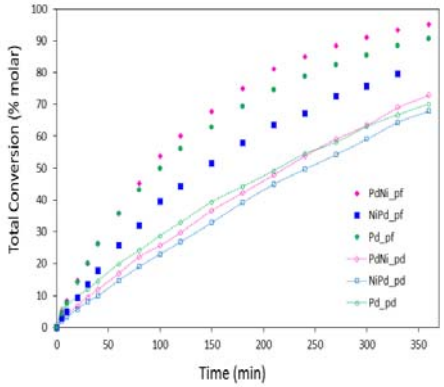

Fig. 1. Styrene total conversion as a function of time in the absence (pf) or presence of poison (pd) for all catalysts.

During the poisoning tests, a decrease in total conversions can be seen as a result of the loss of active sites, and the total conversions are quite similar for all catalysts.In order to compare the sulfur resistance of the catalysts the initial rates of reaction of styrene were determined during the tests with both sulfur-free (r^0_{sf}) and sulfur-poisoned (r^0_{sp}) feeds. From the initial reaction values and considering a simple linear deactivation model (zero order for deactivation), the fraction of poisoned sites (α) can be calculated as $\alpha = 1 - r^0_{sp}/r^0_{sf}$. Table 2 shows r^0_{sf}, r^0_{sp} and α.

Table 2. Values of fraction of poisoned sites (α)

Catalyst	Sulfur-free		Sulfur-poisoned		
	r^o_{sf} (mol mL^{-1} min^{-1})	R^2	r^o_{sp} (mol mL^{-1} min^{-1})	R^2	α
Pd	0.234	0.991	0.114	0.981	0.51
PdNi	0.240	0.992	0.102	0.993	0.57
NiPd	0.163	0.997	0.089	0.997	0.45

According to the most accepted model for sulfur poisoned of Group VIII metals, poisoning occurs by a donation of electrons from the metals to the sulfur atom.

Bimetallic PdNi catalyst turned out to be the least sulfur resistant, this is likely due to the exposed Ni^0 that promotes a strong adsorption of thiophene and thus an enhanced blocking of active sites. The higher sulfur resistance of NiPd than Pd catalyst could be related to the high surface Cl/Al ratio, indicating that $Pd^{\delta+}$oxychlorinated species prevent the adsorption of thiophene by means of steric effect (big size species) and/or an electronic effect (high electronegativity of chlorine).

4 Conclusions

The effect of the sequence of impregnation was evaluated for a series of bimetallic Pd–Ni catalysts. The properties assessed were the catalytic activity and the sulfur resistance during the selective hydrogenation of styrene. The XPS results point to the presence of different Pd^0, $Pd^{\delta-}$ and $Pd^{\delta+}O_xCl_y$ species. The presence of $Pd^{\delta-}$ species would indicate the formation of a metallic bond or a Pd–Ni alloy. The order of total conversion of styrene in the absence of sulfur was: PdNi≅Pd>NiPd. After the poisoning with thiophene the order changed to: Pd>PdNi≅NiPd. Bimetallic PdNi catalyst turned out to be the least sulfur resistant, this is likely due to the exposed Ni^0 that promotes a strong adsorption of thiophene and thus an enhanced blocking of active sites. The higher sulfur resistance of NiPd than Pd catalyst could be related to the high surface Cl/Al ratio, indicating that $Pd^{\delta+}$species prevent the adsorption of thiophene by means of steric effect and/or an electronic effect.

Keywords: fullerene-containing norbornenes, catalyst grubbs 1'st generation

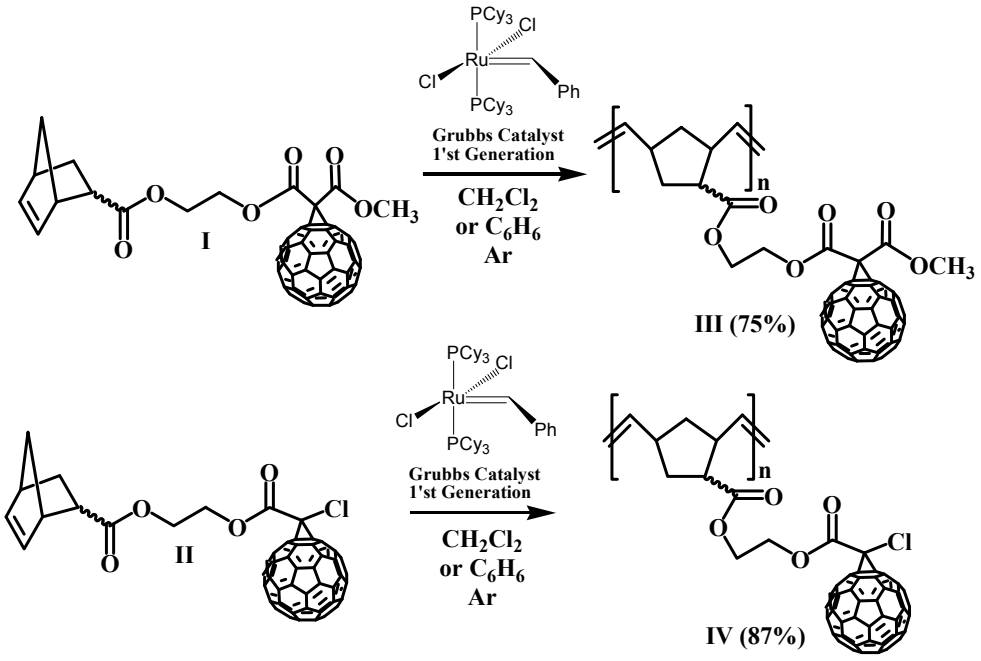
1 Introduction

Fullerene containing thin polymer films are used as acceptor components of bulk heterojunction photovoltaic devices [1-3]. Although organic materials in solar cells are inferior to inorganic ones as far as turnaround efficiency of light (power conversion efficiency, PCE) is concerned, a number of their obvious advantages enables us to consider them as a possible alternative to traditional silicon batteries in future.

Due to low solubility of C_{60} it is difficult to obtain fullerene-based high molecular weight polymers. In this work we report the preparation and characterization of new fullerene-based monomers and a high molecular weight polymer containing C_{60}, obtained by via ring-opening metathesis polymerization.

2 Experimental

The fullerene monomers **I, II** for ROMP was prepared by cycloaddition of malonic and dichloroacetic acid derivatives to C_{60}, purified by column chromatography, and characterized by ^{1}H,^{13}C - NMR, IR, UF- spectrum, mass spectrometry (MALDI-TOF) [4].



3 Results and discussion

Homopolymerization of monomers **I, II** was carried out under inert atmosphere at the presence of the Grubbs 1'st generation catalyst at room temperature in the CH_2Cl_2 solution. During the first 6 hours consumption of the initial monomers (TLC control) and precipitation were observed. The polymers **III**, **IV** are insoluble in $CHCl_3$, C_6H_6, $C_6H_5CH_3$, THF and EtOAc and is partially plumped at keeping in DMSO, so the molecular weight of polymers was impossible to estimate.

Keywords: graft copolymers, iron and nickel, catalytic systems

1 Introduction

Development of new methods for preparation of polymer materials with definite properties is the most important task in modern polymer chemistry. In recent years, the methods of controlled radical polymerization are actively developed, which allow purposefully modify the structure and properties of the polymeric material [1-4]. The effective way towards solution of this problem is realization of copolymerization, i.e. modification of polymer properties through the involvement of monomers of different nature in polymerization. This method permits to obtain statistical, gradient, block and graft copolymers. The graft copolymers are perspective materials due to the possibility of change of their structural constituents, such as the length of the grafting block, the composition and length of the fundamental block. This method opens up wide prospects to obtain materials with new properties.

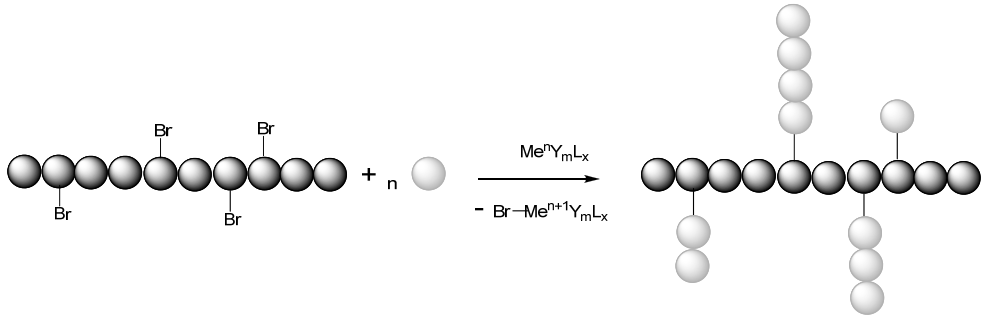
2 Experimental

Vinyl monomers were washed with aqueous alkaline solution and water, dried over calcium chloride and then distilled. Solvents were purified by distillation. Reagents were placed in an ampule. After degassing the content, the ampule was sealed in vacuum. The polymerization was carried out at 25-80°C. Molecular weights were determined by SEC calibrated with polystyrene standards. The monitoring of the polymerization kinetics was made by weight method. The composition of copolymer was studied by the method of IR-spectroscopy.

3 Results and discussion

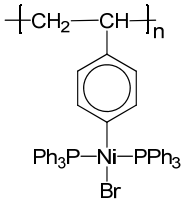
We have developed a method for producing graft copolymers on the basis of brominated polystyrene (**BPS**) in the presence of zerovalent iron and ($NiBr_2$ (PPh_3): Zn) as a catalytic system. BPS acts at the same time as the structural basis of the graft copolymer and initiator in the process of synthesis of graft copolymers (**scheme 1**). The synthesis of BPS was condiucted by bromination of polystyrene in the presence of iron powder and of iron chloride (III). It was established that the nature of catalyst and solvent affect on the yield of BPS. The highest yield of BPS was obtained in the case of the carrying out the reaction in chloroform. BPS structure was confirmed by IR spectroscopy.

It has been shown that the catalytic systems based on iron and nickel allow ones to carry out copolymerization of BPS with monomers of different nature (methyl acrylate (**MA**), methyl methacrylate (**MMA**), butyl acrylate (**BA**), tret.-butyl methacrylate (**t.-BMA**), octyl methacrylate (**OMA**), vinyl acetate (**VA**), acrylonitrile (**AN**). The process proceed in the «grafting from» mode in the temperature range 25-80°C. Exemplified by the synthesis of the graft copolymer of PS-PMMA we analyzed the influence of solvent nature and composition of the catalytic systems on the product yield. The highest yield of the graft copolymer with the lowest content of side products (cross-linking of polymer) was obtained using THF as solvent.



Scheme 1

It was shown that the activity of the catalytic system based on zerovalent iron increases in case of the copolymerization in the presence of PPh_3. The system based on BPS : Fe (0): PPh_3 taken in a ratio of 2: 1: 2 gives the highest yields of PST-PMMA graft copolymers. When using systems based on a nickel complex ($NiBr_2$ (PPh_3) : Zn) it was established that metallic zinc acts as a reducing agent. The note that the catalysis was realized due to zerovalent nickel complexes. The synthesis of the macrocatalyst consisting from BPS and zerovalent nickel was performed **(scheme 2)**. On the base of that macrocatalyst the graft copolymer of PS-PMMA was synthesized with the higher yield relative to the one-step method of synthesis of graft polymers in the presence of $NiBr_2$ (PPh_3): Zn system. In this case formation of crosslinked polymer was not observed at all.



Scheme 2

Zerovalent iron systems were tested in the synthesis of graft copolymers of different natures described above. The structures of the copolymers obtained were proved with the help spectroscopic methods: IR and H^1-NMR spectroscopy. The glass transition temperature was defined for these graft polymers. It was established that in the case of synthesis of the PS-PMMA copolymers using iron and nickel catalytic systems the glass transition temperature of samples is higher than of the initial BPS and PS samples.

4 Conclusions

In such a way we have developed new approaches to the synthesis of graft copolymers of different structure. The proposed technique for obtaining graft copolymers is more effective as compared with the conventional method for producing graft copolymers based on systems polymer - monomer - radical initiator. This method gives a possibility of using zerovalent iron and catalysts based on nickel to modify the properties of the copolymers.

Keywords: Aza-Claisen rearrangement, diazocompounds, triflate, yttrium

1 Introduction.

Catalytic reactions of diazocompounds with unsaturated compounds are widely used in organic synthesis as a convenient method of obtaining practically important polyfunctional compounds of various structures [1–5].

Onto the direction of the catalytic interaction (the cyclopropanation of C=C-bond, the 1,3-dipolar cycloaddition, the introduction of the carbene into bond of C–H or C-heteroatom) and the yield of the produced reaction products are strongly influenced from the structure of both olefins and diazocompounds, as well as the catalyst nature.

Thus, for example, the diazomethane is reacted with allylamines in the presence of $(PhCN)_2PdCl_2$ to form cyclopropanes [2]. The interaction of allylamine with ethyl diazoacetate under the influence of catalysts on the basis of Co, Ni, Rh, Ru results in to the esters of unsaturated *N,N*-dialkylaminoacid by the [2, 3] – rearrangement formed *N*-ylides [3, 6].

Recently, we found triflate activating effect of rare earth elements on the reaction of 1,3-dipolar cycloaddition of diazoesters to electron deficient dipolarophiles to give the corresponding 1- or 2-pyrazolines [7].

2 Experimental/methodology.

In the present work, we studied the catalytic interaction of *N*-allyl-*N*-methylaniline (I) with diazoacetone (IIa) and ethyl diazoacetate (IIb) in the presence of $Y(OTf)_3$. The reaction was performed by 80 ^oC by addition diazocompounds into the benzene to solution of *N*-allyl-*N*-methylaniline (I) and triflate yttrium, with a molar ratio of I : N_2CHCOR : Cat = 5 : 5 : 1.

3 Results and discussion.

We have found that *N*-allyl-*N*-methylaniline (I) reacts with diazoacetone (IIa) and ethyl diazoacetate (IIb) in the presence of $Y(OTf)_3$, forming with the yields 56 and 66% *N*-(2-allylphenyl)-*N*-(acetylmethyl)-*N*-methylamine (IIIa) and ethyl *N*-(2-allylphenyl)-*N*-methylglycinate (IIIb).

This transformation is an example of a tandem reaction [8], which begins with the accession to the amino group of carbene, catalytically generated from diazocompound, and, formation of the intermediate allyl *N*-ylide which is prone to intramolecular aza-Claisen rearrangement at the *o*-position of the benzene ring [9–11].

It should be noted that at the absence of diazocompound the migration of allyl group at the *o*-position do not occurs.

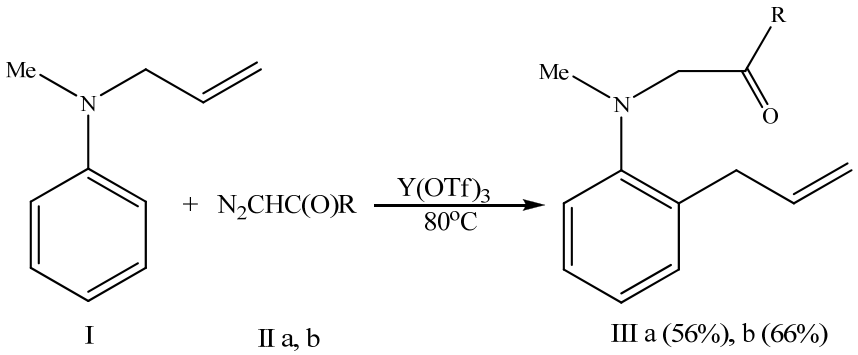

Fig. 1. The interaction of *N*-allyl-*N*-methylaniline with diazoacetone and ethyl diazoacetate.

4 Conclusions.

The possibility of catalytic reactions application of *N*-allyl-*N*-methylaniline with diazocompounds for one-pot synthesis of tertiary amines containing 2-allylphenyl substituent is shown.

Keywords: Fischer-Tropsch synthesis, GTL-FPSO, hydrotalcite, bimodal structure

1 Introduction

Recently, because of the high oil prices and limited petroleum reservoirs, stranded gas fields have received much attention as attractive resources to produce the liquid fuels by GTL-FPSO process [1]. Supported cobalt catalyst have long been used for FTS,especially when long catalyst life times and high selectivities for paraffins are required [2]. The selection of the support for a cobalt catalyst has considerable influence on FTS due to its physicochemical properties. Especailly the support with bimodal structure has taken advantages for FTS, since the pore was in the macropore to enhance mass transfer and the other was in the mesopore to maintiain higher surface area [3]. The hydrotalcite(HT)-like compound possing have bimodal structure was proposed as a new kind of support for FTS in this studies. The general from for HT is $[M_{1-x}^{II}M_x^{III}(OH)_2][A^{n-}]_{x/n}\cdot mH_2O$, where divalent ion may be Mg^{2+}, Zn^{2+} and trivalent ion may be Al^{3+}, Fe^{3+}, Cr^{3+}. The compensation anions may be NO_3^-,CO_3^{2-},SO_4^{2-},Cl^-.Generally, X can have values approximately 0.1-0.5. The HT-based catalyst have been recently reported for several process in the energy field, such as hydrogen production from the reforming process [4]. But the none study reported upto for using of HT with bimodal strucrture as support, in which the coblat is dispersed on the HT surface for FTS. The aim of this work is to examine these aspects, in the case of Co/HT with different pore size prepared to develop highly active and selective bimodal pore-stuctured catalyst for FTS.

2 Experimental/methodology

The supports were prepared by a sol-gel method with hydrotalcite (HT)-compounds $Mg_{2x}Al_2(OH)_{4x+4}CO_3\cdot nH_2O$(Sasol,MG70), Kaolin (Sigma Aldrich) and Al nitrate (Samchun). The different ratios of mentioned components were used for controlling pore size. The required amount of HT was dispersed in ethanol. The solution was mixed with the required amount of kaolin and Al nitrate. The pH of mixture slurry was adjusted by ammonia solution to the range of 9–10, then aging for 12 h at 80 ˚C. It was filtered and washed repeatedly with hot water until neutral pH. The clay was dried at 60 ◦C for 12 h and calcined at 500 ˚C for 5 h. The supports were designated as KIST 1-4. After preparing the supports, The 15 wt% of cobalt was added on the support through multiple steps using aqueous cobalt nitrate solution ($Co(NO_3)_2.6H_2O$ 98 %), following reported literature [5]. It was dried at 60 ˚C for 12 h and calcined at 400 ˚C. The catalysts were characterized by Mercury porosimetry, N_2 physisorption, TPR, XRD, SEM and TEM. Catalyst activity was studied in a fixed-bed continuous down flow reactor of 12.7 mm Id with 0.4 g of catalyst. Catalyst were reduced at 450 °C, using pure hydrogen for 12 h. Reaction was carried out at 20 bar pressure, 250 °C and GHSV of 3000 h^{-1}, with reactant mole ratio of 2 [H_2/CO]. Products were cooled in cold and hot traps and analysed through off-line GC. Non-condensable effluent gases was analysed by online GC.

3 Results and discussion

From the Mercury porosimetry analysis (Fig.1), it was found that the prepared support had bimodal structure compared to the MG70. And the different ratio of HT: Kaolin: Al nitrate made it induced different pore structure respectively. It was confirmed that the support were successfully made by the different ratio and cobalt was successfully impregnated on the prepared support as shown in Fig.2. The variation of cobalt oxide which was affected on the induced physicochemicalm proprtites was observed. The bigger size of Co_3O_4 on KIST 1 and KIST 2 was observed compared to those of KIST 3 and 4. These results were attributed to the existence of higher macro porosity, which led to formation of the lager cobalt crystallite size. And the trend was followed by the sequence of porosity of support (KIST1> KIST2> KIST3> KIST4) [6].

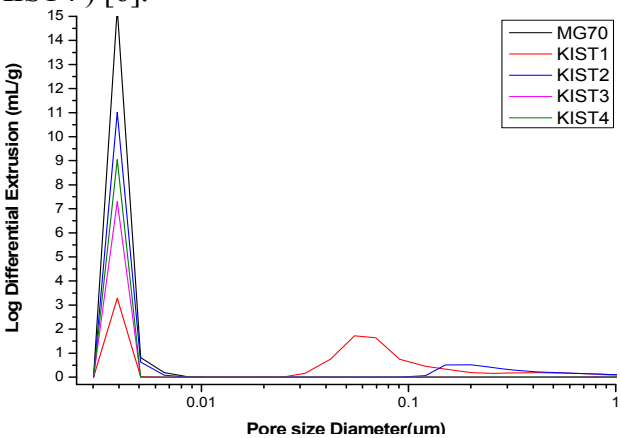

Fig. 1. Mercury extrusion as a function of pore size.

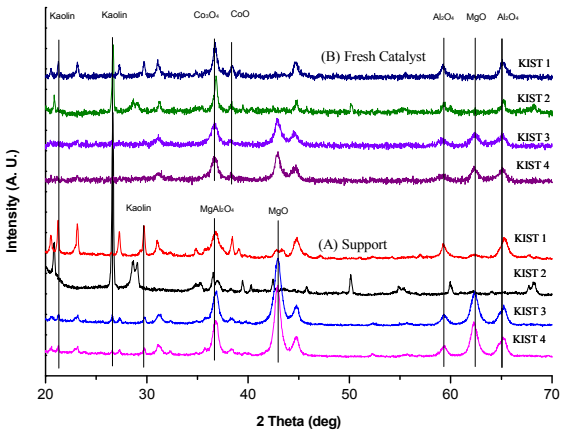

Fig. 2. XRD patterns of prepared catalysts.

4 Conclusions

The Co/MG70 catalyst had the moderate CO conversion and highest CH_4 selectivity in this work. The Co/MG70 had the higher dispersion of cobalt due to the high surface area of support supplied. But the smaller pore of MG70 caused the increase of H_2/CO. In other words, The greater diffusion rate of H_2 compared to CO firstly filled in the pore and the decreased ratio of CO to H_2 might enhance the selectivity of CH_4 and lighter hydrocarbons. And the KIST 3 and KIST 4 catalyst had the lowest CO convserison and moderate C_{8+} selectivity in this work.The Co/KIST3 and Co/KIST 4 had the low dispersion of cobalt due to the low surface area. The large pore diameter made the cobalt particles more aggregated, leading to low cobalt dispersion and low catalytic activity. On the other hands, the highest CO conversion and highest C_{8+} selectivity was observed in the KIST1 and KIST2. The Co/KIST1 and KIST2 had the moderate dispersion of cobalt and highest reducibility due to the lager cobalt crystallite size. The bimodal structure of support maintained the surface area of meso-pore and enhanced the porosity from macro-pore, which provided facile mass-transfer of heavy hydrocarbons.

Deactivation Studies on Non-Oxidative Methane Conversion to Aromatics over Molybdenum Modified HZSM-5 Catalyst

Budde P.K., Upadhyayula S.*

Indian Institute of Technology Delhi, New Delhi, India

* sreedevi@chemical.iitd.ac.in

Keywords: methane, dehydro-aromatization, Bi-functional catalyst, MoO3/HZSM-5, thermo-gravimetric analysis (TGA), temperature programmed oxidation (TPO)

1 Introduction

The declining crude oil reserves have shifted focus on to natural gas as an alternative supply for fuel. Thermodynamic calculations show that methane conversion to aromatics is insignificant below 600ºC, when the formation of solid carbon is included and the formation of carbon is thermo-dynamically favourable at 300ºC. At equilibrium, formation of benzene is not significant as compared to formation of solid carbon [1]. Among the various processes, methane dehydro-aromatization to aromatics over Mo-HZSM-5/Mo-HMCM-22 catalysts seem to be most promising [2]. However, the formation of coke is inevitable. It is a great challenge to reduce the formation of the carbonaceous deposits in methane dehydro-aromatization for its potential industrial applications. This work mainly focuses on improving the catalyst activity and stability by understanding the deactivation mechanism of the catalyst.

2 Experimental/methodology

The molybdenum supported catalyst was synthesized by conventional impregnation of ammonium-heptamolybdenate (AHM) on HZSM-5, SAR-30 followed by drying at 120ºC for 12 hours, which was later calcined at 550ºC for 6 hours. The catalyst activity tests were performed in fixed bed tubular continuous flow quartz reactor at atmospheric pressure. The feed gas was passed over the catalyst at desired temperature and the outlet product mixture was heated to 200ºC to avoid in-line condensation. The standard mixture of 90% CH_4 and 10% N_2 as an internal standard used to analyse the gaseous products from the reactor. Methane conversion and selectivity to aromatics and coke was calculated by carbon balance as described in the literature [3]. Catalysts were pre-treated with 90% CH_4+H_2, H_2 and N_2 which are labelled as A, B and C, respectively. Characterization of coked catalyst was done by using XRD, TPD, TGA, TPO and HRTEM.

3 Results and discussion

The effect of pre-treatment of the laboratory prepared 2%Mo-HZSM-5 catalyst on the methane conversion and product selectivity is shown in Table-1. Catalyst pre-treated with CH_4+H_2 was found to be prone to less coking and higher aromatic selectivity than H_2 and N_2 pre-treated catalyst.

TG-DTG/DTA profiles of the spent catalyst which correspond to the different pre-treated catalyst as illustrated in Fig.-1 below. The weight loss of the catalyst between 100-300ºC is due to the desorption of moisture, latter the weight loss of the catalyst in the temperature range (450-600ºC) can be attributed to combustion of coke formed on the catalyst. DTG/DTA profiles indicate the weight loss of the catalyst and its endothermic and exothermic nature of weight loss of the catalyst. Here, the coke burning-off temperature shifted from 540ºC to 575ºC due to increase in condensation of coke.

Table 1. Methane conversion and selectivity over 2%Mo-HZSM-5 catalyst at 700ºC, GHSV=1200 $cm^3/g.h$,1atm and Time on Stream (60min).

Catalyst	$\%X_{CH4}$	Selectivity (%)					
		C_2-C_3	Benzene	T+X	Naphthalene	CO	Coke
2%Mo-HZSM-5-A	22.3	2.5	67.5	2.8	7	1.8	18.0
2%Mo-HZSM-5-B	18.0	3.5	61	5	4.4	2.6	23.5
2%Mo-HZSM-5-C	5.6	9.4	10.2	2.5	1.2	0.5	76.1

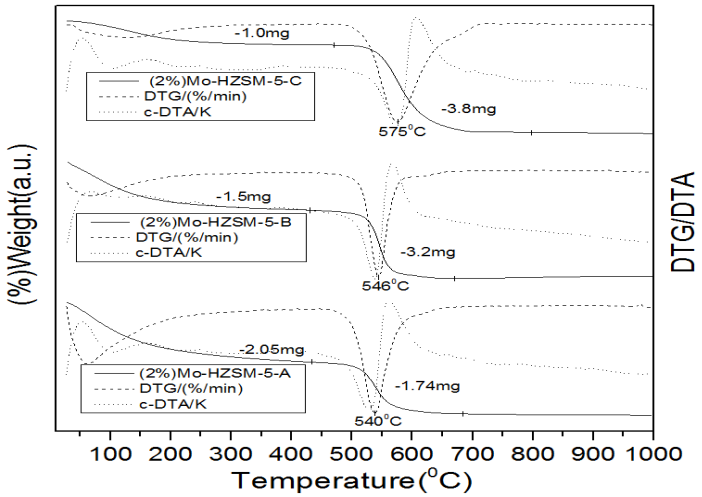

Fig.1: TG-DTG/DTA analysis of 2%Mo-HZSM-5 spent catalyst after 6h (TOS)

4 Conclusions

Molybdenum modified catalyst pre-treated with 90% CH_4+H_2 leads to formation of less coke, higher methane conversion and product selectivity. Coke deposits formed on the catalyst were characterized by TG/DTA, TPO and TEM Techniques. Performance of the catalyst decreased with molybdenum loading. Two combustion temperature regions were observed at higher (6-8%) molybdenum loading. Combustion at lower temperature (300-450ºC) was attributed to Mo_2C and molybdenum associated carbonaceous species, which are located on the external surface of the catalyst. The combustion at high temperature (450-600ºC) was due to coke deposition on the Bronsted acid sites. Kinetic analysis of the TG profiles were done by assuming that the oxidation of the coke is a first order reaction. The activation energy of the catalyst pre-treated with CH_4+H_2 is found to be lower than the N_2 and H_2 pre-treated catalyst. HRTEM images of the coked catalyst show that there is a formation of graphite layer on the Mo_2C active sites, and surrounded by the amorphous carbon on the catalyst surface. Graphite layer formation on the catalytic active site and aromatic coke formed on the Bronsted acid sites are main cause for the deactivation of the catalyst.

Development of Unusual Oxidation State Metal Catalysts for C(sp2)-H Bond Functionalization Electrochemically Induced

Budnikova Y.H.

A.E. Arbuzov Institute of Organic and Physical Chemistry, Kazan ScientificCenter of Russian Academy of Sciences, Kazan, Russia

* yulia@iopc.ru

Keywords: nickel, palladium, electrochemistry, fluoroalkylation, phosphorylation, C-H bond

1 Introduction

Palladium and nickel complexes are extensively employed as efficient catalysts for a wide range of synthetically useful organic transformations such as C–H functionalization, C–C coupling, and oxidation reactions. While the most common oxidation states of palladium and nickel in its organometallic derivatives are 0 and +2, high-valent organopalladium or nickel complexes contain metal atoms in oxidation states +3 and +4. Whereas catalytic processes involving Pd and Ni complexes in oxidation states +2 and 0 have been recognized and studied for several decades, more recent studies have shown that high-valent Pd and Ni species can also act as catalytically active intermediates in various organic transformations. These processes raise the intriguing possibility that new pathways for coupling reactions might be discovered using complexes of higher nuclearity in which redox activity or substrate binding can span multiple metal centers. Electrochemical techniques can be used for the determination of the mechanism of transition metal-catalyzed reactions whatever the transition metal, provided some of the organometallic species involved in the catalytic cycle are electroactive.

Achievements of electrosynthesis mediated by nickel and palladium complexes in unusual oxidation states will be demonstrated. Important advances are associated with the development of synthetic approaches to the C = C, C-Hal, P-Cl, P-P and C-H bonds functionalization in the one-step mild conditions. The key intermediates, such as Ni(I)L, Pd (III)L(immer or monomer complexes) and others have been detected and investigated.

2 Experimental/methodology

Electrosynthesis is useful in transition metal catalysis to generate the active catalyst form without specially added reducing or oxidizing agents. Performed in mild conditions it offers more environmentally non-polluting alternatives to traditional organic synthesis. Understanding mechanistic details of catalyzed reactions may pave the way to the design of new and improved catalysts. Kinetics and thermodynamics of the electron transfer, bond cleavage, substitution, addition and other reactions can provided, as well as intermediate species can be detected characterised by various electrochemical techniques with cyclic voltammetry being the most available and favourable one. However, although electrochemical methods provide a way of mechanistic studying of reactions, they give no information on the structures of intermediates. Electrochemical methods should be used in combination with spectroscopy techniques like NMR, IR, UV–vis–NIR absorption, EPR or EXAFS to provide detailed characterization of the intermediate species.

Our group is interested in the development and mechanistic understanding of transition-metal-mediated electrocatalytic reactions, with a particular focus on fluoroalkylation and phosphorylation reactions. We also wish to gain insight into how to develop more examples of catalytic reactions at inexpensive and readily available first-row late metals such as Ni and Co which are particularly attractive for synthetic purposes, due to sufficiently low ionization

potential to favour oxidative addition, sufficiently weak metal-carbon bonds, tendency to form square-planar complexes and to reach penta-coordination to allow insertion, sufficiently high electron affinity of Ni^{II} complexes to allow reductive elimination and the ability to accept different oxidation states (0, +1, +2, +3, +4) at different stages of a catalytic cycle. Herein, we summarize the advances in electrocatalytic methods which have been shown to be applicable for functionalization of diverse substrates, such as olefins, aryl halides, white phosphorus, chlorophosphines and arenes (ligand directed C-H functionalization), consider the intermediates of catalytic cycles and prospects of this interesting and promising research area.

3 Results and discussion

Electrochemical approaches have opened up new opportunities, such as mild conditions, high rates, selectivity and convenient operation control by these parameters as current density and potential. Thus, the use of transition metal electrocatalysis to obtaine targeted derivatives from olefinic, aromatic, and phosphorus substrates in cross-coupling and ligand-directed C-H activation reactions has shown to be a high potential and powerfull method.

Biocatalysis in Glycerol-based Biorefinery for Fine Chemicals - Conversion of Renewable Glycerol into Value-Added Products

Tudorache M.*, Ghemes G., Gheorghe A., Coman S., Parvulescu V.I.

University of Bucharest, Bucharest, Romania

* madalina.sandulescu@g.unibuc.ro

Keywords: glycerol, lipase, ionic liquid, value-added products, biocatalysis, fine chemicals

1 Introduction

Glycerol is a key aspect of the biodiesel manufacture of biomass due to huge amount of glycerol produced during the biodiesel process (*e.g.* 10 kg glycerol for each 100 kg biodiesel product). The lack of proper management for glycerol entails soon to the decrease of the industry interest in biodiesel due to its high production costs. Another possible consequence is that glycerol will become a potential environmental pollutant due to the large glycerol amount stocked in the environment. Thus, the rescue of the biodiesel market requests the implementation of new technologies involving glycerol as renewable raw material, which could be preponderantly dedicated to the biorefinery leading to value added products of fine chemical industry.

We lunched the idea of a chemo-enzymatic conversion (tandem of biocatalysis and ionic liquid catalysis) of glycerol to value-added products such as glycerol carbonate (GlyC), glycidol (GlyD) and polyglycidol (poly-GlyD) (figure 1). GlyC has numerous applications in cosmetics, pharmaceutics, detergents and adhesives industry. Additionally, GlyD and even more poly-GlyD are important precursors for polymeric industry. Therefore, we proposed green-valorisation of renewable glycerol as a promising alternative for fine chemical industry.

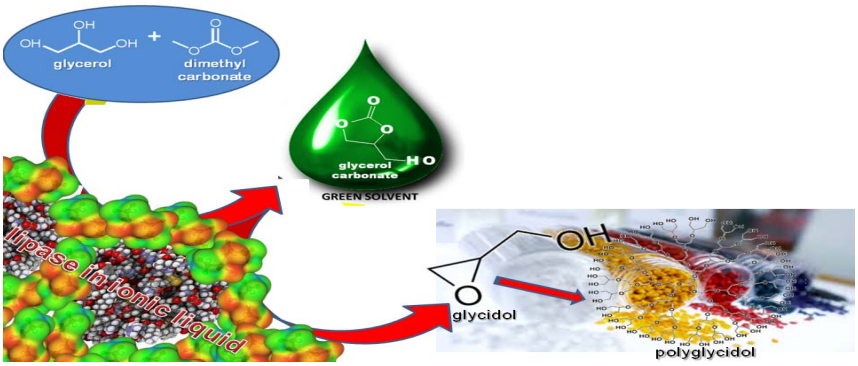

Fig. 1. Chemo-enzymatic catalysis of glycerol conversion into value-added products.

2 Experimental/methodology

Chemicals and substances used for the experiments were purchased from Sigma-Aldrich company (e.g. lipase from various sources, [emim][Cl], [bmim][Cl], [bmim][PF_6], [bmim][BF_4], glycerol, dimethyl carbonate - DMC, standards of GlyC and GlyD, etc).

Biocatalytic synthesis of GlyC/ GlyD has been performed in solvent-free system. Glycerol and DMC (dimethyl carbonate) (Gly:DMC=1:10 molar ratio) were mixed together with the biocatalyst (prepared in a previous step by simple mixing of the enzyme and ionic-liquid) in a 1.5 mL reaction vial (Eppendorf tube). The mixture was incubated for 6h under stirring at 60 ^{0}C. After the reaction, the products were analysed using gas chromatography (GC) coupled to flam ionization (FID) detector. The efficiency of the chemo-enzymatic process was evaluated based on the glycerol conversion and GlyC/GlyD selectivity. Gel permeation chromatographic (GPC)

analysis was performed for the characterization of the poly-GlyD products (average molecular weight and poly-dispersity index).

3 Results and discussion

Chemo-enzymatic process developed for glycerol conversion contains two steps: i) glycerol biotransformation to GlyC and ii) catalytic synthesis of GlyD from GlyC. GlyC synthesis was catalysed by lipase enzyme, while the GlyD production was assisted by ionic liquid catalyst. Spontaneously, GlyD can lead to poly-GlyD under basic conditions.

The biocatalytic process involved glycerol carbonylation with DMC assisted by a lipase biocatalyst [1]. The corresponding system was tested for solvent-free conditions using an excess of DMC. For this stage, the lipase biocatalyst was designed as free/ immobilized enzyme leading to different performance of the biocatalytic system for every model (*e.g.* GlyC yield of 59 and 55 % for free/ immobilized lipase) [2,3].

Further, the biocatalyst was designed as ionic liquid-coated enzyme and dedicated to the GlyD synthesis. Chemo-enzymatic model of the catalyst was prepared for different ionic liquid (e.g. [emim][Cl], [bmim][Cl], [bmim][PF_6], [bmim][BF_4]). Also, a screening of the lipase enzyme has been performed. Catalytic tests under the optimum conditions revealed the possibility to use lipase from *Candida antarctica* source combined with [bmim][BF_4]. The catalytic performance are expressed as 53 % glycerol conversion, 30 % selectivity in GlyD and 50 % selectivity in GlyC. Also, poly-GlyD product was obtained by spontaneous polymerization of GlyD under basic condition leading to a polymeric compound characterized by a molecular weight in the range of 300-500 Da with a dispersity index of n=4 and branched structure.

4 Conclusions

The proposed concept for renewable glycerol valorisation based on chemo-enzymatic process is sustained by promising experimental data, which will be presented and discussed during the presentation.

Direct Catalytic Oxidation of Lower Alkanes

Chepaikin E.G.*, Bezruchenko A.P., Borshch V.N., Menchikova G.N.

Institute of Structural Macrokinetics and Materials Science Russian Academy of Sciences, Chernogolovka, Russia

* grig@ism.ac.ru

Keywords: homogeneous, catalysis, alkanes, dioxygen, oxidation, carbon, monoxide, DFT, calculation

1 Introduction

The direct functionalization of alkanes with dioxygen to the useful oxygenates remains a key challenge [1]. The homogeneous catalytic systems for the oxidative functionalization of alkanes C_1-C_4 were designed. These systems include complexes of rhodium and redox catalysts – iodine, copper or iron compounds. The most effective medium for the oxidation of alkanes is trifluoroacetic acid. To activate dioxygen, by analogy with the action of the biocatalysts, a reducing agent – carbon monoxide – is introduced in the gas mixture. The redox catalysts in the reduced form are converted dioxygen to the active two-electron oxidizing agents – hydrogen peroxide or its equivalents ((hypoiodic acid or metal peroxides) for the reactions:

$$2Red + O_2 + 2HX \rightarrow 2\,Ox^+ + H_2O_2 + 2X^-; \qquad 2HI + O_2 \rightarrow 2HOI;$$
$$2Cu^{I} + O_2 \rightarrow Cu^{II}\text{–O–O–}Cu^{II}; \quad Cu^{I} + Rh^{III} + O_2 \rightarrow Cu^{II}\text{–O–O–}Rh^{IV}$$

2 Experimental/methodology

The oxidized forms are reduced by carbon monoxide and alkane with catalysis by rhodium complexes. The mechanisms of methane oxidation are proposed [2]. In rhodium-iodide-chloride (Rh-I-Cl) system an active oxidant is hypoiodide, and in the rhodium-copper-chloride (Rh-Cu-Cl) – heterometallic peroxocomplex. DFT calculations to optimize the structure of the intermediates confirm the feasibility of the proposed mechanisms. Based on the experimental data there is assumed that the Rh-I-Cl and Rh-Cu-Cl catalytic systems operate according to the equations 1-4 and 5-9 respectively. The scheme represented by the equations 1-4 show methane oxidative carbonylation to acetic acid:

$$[Rh(CO)_2ClI]^- \textbf{(I)} + OI^- \rightarrow [Rh(CO)_2Cl(OI)]^- \textbf{(II)} + I^- \quad (1)$$
$$\textbf{II} + CH_4 \rightarrow [Rh(CH_3)(CO)_2Cl(OH)I]^- \textbf{(III)} \quad (2)$$
$$\textbf{III} + CO \rightarrow [Rh(CH_3CO)(CO)_2Cl(OH)I]^- \textbf{(IV)} \quad (3)$$
$$\textbf{IV} \rightarrow \textbf{I} + CH_3COOH \quad (4)$$

Methanol formation by the methane oxidation is described according to equations 5-9.

$$RhCl_3(H_2O)_3\,\textbf{(V)} + CO \rightarrow RhCl_3(H_2O)_2(CO)\,\textbf{(VI)} + H_2O \quad (5)$$
$$\textbf{VI} + CuCl \rightarrow RhCl_3(H_2O)_2(CO)CuCl\,\textbf{(VII)} \quad (6)$$
$$\textbf{VII} + O_2 \rightarrow RhCl_3(H_2O)_2(CO)(O_2)CuCl\,\textbf{(VIII)} + H_2O \quad (7)$$
$$\textbf{VIII} + CH_4 \rightarrow RhCl_3(H_2O)_2(CO)(O_2)(CH_4)CuCl\,\textbf{(IX)} \quad (8)$$
$$\textbf{IX} + 2H_2O \rightarrow \textbf{V} + CH_3OH + CO_2 + CuCl \quad (9)$$

The geometry of complexes I-IV and V-IX was optimized by DFT calculations with PBE exchange-correlation potential (program package FireFly [3]). The optimized structures are presented in Fig. 1 and 2.

3 Results and discussion

The calculated heats of reactions 1-4 are (kcal/mol): - 26.4, - 28.5, - 27.4, - 35.9, respectively. For the reactions 5-9 the following values of the heats are calculated (kcal/mol): - 6.8, - 29.4, - 16.4, - 37.6, - 32.4 respectively.

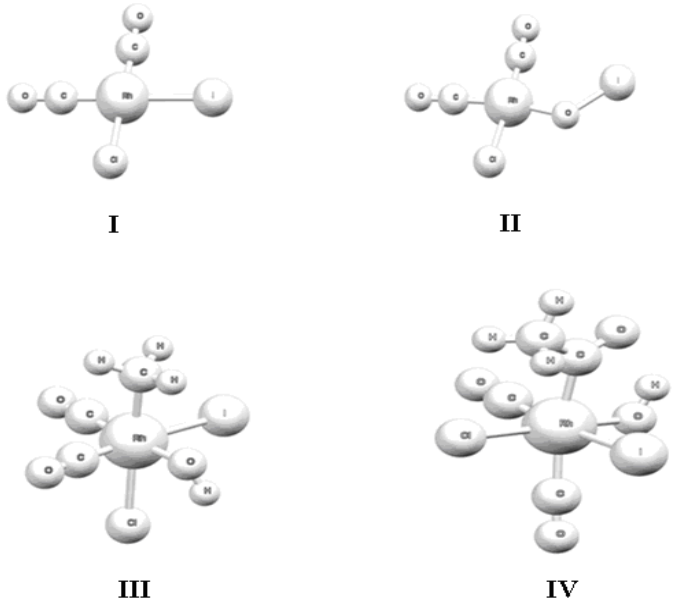

Fig. 1. Optimized structures of complexes **I-IV**

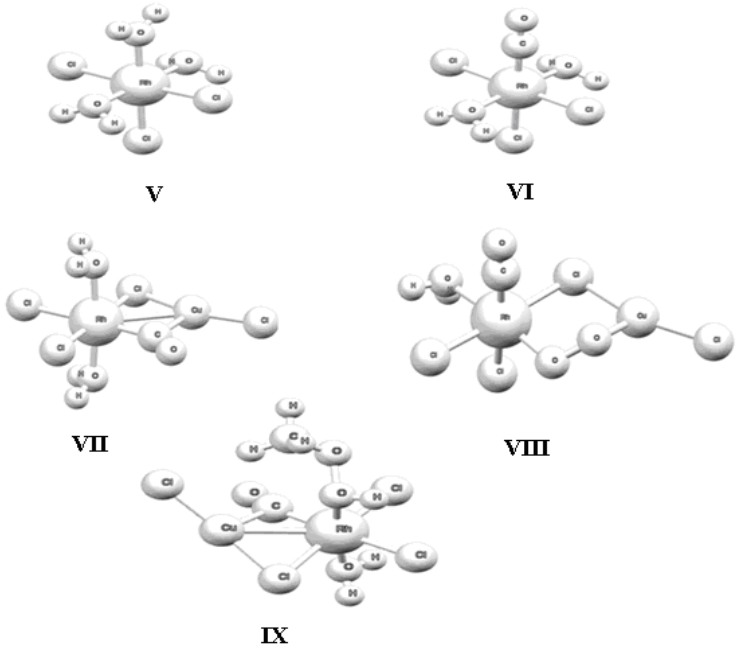

Fig. 2. Optimized structures of complexes **V-IX**

Preparation of Substituted Methylenebisphenol Using Heterogeneous Acid Catalyst

Arslanova G.G., Saigitbatalova S.Sh.*, Cherezova E.N.

Kazan National Research Technological University, Institute of Polymers, Kazan, Russia

* saygitbatalova@mail.ru

Keywords: acid catalyst, heterogeneous catalyst, methylenebisphenol, stabilizer

1 Introduction

Stabilizers are used for the protection of polymers against aging and the major group of that stabilizers relates to antioxidants. Methylenebisphenols (MBP) having at 2 and 6 position over hydroxyl group alkyl substituents [1] have high antioxidant capacity. Productional MBP preparation method is the reaction of disubstituted phenols and formaldehyde under homogeneous catalysis in the presence of strong acids. This synthesis technology has some significant drawbacks, including: a large amount of waste water and the need to neutralize the catalyst.

In this research to overcome the above drawbacks in the synthesis of the MBP stabilizers used anhydrous formaldehyde precursors which form formaldehyde under acidic catalysis.

2 Experimental/methodology

For MBP preparation based on 2,6-di-tert-butylphenol (2,6-DTBP) and 2,4-di-tert-butylphenol (2,4-DTBP) trioxane and 1,3-dioxolaneare was used as the second reagent. The reaction was conducted in the presence of formic acid. As the co-catalyst was used $HClO_4$. Also a number of heterogeneous catalysts were tested: Purolite Ct 151, Amberlist 35, 36Wet, Rezinex, Levatit a2626, KY-2. To find the optimal synthesis conditions it's conducted with reactant ratios varying: 2,4 DTBP (2,6-DTBP) to trioxane from 2:0.33 to 2:0.43 mol., 2,4 DTBP (2,6- DTBP) to 1,3-dioxolane from 2:1 to 2:3 mol., reaction time from 2 to 6 hours, the temperature from 90 to 105 ° C. After synthesis, the reaction mass was cooled, the precipitate was filtered off. The reaction products were characterized by melting point, ^{1}H NMR -, IR- spectroscopy and elemental analysis.

3 Results and discussion

During the reaction formaldehyde derivatives underwent decyclization under the acidic catalysys and formed protonated formaldehyde which is then joined the electrophilic substitution reaction with the 2,4- DTBP and 2,6- DTBP forming 2,2'-methylene-bis(4,6-di-tert-butylphenol) and 4,4'-methylene-bis(2,6-di-tert-butylphenol) as shown on scheme:

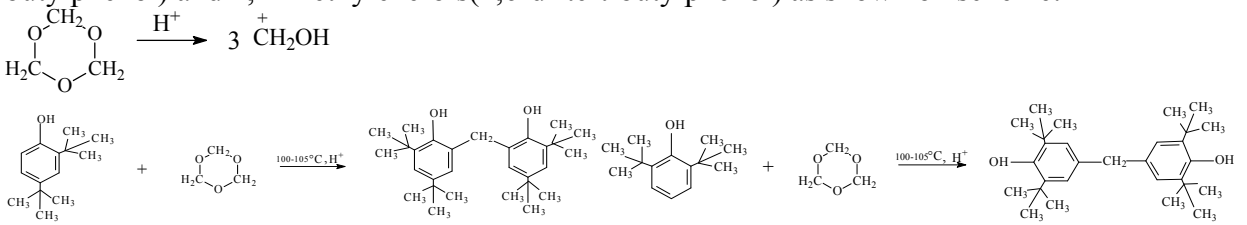

Figure 1, 2 shows the influence of the reactant ratio on the target product yeld in the reaction of 2,6- DTBP and 2,4-DTBP with trioxane in the presence of formic acid and HClO4.

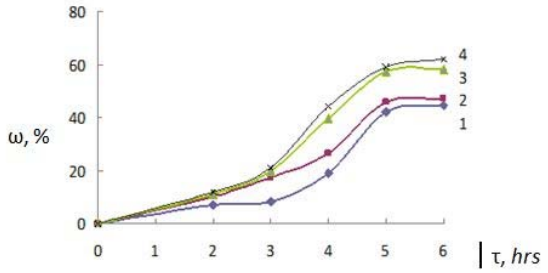

Fig.1. Influence of the reactant ratio on the yeld of 4,4'-methylene-bis(2,6-di-tert-butylphenol): 1 – 2,6- DTBP:$(CH_2O)_3$= 2:0,33; 2 - 2,6-DTBP:$(CH_2O)_3$= 2:0,363; 3 – 2,6-DTBP:$(CH_2O)_3$= 2:0,396;4 - 2,6- DTBP:$(CH_2O)_3$= 2:0,430.

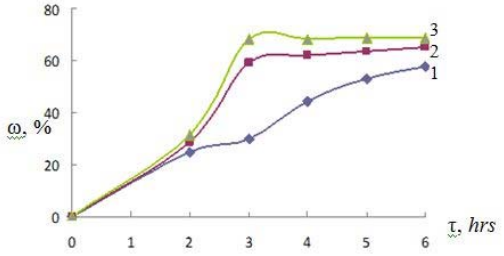

Fig.2. Influence of the reactant ratio on the yeld of 2,2'-methylene-bis(4,6-di-tert-butylphenol): 1 – 2,4- DTBP:$(CH_2O)3$= 2:0,33; - 2,4-DTBP:$(CH_2O)3$= 2:0,363; 3 – 2,4-DTBP:$(CH_2O)3$= 2:0,396.

^{1}H NMR spectrum of 2,2'-methylene-bis(4,6-di-tert-butylphenol) (acetone-d_6, 400 MHz, ppm, *J*/Hz): 1,41 s and 1,23 s (36H, CH_3); 2,08 s (2H, CH_2); 3,98 s (2H, OH); 7,08 d and 7,19 d (4H, Ar-H). Gross formula $C_{29}H_{44}O_2$: calculated C,% - 82,08, H,% - 10,38, O,% - 7,54; found C,% - 82,42, H,% - 10,524, O,% - 7,056.

^{1}H NMR spectrum of 4,4'-methylene-bis(2,6-di-tert-butylphenol) (acetone -d_6, 400 MHz, ppm, *J*/Hz): 1,4 s (36H, CH_3); 3,80 s (2H, CH_2); 5,82 s (2H, OH); 7,06 s (4H, Ar-H). Gross formula $C_{29}H_{44}O_2$: calculated C,% - 82,08, H,% - 10,38, O,% - 7,54; found C,% - 81,96, H,% - 10,439, O,% - 7,601. ^{1}H NMR spectrum data and elemental analysis corresponded to the formation of the target substances.

4 Conclusions

4,4'-methylene-bis (2,6-di-tert-butylphenol) and 2,2'-methylene-bis (4,6-di-tert-butylphenol) were obtained by the reaction of 2,4- and 2,6- disubstituted phenols with trioxane and 1,3-dioxolane. By selecting of the optimum reaction conditions and decyclization catalyst complex 62 wt % yield was achieved for the reaction of 2,6-DTBP with trioxane and for the 2,4-DTBP - 68 wt %, for the reaction with 2,6-DTBP 1,3-dioxolane highest yield was 81 wt %.

Keywords: bio-diesel, glycerol, glyceric acid, oxidation catalyst

1 Introduction

In accordance to the directive 2009/28/EC of the European Parliament and of the Council of April 23, 2009 on the promotion of the use of energy from renewable sources in the European Community Member States, a mandatory 10% minimum target is to be achieved by all Member States for the share of biofuels in transport petrol and diesel consumption by 2020 in a cost-effective way [1]. Bio-diesel fuel is the most perspective kind of biofuel. Glycerol is a bio-diesel manufacturing by-product, its amount reaching up to 10% of the total mass of the products mixture, thus making it important to find a solution for the glycerol utilization problem. The glycerol water solution oxidation by oxygen in presence of supported gold catalysts demonstrates great potential in this regard. There is a wide range of valuable products that can be formed in the process of glycerol oxidation, e.g. dihydroxyacetone, hydroxypiruvic acid, glyceric aldehyde, glyceric acid, tartronic acid, ketomalonic acid, lactic acid and so on. Many authors report that reaction's conditions lead to selective formation of one of the glycerol's oxidation products [2-5], but there is a lack of publications where attention is drawn to the mathematical description of the oxidation process. These studies are necessary, as the knowledge of the process's kinetic parameters, like rate constants, rate dependencies on the process parameters, reaction activation energy value, is highly important on the stages of development of the manufacturing process technology, as well as for correct reactor design. Taking the aforementioned into account, this work is devoted to the study of the formation of glyceric acid by oxidizing glycerol with molecular oxygen in presence of commercial 1.5%Au/TiO_2 supported catalyst in the kinetic regime to find the reaction rate constants, kinetic equation parameters and the reaction activation energy value.

2 Experimental/methodology

The glycerol oxidation experiments were performed in an ROTH, Model II autoclave reactor in the kinetic region. High performance liquid chromatography (HPLC) method was used for detection of glycerol and its oxidation products. For that purpose a SHIMADZU Nexera chromatograph with ion-exchange column WATERS IC-PAC Jon-Exclusion 50 A, 7 µm (300×7.8 mm) was used. UVVIS detector SHIMADZU SPD20A with wavelength 210 nm and 40 °C was used for products identification and quantitative detection, ELSD detector ELSDLTII with 30 °C and 350 kPa was used for glycerol concentration detection in the sample. A transmission electron microscope JEOL JEM 2100 at 200 kV voltages was used to find out the size of gold particles and their distribution on the catalyst's surface.

3 Results and discussion

The following process parameters were varied during the experiments: glycerol initial concentration (0.1-0.3 mol/L), oxygen partial pressure (1-10 atm), amount of the catalyst (by varying glycerol to gold molar ratio from 1000 to 10000 mol/mol), base concentration (by varying base to glycerol molar ratio from 0.5 to 5 mol/mol) and temperature (55-70 °C). The glyceric acid was the main reaction product in the studied conditions. Glycolic, tartronic, oxalic, lactic, acetic and formic acids were detected as the reaction by-products. The experiments'

kinetic results were processed by means of MatLab software based on non-linear regression and statistical analysis (residual, R2 and F-tests).

4 Conclusions

The experimentally supported kinetic model of glycerol oxidation to glyceric acid is proposed as the result of the study. Reaction rate constants are calculated and the reaction activation energy value is found to be 145 kJ/moL. A possible glycerol oxidation reaction kinetic mechanism is proposed. The optimal parameters for selective glycerol to glyceric acid oxidation are identified for full glycerol conversion.

Keywords: niobium, magnetic nanoparticles, glucose, lactic, acid succinic acid

1 Introduction

Last decades confirmed catalysis as a strategic field of science representing the new way to meet the challenges of sustainability. In this context, one of the big challenges is the development of cleaner catalytic processes to convert biomass to multiple platform molecules as strategic precursors for valuable products [1]. In most of the cases, to achieve such a goal, the development of new catalysts is necessary. In this context, a special attention is drawn to the solid catalysts, since the separation processes represent more than half of the total investment in equipment for the chemical and fuel industries [2]. However, these catalysts should also be highly selective to guarantee the cost-effectiveness of the process. Such a requirement can be met by nanocatalysts. Unfortunately, isolation and recovery of such tiny nanocatalysts from the reaction mixture is not easy, this limitation hampering the economics and sustainability of nanocatalytic protocols. To overcome this issue, the use of magnetic nanoparticles has emerged as a viable solution; their insoluble and paramagnetic nature enables easy and efficient separation from the reaction mixture with an external magnet [3]. Further, the stability, durability, and costs are other conditions that should be accomplished for their widespread usage in industry. In this context, the main objective of this work was the design and development of Nb-based magnetic nanocomposites suitable for the glucose conversion into biochemicals.

2 Experimental/methodology

Nb-based magnetic nanocomposites were prepared in three steps: i) the synthesis of the magnetite nanoparticles (MNP) by co-precipitation, ii) the coating of MNP with Nb_2O_5 (Nb oxalate precipitation with NaOH, in the presence of CTAB as surfactant), and iii) the surfactant decomposition through the sample calcination at 525°C. As a function of the surfactant loading, the catalysts were denoted sNb@NMP or 3sNb@MNP (denoting a loading three times higher of surfactant). The catalysts were characterized by XRD, TEM, magnetic measurements, FTIR and Raman spectroscopy. Activity tests in batch mode were carried out in a glass-pressure autoclave (Top 45 model, Top Industrie), following two different procedures: i) *glucose decomposition* in water, at 180°C, under stirring, for 4 h; ii) *glucose oxidation* in water, at 180°C and 10 bar O_2, under stirring, for 4 h. Irrespective of the route, after reaction the catalyst was magnetically recovered by placing a permanent magnet on the reactor wall and the water-soluble products were separated by distillation under vacuum. The recovered products from the liquid phase were sylilated, diluted with 1 mL of toluene and analyzed by GC-MS Carlo Erba Instruments QMD 1000 equipped with a Factor Four VF-5HT column.

3 Results and discussion

Tailoring the catalysts in the range of "nano" sizes may eliminate the important disadvantage of mass transfer limitations usually encountered on solid catalysts. Indeed, in the presence of tiny Nb@MNP particles (10 nm from TEM) the conversion of glucose was almost totally (90-100%) after only 4h (Table 1).

Table 1. Catalysts performances in the glucose decomposition and oxidation

Entry	Catalyst	P_{O2}, atm	C (%)	S (%)				
				LA	2-GlyA	1-HPA	2,3-GlyA	SA
1	sNb@MNP	-	100	51.7	45.2	-	-	-
2	sNb@MNP	10	100	30.0	7.7	20.2	-	36.1
3	3sNb@MNP	-	98.2	26.4	14.0	2.5	1.8	-
4	3sNb@MNP	10	100	12.0	12.9	11.2	-	60.0

Reaction conditions: 90 mg glucose, 50 mg catalyst, 10 ml H_2O, 180°C, 4 h. The differences in selectivity till 100% are monosaccharides. LA – lactic acid, 2-GlyA – glycolic acid, 1-HPA – 1-hydroxypropionic acid, 2,3-GlyA – glyceric acid, SA – succinic acid

Most important, in the presence of these catalysts, different platform molecules can be obtained, in different proportions, as a function of the reaction conditions. Thus, in the absence of oxygen, lactic acid is the most important product (51.7%, entry 1, Table 1); under oxygen pressure, the selectivity changed in the favor of succinic acid as the main product (60.0%, entry 4, Table 1). CTAB also exhibited a high influence upon the catalyst characteristics. While sNb@MNP is more selective to lactic acid, 3sNb@MNP displays a high selectivity to succinic acid. Another important parameter of the process is the concentration of glucose. Low working concentrations avoid competitive side reactions such as condensation and dehydration to insoluble humins [4].

As expected, the association of these catalysts with magnetic nanomaterials (MNP) allowed their simple isolation and recovery from the reaction mixture by applying an external magnetic field. Moreover, all catalysts were proven to be stable under the investigated hydrothermal reaction conditions.

4 Conclusions

The obtained catalytic results are very promising for the development of novel magnetic nanocomposites with high activity and selectivity in the synthesis of biochemicals from real biomass sources. It is the first time, in our best knowledge, where, changing the reaction conditions, the same catalyst is highly selective to different important platform molecules (lactic acid *versus* succinic acid. These important characteristics open the possibility to generate a practical process for LA or SA production in which lignin components are not always converted and humins are also formed as solid residues

However, the Nb@MNP system presented here is still under investigation with the objective to further improve its catalytic selectivities and to extend the scope of the reaction to the one-pot cellulose degradation to biochemicals.

Levulinic Acid Intercalated into LDH - a Novel Heterogeneous Organocatalyst for the Trans-Cinnamic Ester Epoxidation

Paul D., Candu N., Rizescu C., Marcu I.C., Tudorache M., Parvulescu V.I., Coman S.M.*

Keywords: epoxidation, organocatalysis, LDH, levulinic, acid, hydrogen, peroxide, phenyl, glycidate

1 Introduction

The epoxidation represents one of the most useful synthetic transformations in organic chemistry [1], since the epoxide ring may be opened in several ways allowing building complicated organic structures. Nevertheless, although several epoxidation methods of alkenes have been developed in the recent past, the epoxidation of cinnamic ester is not so common.
The most common procedure for the epoxidation is using hydrogen peroxide under strong alkaline conditions applying inorganic bases. However, while H_2O_2 is an ideal oxidant because it is both cheap and safe, the use of inorganic bases is undesirable, because they are hazardous and lead to the production of a large amount of wastes. One of the best ways to avoid these disadvantages is changing the stoichiometric process to a catalytic one. In this context, organocatalysis has been suggested as a possible alternative, bringing several advantages upon classical catalysis. However, in spite of the recent improvements, homogeneous organocatalysis has still the main "classical" homogeneous catalysis disadvantage, i.e., the difficulty in recovery and re-use of the organocatalytic species. Therefore, making organocatalysts insoluble and, consequently, easily recoverable and reusable may provide a "sustainable development" in this field.

The layered double hydroxides (LDH) are often preferred in chemical processes to other types of catalysts due to their versatility, simplicity, easy to modify properties and low price. Moreover, such materials represent an important basis for the development of new materials with controlled structure, controlled accessibility to the active sites, adjustable pore size and high surface areas [2]. The ability to retain and change the inorganic with organic anions makes unique these materials.

Taking into account these valuable findings we reported, not long ago, a green asymmetric epoxidation of the *trans*-methylcinnamate to (2R, 3S)-phenyl glycidate, based on the use of an efficient and recyclable organocatalyst: chiral ketone@SBILC@MWCNT@Fe_3O_4 (Y = 35%, S = 100% and e.e. = 100%) [3]. Here we report the development of a novel LA@LDH heterogeneous organocatalyst for the epoxidation of *trans*-methylcinnamate. Although the levulinic acid (LA) not generates enantiomerically pure phenyl glycidate but rather racemic mixtures several advantages like the easy catalyst preparation from cheap and renewable raw materials, the heterogeneous character of the organocatalyst, the use of H_2O_2 and the absence of any inorganic soluble base recommend it as a "green" candidate for such a reaction. All these green elements can successfully compensate any additional costs related to the separation of enantiomers from the obtained racemic mixture.

2 Experimental/methodology

Three types of hydrotalcites (Zn-Al-Cl, Mg-Al-Cl, Mg-Al-CO_3) were prepared and characterized according to procedures described in literature [4]. As intercalation method of the levulinate between the LDH layers was chosen the ionic exchange methodology. The prepared catalysts were characterized by X-ray diffraction (XRD) and infrared diffuse reflectance

spectroscopy with Fourier transform (DRIFT) and tested in the epoxidation of *trans*-methylcinnamate.

3 Results and discussion

Rapid information upon the successful organic anion intercalation between layers of hydrotalcite can be obtained from the X-ray diffraction analysis. Although the literature shows that Mg-Al-LDH is stable in the pH range = 3-10 and has a capacity exchange about 220 meq/100 g, XRD analyzes of LDH-Cl samples show that ionic exchange of levulinate not happened. DRIFT analysis confirms XRD. A possibly explanation for this failure is related to the nature of the chlorine anion, more powerful bonded than carbonate in the LDH structure and, therefore, more difficult to exchange, according to Miyata [5]. Indeed, the ion CO_3^{2-}, more loosely than Cl^-, was easily replaced from the LDH structure by organic carboxylate. Although the X-ray diffraction pattern of LDH-levulinate (LA@LDH) produced no confirmation of the Mg-Al-CO_3 exchange, the DRIFT analysis indicates the presence of the levulinate in LDH. The presence of the band assigned to the carbonyl (-C=O), located at 1750 cm^{-1} represents a firm confirmation. It is therefore possible that the organocatalyst is not entered in-between the hydrotalcite layers remaining anchored only at LDH corners, with the LDH-CO_3 layers unchanged.

Using this catalyst, the cinnamate conversion was from low to moderate (0-12%). However, the selectivities in phenyl glycidate reached very high levels (97.2%).

4 Conclusions

The LA@LDH was found to be useful as a heterogeneous organocatalyst in the epoxidation reaction of *trans*-methylcinnamate. The reaction was performed with hydrogen peroxide as epoxidation reagent and in the absence of an inorganic base (providing wastes) in the reaction medium. The obtained catalytic results display a particular importance for research in the field: in our best knowledge it is the first time when LA was used not as raw material but as organocatalyst for an organic synthesis.

The system presented here is still under investigation for further optimizations.

Keywords: polyurethane, dissociation, coordination, compounds, catalysis

1 Introduction

Polyurethanes are the polymers for creating a material with a wide range of operational parameters - high hardness, high elastic modulus, high elasticity, resistance to abrasion, solvents, oils and high strength. It was shown [1] that copper coordination compounds (CCCs), produced using N,N'-diethylhydroxylamine (DEHA) and (γ-aminopropyl)triethoxysilane exhibit catalytic activity in reactions of low-temperature dissociation of urethane groups and are capable of interacting with isocyanate groups with the subsequent formation of azoaromatic derivatives. A specific feature of how these complex compounds are formed is that a larger part of copper(II) is converted to copper(I). Transition metal coordination compounds (TMCCs) based on copper and cobalt is a more effective, compared with CCC, catalyst for the reaction of dissociation of urethane groups, accompanied by the release of TDI (and, accordingly, by an increase in the concentration of NCO groups). For example, a third of urethane groups of the prepolymer undergo dissociation with CCC, whereas in the case of TMCC, nearly all urethane groups may dissociate

2 Experimental/methodology

We prepared coordination compounds from copper (II) chloride ($CuCl_2 \cdot 2H_2O$); cobalt(II) chloride ($CoCl_2 \cdot 6H_2O$); (γ-aminopropyl)triethoxysilane (AGM-9, Aldrich, 98%); and N,N'-diethylhydroxylamine (DEHA, Aldrich, 99%). Copper and cobalt chlorides were freed of crystallization water by their heating at 120°C for 48 h.

The coordination compounds were obtained at the molar ratios $[CuCl_2]:[CoCl_2]:[DEHA]:[AGM] = 1:1:1.48:0.25$ and $[CuCl_2]:[DEHA]:[AGM] = 1:1.48:0.25$. $CuCl_2$ was dissolved in DEHA under cooling to 5–10°C and permanent agitation, and then cobalt(II) chloride and AGM were added at 20–25°C.

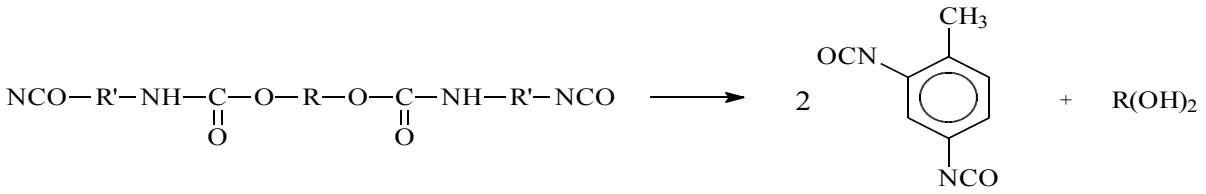
To synthesize polyurethanes, a calculated amount of TMCCs was introduced into a polyurethane melt and the reaction system was agitated for 1 h at a residual pressure of 0.7 kPa and T = 80°C. Then, preliminarily melted and heated (to 110°C) 4,4'-methylenebis(2-chloroaniline) MOCA was introduced. After the synthesis was complete, the reaction mass was cast into molds preliminarily heated to 100°C, which were then kept in a heating box at 100°C for 24 h. Before being studied, the polyurethane samples were kept at room temperature for two weeks. The content of isocyanate groups in the reaction system was determined by titrimetry.

3 Results and discussion

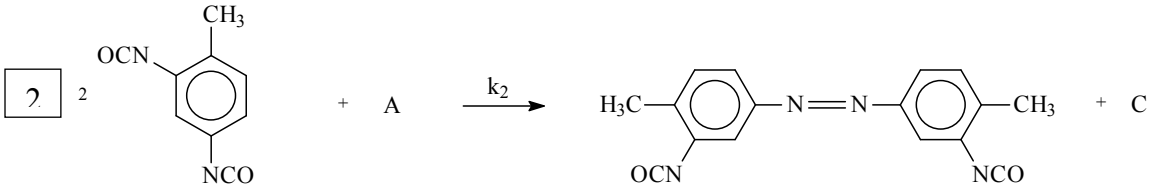
Heteronuclear coordination compounds obtained based on copper and cobalt chloride. This compounds shows the ability to catalyze the low temperature dissociation of urethane groups. As the urethane oligomers were used reaction products of ether-diol oligomers with double

molar excess of 2,4-toluene diisocyanate. It was established that the dissociation is accompanied by the formation of urethane groups, carbodiimides, and the release of 2,4-toluene diisocyanate (Fig.).

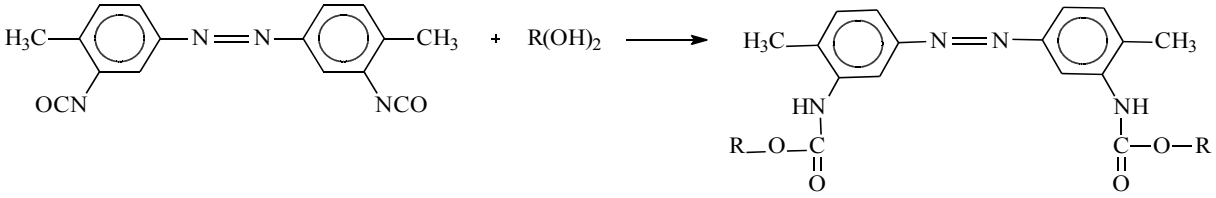
(1) Dissociation of urethane groups



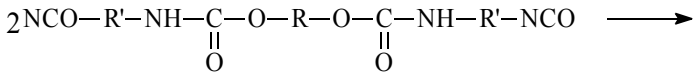
(2) Formation of an azoaromatic compound



(3) Urethane formation



(4) Formations of carbodiimides



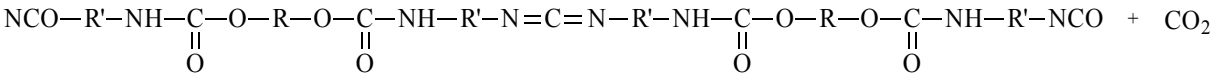


Fig. Scheme of the catalysis of low-temperature dissociation of urethane groups

The isocyanate groups of 2,4-toluene diisocyanate in para-positions and the copper ions enter to the oxidation-reduction reaction. It has been shown that cobalt ions, exhibiting a high coordinating ability in comparison with copper ions, bind formed azoaromatic fragments. Coordinating interaction has a significant impact on the supramolecular organization of polyurethanes, and the complex of physical and mechanical and electrical properties.

4 Conclusions

It was shown that transition metal coordination compounds based on copper and cobalt exhibit catalytic activity in reactions of low-temperature dissociation of urethane groups.

Palladium-Catalysed Synthesis of Markovnikov Vinyl Sulphides with Aliphatic and Aromatic Thiols

Degtyareva E.S.*, Ananikov V.P.

N. D. Zellinsky Institute of Organic Chemistry, Russian Academy of Sciences, Moscow, Russia

* ed@ioc.ac.ru

Keywords: hydrothiolation, alkanethiols, stereoselective, Markovnikov, addition, palladium catalyst

1 Introduction

Formation of the C-S bond is a topic of the great interest because such molecules are used in total synthesis, in material science, and in pharmaceutical industry [1]. The simplest way of sulphides preparetion involves an addition of thiols to unsaturated hydrocarbons. Alkyne hydrothiolathion, which is carried out via radical, nucleophilic or metal catalyzed methods, can lead to the linear anti-Markovnikov products or to the branched Markovnikov vinyl sulphides.

The first example of the selective addition of aromatic thiols was published in 1992 by A. Ogawa [2], where the major product of the reaction between aromatic thiol and alkyne was Markovnikov isomer. Since then usage of number of late transition metal catalysts and f-element catalyst (Ni, Pd, Pt, Rh, Th, U, Zr) was reported as efficient method of branched vinyl sulphides synthesis. In spite of the surge of attention to such transformations main results were achieved with benzyl and aryl thiols, while insertion of the less reactive alkyl thiols is still very limited. Best results in this direction were achieved by J. Love's and T. Marks's groups [3], they mentioned reducing of the efficiency of the developed catalytic systems from primary to secondary thiols, and no products were observed with tertiary thiol [3d].

2 Results and discussion

We have examined a variety of metal complexes on the basis of Au, Cu, Ni, Pd for the catalytic reactivity in the addition reaction with aliphatic thiols and we have found that Pd complexes allow to proceed such kind of transformation with regioselective formation of Markovnikov type vinyl sulphides.

3 Conclusions

The present study is dedicated to the development of the universal catalytic system for Markovnikov-selective hydrothiolation of variety of terminal alkynes by aliphatic, benzylic, and aromatic thiols. The comparison will be made between Cu, Au, Ni, Pd complexes bearing various ligands and substituents. Detailed study of the catalytic system and optimization of the conditions for the synthetic procedure will be presented and discussed.

Keywords: 5-hydroxymethylfurfural, 2,5-furandicarboxylic acid, platinum, carbon nanotube, oxidation

1 Introduction

The selective oxidation of 5-hydroxymethylfurfural (HMF) into 2,5-furandicarboxylic acid (FDCA), a promising renewable alternative to petroleum-derived terephthalic acid, is one of the most attractive reactions for establishing the biomass-based sustainable chemical processes [1]. Several efficient catalytic systems based on noble metal catalysts (e.g. Au/CeO_2 and Pt/C), have been developed for conversion of HMF to FDCA in aqueous solution. However, these systems required the presence of equivalent strong bases (e.g. NaOH) to obtain high FDCA yields [2,3]. So far, very limited catalysts were reported to be active for the oxidation of HMF in the absence of liquid bases [4,5]. Although hydrotalcite, a solid base, supported Au catalyst exhibited superior performance for FDCA production without addition of a liquid base, the catalyst could not be used recyclably probably due to the reaction between the basic support and the acid products. Herein, we report carbon nanotube (CNT)-supported Pt (Pt/CNT) as a highly efficient and stable catalyst for the oxidation of HMF to FDCA under mild conditions in water in the absence of any bases. The mechanism of the catalytic reaction will also be discussed in detail.

2 Experimental

CNT-supported Pt catalysts were prepared by a microwave-assisted ethylene reduction method. The catalysts were characterized by N_2-physisorption, TEM, XPS and TPD. The catalytic conversion of HMF was carried out in a Teflon-lined stainless-steel autoclave. The liquid products were analyzed by a HPLC.

3 Results and discussion

We examined the catalytic behaviors of Au, Pt, Pd and Ru nanoparticles loaded on CNTs for the oxidation of HMF to FDCA in neutral water under O_2. Among all the catalysts, Pt/CNT exhibited the highest HMF conversion and FDCA selectivity. An FDCA yield of 98% was attained over the Pt/CNT catalyst at 368 K for 14 h. The Ru/CNT and Pd/CNT mainly provided 2, 5-diformylfuran (DFF) and 5-formyl-2-furancarboxylic acid (FFCA) with HMF conversions of 47% and 13%, respectively. The Au/CNT afforded a 23% HMF conversion and a 79% FFCA selectivity. Thus, Pt was a unique active component for the aerobic oxidation of HMF to FDCA without any bases.

We further investigated the catalytic performances of Pt loaded on several supports such as Al_2O_3, hydrotalcite (HT), armberlyst-15 and active carbon (AC). CNT- and HT-supported Pt catalysts showed superior performances. However, the Pt/HT catalyst could not be used

repeatedly due to the leaching of the basic HT support in the acidic solution. Pt/CNT was very stable and was recyclable without significant decreases in catalytic performance.

We found that the functional groups on CNT exerted significant effects on catalytic behaviors of the Pt/CNT catalysts. The Pt/CNT catalyst with a higher concentration of oxygen-containing groups, in particular C=O, showed higher selectivity and higher activity for the oxidation of HMF to FDCA. The influence of modification of a Pt catalyst with different model organic molecules were performed and the results confirmed that the C=O functional groups were benefit for the formation of FDCA (Table 1). We speculate that the carbonyl functional groups on CNT may facilitate the adsorption of HMF and the reaction intermediates.

Table 1. Effect of modification by model organic molecules on performances of Pt/ZrO_2.

Model molecules	HMF conv. (%)	Selectivity (%)			FDCA yield (%)
		DFF	FFCA	FDCA	
None	81	37	53	8.2	6.7
Benzoic acid	75	49	47	3.4	2.6
phenol	84	20	63	17	14
quinone	91	12	49	39	35

Reaction conditions: HMF, 0.5 mmol; HMF/Pt =100 (mol/mol); H_2O, 20 ml

The reaction mechanism for the oxidation of HMF has been investigated over the Pt/CNT catalyst. Our time-course result (Fig. 1) suggests that the first step over our Pt/CNT catalyst is the oxidation of the hydroxyl group in HMF to a carbonyl group (Fig. 1B, route a). Then, the two carbonyl groups were successively oxidized to carboxylic groups. This reaction mechanism is quite different from that proposed in other studies for the oxidation of HMF in the presence of a base, where the formation of carboxylic group is the first step (Fig. 1B, route b).

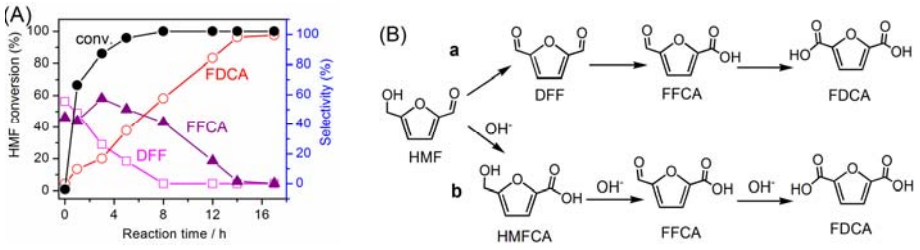

Fig. 1 (A) Time course for aerobic oxidation of HMF over Pt/CNT catalyst. (**B)** Reaction paths proposed for the conversion of HMF to FDCA.

4 Conclusions

Pt/CNT was a highly efficient catalyst for the selective oxidation of HMF to FDCA under O_2 in water without addition of any bases. An FDCA yield of 98% could be attained over this catalyst at 368 K. Pt nanoparticles and the oxygen-containing functional groups on CNTs played key roles in the selective oxidation of HMF. Pt nanoparticles were proposed to activate O_2 and HMF, while the oxygen-containing groups such as C=O enhanced the adsorption of HMF and the intermediates, i.e., DEF and FFCA onto catalyst surfaces. Our kinetic studies suggest that the reaction mechanism over the Pt/CNT is different from that proposed for the catalytic systems with a strong base additive.

Transformation of Glycerol to Acrolein over Isomorphously Substituted Iron Zeolites

Laforge S.L.S, Mijoin J.M.J, Pouilloux Y.P.Y, Mounguengui D.M. *

Institut des Milieux et Matériaux de Poitiers (IC2MP), UMR CNRS 7285, POITIERS Cedex 9, France

Keywords: zeolite, glycerol, petrochemical, iron, acrolein, isomorphous substitution

1 Introduction

Research on sustainable energy and transformation are part of alternative current challenges to the use of fossil fuels for a more sustainable future. Glycerol from biomass is becoming more abundant. It is a by-product of the transesterification of biodielsel and can turn into a variety of value-added product like acrolein. Acrolein is an important petrochemical intermediate formed by dehydration of glycerol, it serves among other things to make the acrylic acid for the manufacture of paints, adhesives or plastics [1]. Acrolein can also be produced by oxidation of propene from fossil fuel over bismuth molybdate, the yield of acrolein achieve almost 82% on this catalysts [2]. Zeolites are among the most used acid catalysts for this process with high yields. Nonetheless, the problem of these materials is the rapid deactivation by coke over time on stream. Recent studies have shown that the addition of a metal in the zeolite and the work in oxidative medium may reduce this deactivation [3]. The aim of this study is to compare two iron zeolites (Fe-MFI and Fe-BEA) prepared by post-synthetic isomorphic substitution [4] from mothers commercial zeolites MFI (Zeolyst, CBV15014) and BEA (Clariant, HCZB 150.5) with the same Si / Al ratio of 60 for the dehydration of glycerol to acrolein.

2 Experimental/methodology

The preparation consists in an NH_4F aqueous attack of the zeolite framework which involves the removal of aluminum lattice and the substitution by iron introduced as FeF_3, $3H_2O$ for 3 hours at 75 °C. After, the samples were filtered, washed and dried in the oven à 100°C for 24H. Finally, the zeolites were calcinated at 500°C on air (150 $ml.min^{-1}$) to obtain the protonic form of the iron zeolites. The isomorphous substitution stabilizes iron in the framework of zeolite in order to modulate acidity and create redox site over the materials. Reaction was carried out at 320°C in vertical furnace. The feed was a 10 mol% aqueous solution of glycerol introduced with a syringe pump (0.1$ml.min^{-1}$) at atmospheric pressure in the reactor. 300 mg of catalyst (GHSV= 2770 h^{-1}) were used in N_2 or air (15 $ml.min^{-1}$) as a carried gas. Different characterization techniques (IR, BET, MALDI-TOF, GC-MS) coupled with the method of analysis of "coke" developed at IC2MP [5] allow to shed light on the nature and type of coke formed on each catalyst to explain its influence on the catalytic properties and better understand the role of iron in zeolites.

3 Results and discussion

X-ray diffraction and nitrogen adsorption at 77K show that the physical and textural properties (table 1) of zeolites are conserved after preparation. In the first time, the reaction was carried out over H-BEA on air (15 ml/min) but the catalyst was rapidly deactivated (fig.1). The addition of 0,6wt% of iron (measured by ICP) on zeolite BEA (Fe-BEA(0,6%)) improves the catalytic performances. H-MFI is better than BEA catalysts. Fe-MFI(0,6%) is clearly the best catalyst with acrolein yield reaching 95% at the beginning of the reaction for total glycerol conversion and still 75% after 8h of the reaction (fig.1).

Table 1. Nitrogen adsorption at 77K of fresh catalysts after preparation

Zeolite	Total surface area ($m^2.g^{-1}$)	External surface area ($m^2.g^{-1}$)	Micropore volume ($cm^3.g^{-1}$)	Mesoporous volume area ($cm^3.g^{-1}$)
H-BEA	630	126	0,21	0,51
Fe-BEA (0,6%)	634	123	0,22	0,49
H-MFI	394	70	0,15	0,08
Fe-MFI (0,6%)	381	62	0,15	0,08

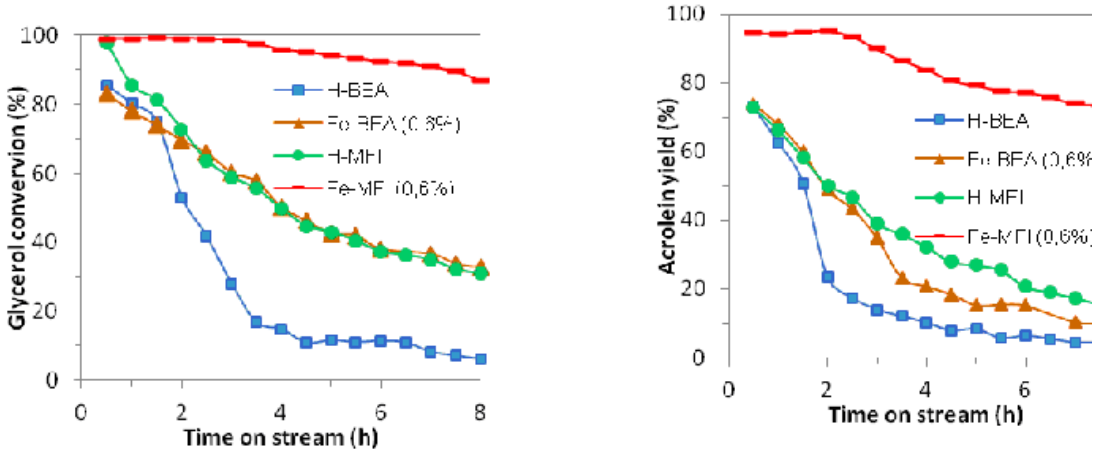

Fig. 1. Glycerol conversion and acrolein yield over MFI and BEA zeolites with and without iron at 320°C with time on stream on air (15 ml/min).

3 Conclusions

The post synthesis isomorphous substitution is easy to implement and allows the insertion of iron in the framework of zeolite with conservation of physical and textural properties. The BEA zeolite deactivates faster than MFI zeolite for the dehydration of glycerol to acrolein. Iron in BEA and MFI zeolites increases the catalytic performances with important reduction of deactivation. Fe-MFI (0,6%) give the best result for dehydration of glycerol to acrolein over zeolite.

Keywords: glycerol selective oxidation, H_2O_2/Fe-SiO_2 system, dihydroxiacetone (DHA)

1 Introduction

In recent years, biodiesel production from transesterification of fatty acids is receiving increasing attention associated with the development of alternative energy sources. Due to glycerol is the main by-product of biodiesel and its demand cannot compensate that production, new efficient procedures for the transformation of glycerol into value-added chemicals are being studied [1]. Glycerol catalytic oxidation is one of the non-commercialized routes so far due to the commercial relevance of most of the possible reaction products [2]. The partial oxidation of glycerol has been intensively investigated using Au, Pd and Pt catalysts at different operating conditions (25-100 ºC; 1-10 atm) and, mainly, O_2 as reagent [3]. Most of the systems produce a mixture of valuable oxygenated compounds such as dihydroxyacetone (DHA), glyceric acid (GCE), glycolic acid (GCO), lactic acid (LAC), formic acid (FOR), being crucial the control of product selectivity [4].

In this work, we reported the selective oxidation of glycerol in aqueous solution to high commercial value products by means of the H_2O_2-Fe/SiO_2 system.

2 Experimental/methodology

Oxidation runs were carried out in stirred batch reactor (700 rpm) at atmospheric pressure and temperatures within the interval 50 – 90 ºC. The starting concentrations of glycerol and H_2O_2 were 50 and 64.6 $g \cdot L^{-1}$, respectively. The initial pH was adjusted to 3.0 with nitric acid. The reaction was performed using a homogeneous catalyst (aqueous solution of $Fe(NO_3)_3 \cdot 9H_2O$, Fe: 10 $mg \cdot L^{-1}$) and a solid catalyst (Fe/SiO_2, 4 $g \cdot L^{-1}$).

The 4.0 wt.% Fe/SiO_2 catalyst was prepared by wetness incipient impregnation using an $Fe(NO_3)_3 \cdot 9H_2O$ aqueous solution as precursor and SiO_2 (Merck) as support. Once impregnated, the catalyst was dried at 60 ºC for 12 h and calcinated at 300 ºC for 4 h. The catalyst was characterized by the following techniques: 77 K N_2 adsorption-desorption isotherms, total reflection X-ray fluorescence spectrometry (TXRF), elemental analysis, thermogravimetric analyses in air atmosphere (TGA), and X-ray diffraction (XRD).

The progress of the reaction was followed by periodically withdrawing, separation of the catalyst by filtration and analyzing liquid samples. Glycerol and the organic by-products were quantified by U-HPLC (Thermo Scientific) equipped with RI and UV-vis detectors and by ionic chromatography (Metrohm 790 Personal IC). A TOC Analyzer (Shimadzu TOC-VCSH) was used to measure the total organic carbon. Residual H_2O_2 concentration and iron leached were determined by colorimetric titration using a UV/vis spectrophotometer (Cary 60, Agilent). The formation of Ti(IV)-H_2O_2 complex was quantified at 410 nm while the iron concentration was measured by means of o-phenantroline method at 510 nm.

3 Results and discussion

The Fe/SiO_2 catalyst exhibited a surface area of 420 $m^2 \cdot g^{-1}$ with a mesopore volume of

0.73 $cm^3 \cdot g^{-1}$ and a mean pore size of 4.8 nm. Composition analyses via TXRF showed an iron loading of 4.4 wt.%.

The glycerol oxidation by means Fenton process resulted in a high transformation of glycerol and H_2O_2 towards a mixture of oxygenated compounds such as GCE, GCO, FOR, glyoxylic acid (GCX) and hydroxypyruvic acid (HYP) at different concentrations depending on the operating conditions. In order to improve the reaction selectivity a Fe/SiO_2 catalyst was employed. Table 1 shows the effect of the temperature (50-90 ºC) on conversion and products distribution upon oxidation of glycerol solutions by means of the H_2O_2-Fe/SiO_2 system. Increasing temperature led to a higher glycerol and hydrogen peroxide conversion, but it was also accompanied by an increase of the mineralization. Interesting yield to DHA, glyceraldehyde (GDA) and FOR were obtained at 50 ºC, while an increase of the reaction temperature was associated with a high selectivity to FOR production. The catalyst remained stable along reaction time, leaching iron only when total H_2O_2 consumption is achieved.

Table 1. Conversion, molar products distribution and CO_2/TOC_0 molar ratio obtained in the glycerol oxidation at 4 h.

System	T (ºC)	X_{H2O2} (%)	$X_{glycerol}$ (%)	Product distribution (%)					$CO_2/\mathbf{TOC}_0$ (%)
				DHA	GAD	LAC	GCO	FOR	
Fenton	70	100	99.2	-	-	-	8	90	9
Fe/SiO_2	50	23	25	38	36	-	-	26	< 2
Fe/SiO_2	70	50	72	17	5	1	1	76	12
Fe/SiO_2	90	100	97	10	-	-	1	89	21

Assuming an apparent pseudo-first kinetic order reaction rate for glycerol oxidation a fairly good fit was obtained. An apparent activation energy of 80 kJ/mol for glycerol transformation was determined.

4 Conclusions

The H_2O_2-Fe/SiO_2 system is an attractive alternative to oxidize glycerol towards value-added compounds. The reaction effluent consists of high value commercial products in variable concentrations depending on the operating conditions. Future efforts will be focused on the selective formation of DHA, a product with the highest commercial value due to its demand in the cosmetics industry.

Keywords: hydroxyl, groups, oxidation of hydrogen

1 Introduction

The oxidation of hydrogen on silver is of interest for the theory of chemical kinetics and catalysis and can be used as a model redox catalytic reaction. This reaction makes it possible to elucidate quite clearly the nature of surface intermediates, which may assist to understand the mechanism of many important catalytic hydrogenation and oxidation reactions. The titled reaction is also of general theoretical interest for solving the problems related to reactivity of the silver surface and oxygen adsorbed on this surface. This reaction is also of practical importance for power engineering, in particular, for the development of fuel cells.

2 Experimental

The study was carried out with polycrystalline silver that was obtained via the reduction of silver oxide by hydrogen. Silver oxide was obtained by precipitation from an aqueous solution of silver nitrate with potassium hydroxide. After the precipitation, silver oxide was carefully washed with distilled water and dried. The study was performed using the volumetric static method in a glass vacuum setup equipped with McLeod gauges for pressure measurements. Hydrogen was purified by diffusion through a heated palladium capillary. Oxygen was produced by vacuum decomposition of potassium permanganate (chemical purity). The setup comprised several vessels, which made it possible to prepare the hydrogen-oxygen mixtures with specified pressure and composition. A 'stationary adsorbed layer' was obtained by consecutive transformations of three portions of a stoichiometric hydrogen-oxygen mixture, a conversion of the mixture in each portion being close to 30%.

3 Results and discussion

The earlier proposed mechanism of hydrogen oxidation over silver was considered:

$$O_2 + 2\square = 2O_{(ads)}; \quad \text{(I)}$$

$$H_2 + 2O_{(ads)} = 2OH_{(ads)}; \quad \text{(II)}$$

$$H_2 + 2OH_{(ads)} = 2H_2O. \quad \text{(III)}$$

Experiments on durable adsorption of oxygen at clean surface of silver at 298 K at initial pressure of oxygen 24.9 Pa have revealed the existence of two stages of oxygen sorption: the fast one and the slow one. Surface adsorbed oxygen forms at the first fast stage. The rate of the second stage obeys the law $\frac{N^2_{O_{(ads)}}}{t} = \text{const}$. Therefore the second stage is the diffusion of oxygen atoms into the metallic silver bulk.

The titration of adsorbed oxygen by hydrogen at 298 K and initial hydrogen pressure of 24.8 Pa showed that the only oxygen species interacting with hydrogen are those adsorbed at the surface. The quantity of surface oxygen in the experiments was 2.10×10^{-6} mol/m^2, which is close to approx. 56 % of hydrogen consumed (3.78×10^{-6} mol/m^2). The interaction of hydrogen with surface oxygen occurs in two stages: the fast one and the slow one till the reaction ends.

The quantity of hydrogen sorbed at the first (fast) stage is equal to the amount of surface adsorbed oxygen. This unambiguously indicates that hydroxyl groups form at this stage (see eq. II). At the second (slow) stage, hydrogen interacts with the surface hydroxyl groups giving water (eq. III). Reaction rate constant for the process of hydrogenation of the adsorbed hydroxyl group layer is equal to 3.15×10^{-5} $s^{-1}Pa^{-1}$ when related to the hydrogen pressure. Representing the experimental data on the slow interaction of hydrogen with the adsorbed oxygen layer in coordinates of equation:

$$\ln\left(\frac{1}{1-x}\right) = kt, \qquad (1)$$

gives the reaction rate constant k equal to 3.26×10^{-5} $s^{-1}Pa^{-1}$, which coincides to the reaction rate constant of adsorbed hydroxyl layer hydrogenation.

Therefore this is surface adsorbed oxygen species which interact with hydrogen. Oxygen which has diffused into the silver bulk (subsurface oxygen) doesn't participate in the reaction. Interaction with hydrogen occurs into two stages: fast and slow, the latter is of the first order with respect to hydroxyl groups.

Consecutive oxidation of three portions of the stoichiometric mixture $2H_2+O_2$ with total pressure of 22.8 Pa was performed over two samples: the sample, which was protractedly exposed to oxygen, and the pure silver surface. Each portion contacted the sample until the conversion extent of the mixture achieved 30 %. It was observed that the initial rates of quasi-steady state oxidation of the tree portions didn't differ for the two samples under the study. In other words, subsurface oxygen doesn't affect the rate of hydrogen oxidation.

Synthesis of water (stage III) is the central stage of the catalytic reaction. Stage (II) is fast related to the stage (III). Then the adsorbed layer at silver surface consists of hydroxyl groups and the rate hydrogen interaction with this surface is the rate of stage (III).

The reaction of hydrogen with the adsorbed layer was studied at initial hydrogen pressure of 15.7 Pa and 298 K. The adsorbed layer was prepared by subsequent conversion of 3 portions of $2H_2+O_2$ mixture. The initial rate of the interaction of hydrogen with the «stationary adsorbed layer» is 6.00×10^{-10} $mol\cdot m^{-2}s^{-1}$, while the steady state rate of the hydrogen oxidation for the stoichiometric mixture is 1.18×10^{-9} $mol\ m^{-2}\ s^{-1}$. This means that hydrogen is consumed at two stages of the process: stage II and stage III. The interaction of hydrogen with the stationary adsorbed layer is described by equation (1), i.e. the reaction rate obeys the first order kinetic law with respect to surface hydroxyl groups. The stage III can be expressed as two consecutive processes:

$$H_2 + OH_{(ads)} = H_2O + H_{(ads)}. \qquad (IV)$$

$$H_{(ads)} + OH_{(ads)} = H_2O + 2\square. \qquad (V)$$

Stage V is fast, stage IV is the elementary rate-determining stage (RDS) of the entire process of hydrogen oxidation over silver. The rate constant of stage IV is 4.87×10^{-5} s^{-1} Pa^{-1} at 298 K and hydrogen pressure of 15.6 Pa.

4 Conclusions

The proposed mechanism (I-II-IV-V) of the catalytic reaction of hydrogen oxidation over silver has one common principle feature with the mechanism of branching chain reaction of hydrogen burning: hydroxyl groups are the only species which give water by direct interaction with hydrogen molecules.

Keywords: ionic liquids, carbon, monoxide, catalysis, palladium, carbonylation, carboxylic acids

1 Introduction

Transition metal-catalyzed carbonylation of unsaturated hydrocarbons, alcohols and halides is a direct one-step route to carboxylic acids and esters. In presented work we systematically studied application of some ionic liquids such as molten tetrabutylammonium and 1-butyl-3-methylimidazolium derivatives as a media for these reactions.

2 Experimental

This approach provides a number of unusual possibilities. The most striking result is higher activity of phosphine-free palladium catalyst than that of “traditional” Pd-phosphine complexes. Bromide-containing ionic liquids stabilize palladium in the form of nano-sized suspension, as demonstrated by TEM. For unsymmetrical olefinic substrates, regioselectivity depends on anion nature in ionic liquid. In particular, chloride improves selectivity to 2-phenylpropanoic acid in carbonylation of styrene. Due to high solubility of catalyst in molten salt, it can be used repeatedly by simple extraction of products from reaction mixture with diethyl ether. In dodecene-1 carbonylation, ten cycles were carried out without loss of activity and selectivity. Importantly, reloading procedure may be performed in air atmosphere.

3 Results and discussion

Reaction scheme for the carbonylation of 1-phenylethanol into phenylpropanoic acids is proposed. Hydroxycarbonylation of benzyl halides in ionic liquids proceeds fast in the absence of base. Therefore, formation of stoichiometric amount of halide salt may be avoided.

Keywords: iodobenzene, benzaldehyde, reductive carbonylation, rhodium, synthesis gas

1 Introduction

Aromatic aldehydes are useful products because of diverse reactivity of formyl group. Usually they are synthesized by Gattermann–Koch, Reimer–Tiemann, Vielsmeier–Haag, and Duff reactions. However, these methods suffers from drawbacks like low yield, poor selectivity and generating waste and side products [1,2]. Alternatively, catalytic formylation (reductive carbonylation) of aryl halides with synthesis gas in the presence of palladium phosphine complexes was firhst reported in 1974 by Schoenberg and Heck [3] and lately by Beller [4-6] and Nagarkar [7] groups.

Somewhat surprisingly, up to now rhodium was unexplored as a catalyst for reductive carbonylation of aryl halides. This encouraged us to test rhodium salts and complexes in reductive carbonylation of iodobenzene as a model substrate.

2 Experimental

Catalytic runs were carried out in a pressurized 50 mL glass-lined steel reactor equipped with a magnetic stirrer and arrangements for automatic temperature control. The reactor was charged with reagents and catalyst, flushed with CO/H_2 (1/1) and filled with synthesis gas up to desired pressure. Then the stirrer was switched on and the reactor was heated to desired temperature. After reaction complete the reactor was cooled to ambient temperature and depressurized, the reaction mixture was extracted with ether and analyzed by GC with nonane as an internal standard. Product composition was confirmed by ^1H NMR analyses.

3 Results and discussion

Reductive carbonylation of iodobenzene gives benzaldehyde (Fig. 1)

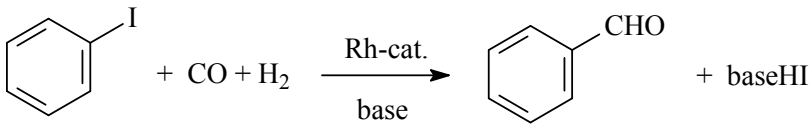

Fig. 1. Reductive carbonylation of iodobenzene

Rhodium phosphine complexes such as $HRh(CO)(PPh_3)_3$ and $RhCl(CO)(PPh_3)_2$ were found to be excellent catalysts They surpass $PdCl_2(PPh_3)_2$ in respect to activity and selectivity to benzaldehyde (Tab. 1). Aromatic solvents such as toluene and o-xylene seems to be the most suitable medium. Other solvents such as heptane, 1,4-dioxane, MEK, DMF and acetonitrile gave poor yield of benzaldehyde. In methanol solution, methyl benzoate was the main product.

Reaction is highly sensitive to the nature of the base. Replacing NEt_3 with NBu_3 resulted in almost threefold reduction in benzaldehyde yield. Somewhat higher but still low yield was achieved with Hünig's base. Inorganic bases such as potassium and cesium carbonates gave poor iodobenzene conversion and benzaldehyde yield.

Table 1. Effect of catalyst on reductive carbonylation of iodobenzene. Reaction conditions: 4.5 mmol PhI, 22 μmol catalyst, 1.5 equiv. NEt_3, 5 mL toluene. *P* 1 MPa (CO/H_2 1/1), 4 h.

Catalyst	T, °C	Conversion,%	Yield (%)		
			PhCHO	benzene	biphenyl
$PdCl_2(PPh_3)_2$	100	67.0	48	0.1	3.5
$RhCl_34H_2O$	100	18.0	2.3	10.6	2.4
$HRh(CO)(PPh_3)_3$	100	65.9	58.7	7.0	–
$RhCl(CO)(PPh_3)_2$	100	67.0	56.9	7.0	–
$RhCl(CO)(PPh_3)_2$	90	43.9	37.2	0.1	–
$RhCl(CO)(PPh_3)_2$	110	100	85.4	11.9	–
$RhCl(CO)(PPh_3)_2$	120	100	85.3	11.8	2.8

Synthesis gas pressure effects on the reaction indexes. Iodobenzene conversion reaches 100% at a total pressure of about 1–1.5 MPa and slightly decreases at higher pressure. Both selectivity and yield of benzaldehyde increase with pressure increasing while selectivity to benzene decreased. Biphenyl is a main product at atmospheric pressure but it fully disappears at a pressure 1 MPa and higher.

4 Conclusions

In conclusion, rhodium (I) triphenylphosphine complexes are good catalysts for reductive carbonylation of iodobenzene. The best catalyst formulation found: 0.5% $RhCl(CO)(PPh_3)_2$, 150% NEt_3, toluene. At 110°C and 1.5 MPa (CO/H_2 = 1/1) iodobenzene is totally converted within 2 hours giving benzaldehyde with the yield of 88%.

Keywords: monocrystalline graphene synthesis, STM, DFT, gold intercalation surface, atomic structures surface, segregation

1 Introduction

In the wake of impressive experiments performed at 'the Manchester group' on a single atomic sheet of graphite transferred on silicon oxide by means of 'Scotch Tape technology' [1,2], the academic community has struggled to create an intelligent technique for graphene layers production on a solid state surface. This issue has not been appropriately addressed so far. Both methods viewed as most promising - high-temperature annealing of hexagonal silicon carbide and cracking of hydrocarbons on surfaces of some metals (Ni, Ru, Re, etc.) – require gold intercalation under graphene to create a quasi free-standing graphene layer (the Dirac point being at the Fermi level) [3,4]. Also, the graphene electronic structure (the Dirac cone energy position, the formation of an energy band gap, etc.) varies depending on the intercalated metal (Ag, Cu, Si, Cs, etc.). The conditions under which metal intercalation under graphene is possible have been found empirically, while the intercalate atomic structure and the process explaining how alien atoms settle under a graphene layer have remained unknown.

This paper presents the results of a study of synthesis of graphene during propene adsorption at 300°C/ annealing at 500°C cycle with following gold intercalation process under the graphene monolayer on Ni(111).

2 Experimental and calculation details

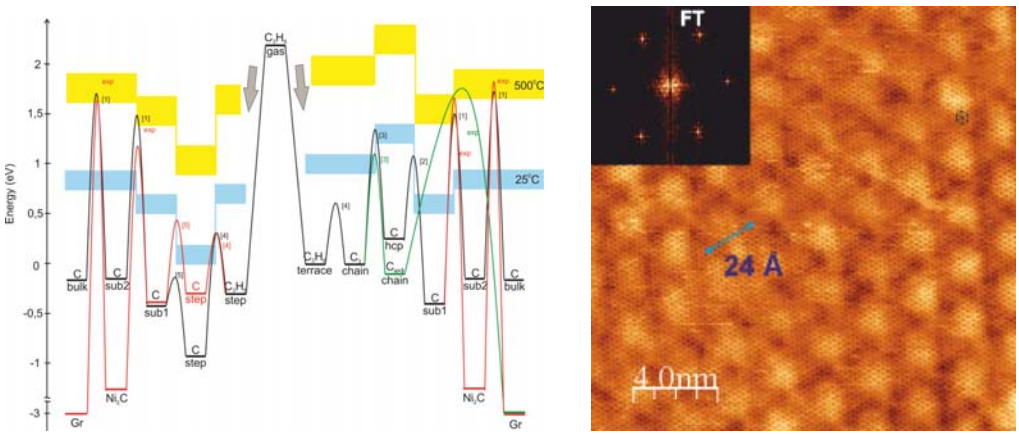
The experimental study was performed in ultra-high vacuum using low-energy electron diffraction, Auger electron spectroscopy, and scanning tunneling microscopy (STM). The graphene on a Ni(111) surface was formed by a sequence of "propene adsorption at 300°C/annealing at 500°C" cycles, in which gold was first deposited on a graphene layer at 300°C, and then the entire Au/Gr/Ni(111) system was annealed at 450 °C.

The first-principles calculations were performed by using the Vienna ab-initio simulation package (VASP) based on the density functional theory. Parameters of calculations: - GGA PBE exchange-correlation functional has been used as the basis for the DFT-D2 (Grimme) correction; - PAW pseudopotentials; 5-layers Ni(111) slab with 18 A vacuum region. For calculations with molecule C_3H_6 we use LDA functional and 4-layers slab.

3 Results and discussion

Figure 1a shows energy diagram of propene molecule dehydrogenation (on terraces) and dissociation (on steps) at RT (25 °C) adsorption and following carbon atoms transformation into nickel carbide and graphene at 500 °C on Ni(111). The all energy levels and potential barriers have been calculated within DFT and with Nudged Elastic Band (NEB) approach. In Fig.1b, the

resulting graphene monolayer on Ni(111))-9.5×9.5-Au is presented. ARPES measurements show perfect Dirac cone in electron dispersion corresponding to quasi free-standing graphene.



a) b)

Fig. 1 a) Energy diagram of C_3H_6 transformation and carbon structures formation on Ni(111) during propene adsorption at 300°C/annealing at 500°C cycle; b) STM image of Gr/Au/Ni(111) after gold intercalation: dislocation loop superstructure Ni(111))-9.5×9.5-Au and graphene atomic structure are clearly seen. Fourier transform image is presented as insert

4 Conclusions

1. New precise temperature programmed method for graphene synthesis on Ni(111) has been proposed and tested. As a result, monocrystalline graphene monolayer of size 6×6 mm has been grown on Ni(111).
2. Mechanism of Gr synthesis includes the following steps:

- hydrocarbon molecules dehydrogenation on terraces and complete dissociation on step edges
- carbon atomic chains formation on terraces
- carbon atoms diffusion under surface through step edges and their accumulation between nickel atomic layers in subsurface area
- at annealing, carbon atom segregation on surface with Ni_2C formation and then transformation into graphene

3. As a result of gold intercalation at 450 °C, graphene monolayer on Ni(111) is detached from nickel without any damage. Network of dislocation loops Ni(111)-9.5×9.5-Au is real indication of gold intercalation under graphene monolayer.

Keywords: aromatic amines, photooxidation, phthalocyanines, heterogeneous, sensitizers

1 Introduction

Non-transition metals phthalocyanines (PcM, M = Zn, Al and others) have proved to be effective photosensitizers. Under visible light irradiation they react in triplet state with dioxygen, generating singlet oxygen ($^1O_2$) with high quantum yields. Because of such properties phthalocyanines are used in synthesis, ecology [1] and medicine (PDT) [2]. Photooxidation can be carried out both in PcM solution and with PcM supported on various carriers. The last version is more preferable due to obvious advantages of heterogeneous sensitizers (HS), such as ease of their separation from the reaction medium and possibility of a reuse.

Sulfo and carboxy substituted PcZn and PcAl immobilized on anionic exchanger Amberlite IRA 400 have been examined as HS for oxidative phenols destruction [3]. We have prepared HS by equilibrium adsorption from solutions of R_4PcZn and R_4PcAl (R=3-PhSO_2-5-*t*-Bu, 3-PhSO_2, 3-PhS, 4-*t*-Bu and others) on various carries (NH_2-SiO_2, Al_2O_3, SiO_2, Amberlite 200, Amberlite XAD7HP and others). Some of them showed high activity and selectivity in aromatic amines and phenols photooxidation [4, 5].

The purpose of the work is research of various factors influence on efficiency of selective aniline and its methyl derivatives photooxidation, sensitized by HS on the basis of the substituted PcZn, with formation of *p*-hydroxylation products.

2 Experimental/methodology

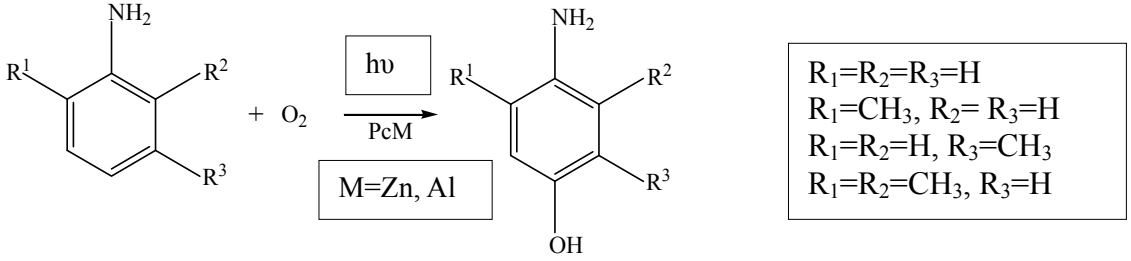
Photooxidation of aromatic amines in the water-organic mixtures (H_2O-CH_3CN, H_2O-CH_3OH) was carried out in the glass reactor (ø 35 mm) at continuous stirring and saturation with oxygen. The light-emitting diodes (λ = 664 nm) 0.2 W everyone were used as a light source. The reaction was monitored by seeding of sample aliquots at the certain intervals. Conversion of substrate and yield of product were measured by HPLC on HP 1100 Agilent series, equipped with Zorbax EclipseXDB-C8 column (4.6x150 mm, 5μm) and UV-detector (at 250 nm), the mobile phase consisted of a mixture H_2O-CH_3CN (40:60), a flow rate was 1 ml/min, internal standart – naphthalene.

Two methods were used for immobilization of R_4PcZn (R = 3-PhSO_2-5-*t*-Bu, 3-PhSO_2, 3-PhS and 4-*t*-Bu) on carriers, namely, method of equilibrium adsorption on the amino-modified silica gel (NH_2-SiO_2) or Amberlite XAD 7HP (Amb.), and also by covalent attaching of R_4PcZn sulfochlorides to NH_2-groups of carrier.

3 Results and discussion

The nature of a substituent in aniline molecule has considerable impact on its photooxidation rate. It was shown that toluidines are oxidized faster than aniline whereas introduction of Cl atom in aniline molecule slows down this reaction. Such influence of substituent properties is corresponded with the electrophilic nature of oxidizer – singlet oxygen ($^1O_2$). Its participation in aniline photooxidation is confirmed with use of standard tests: by acceleration of the process in D_2O in comparison with H_2O and delay at addition of NaN_3.

Photooxidation of aniline and its methyl derivatives in the presence of HS results in *p*-aminophenol formation.



Activity and stability of sensitizers, the nature of carrier, property of solvent, concentrations of sensitizer and substrate etc. belong to effecting factors.

The HS bearing substituents R = 3-$PhSO_2$-5-*t*-Bu or 3-$PhSO_2$ in benzene rings of R_4PcZn possess highest efficiency in sensitized anilines photooxidation with dioxygen. These substituents provide at the same time monomeric state of PcZn on carrier surface and photostability. HS on the basis of PcAl were less active, than Zn-analogs.

Reaction doesn't occur in water free organic solvents, and it proceeds quicker in the CH_3CN-H_2O mixture, than in CH_3OH-H_2O that probably is connected with longer lifetime of $^1O_2$ in CH_3CN (30 micro sec) in comparison with CH_3OH (7 micro sec).

The yield of 4-amino-3,5-xylenol was 74% at almost full conversion of 2,6-xylidine in optimum conditions for irradiation time 150 min in CH_3CN-H_2O 1:1. The same conversion and yield were received with the attached HS SiO_2-NH-SO_2-(3-$PhSO_2$)$_4$-PcZn in the MeOH-H_2O 1:1 mixture.

4 Conclusions

It is shown for the first time that photooxidation of anilines leads to products of *p*-hydroxylation in the presence of the heterogenized sensitizers on the basis of the substituted zinc phthalocyanines adsorbed on Amb. or NH_2-SiO_2, or in sulfochlorid form covalent attached to NH_2-SiO_2. Selectivity of *p*-aminophenol formation is more 70%. The most effective heterogenized sensitizers, namely, adsorbed (3-$PhSO_2$-5-*t*-Bu)$_4$PcZn on Amb. and attached (3-$PhSO_2$)$_4$-(SO_2Cl)$_n$-PcZn to NH_2-SiO_2 can be used in several times. Thus the total of photocatalysts turnovers number is more than 4000.

Keywords: cellulose, hypercrosslinked, polystyrene, hydrolytic, hydrogenation, sorbitol

1 Introduction

Cellulose is one of the mostly wide-spread organic materials on the earth. It has been estimated that 10^{11}–10^{12} tons of cellulose are synthesized in nature annually. It is mostly combined with hemicelluloses and lignin in the plant cell walls [1]. Cellulose is considered a likely alternative to fossil fuels as its renewable resources can provide the production of raw materials for the chemical industry and second-generation biofuels on a large scale [2 - 4].

In this paper a new type of Ru-containing catalysts based on non-functionalized and functionalized hypercrosslinked polystyrene (HPS) is proposed for cellulose hydrolytic hydrogenation. HPS is characterized by ultra-high porosity and excellent sorption properties and was successfully used as a support for nanocomposite catalysts.

2 Experimental

Low-temperature nitrogen adsorption was carried out with the surface analyzer Beckman Coulter SA 3100 to determine specific surface areas and porosity of the catalysts and the initial HPS samples. Before the analysis the samples were degassed at 120 °C in vacuum for 1 hour using the device for preliminary preparation of the samples (Coulter Corporation, USA).

Transmission electron microscopy was performed with a Techai G 30S-TWIN (FEI, USA) operated at accelerating voltage of 300 kV. Ru-containing HPS powders were embedded in epoxy resin and subsequently microtomed at ambient temperature. Images of the resulting thin sections (*ca.* 50 nm thick) were collected with the Gatan digital camera and analyzed with the Adobe Photoshop software package and the Scion Image Processing Toolkit.

3 Results and discussion

We studied the influence of the Ru content, Ru/cellulose ratio, and the type of HPS on the catalytic properties in cellulose hydrolytic hydrogenation. The highest yields of hexitol ($\eta_{hex.}$) were obtained with the catalysts containing 1 wt.% of Ru in HPS.

Table 1 show the porosity data of the initial HPS samples and the catalysts obtained from the nitrogen physisorption measurements. As shown in Table 1, MN-270 has the highest surface area as well as the specific surface area of micropores compared to the other supports

The specific surface areas of the catalysts based on MN-270 and MN-500 are lower than those of the initial supports. In the case of MN-270 where the decrease does not exceed 15%, this is easily understood as Ru nanoparticles fill the pores and the matrix can shrink because the reduction by hydrogen is carried out at 300 °C. However, for MN-500 and 1% Ru/MN-500, the surface area decreases by a factor of 5. This fact is explained by desulfurization of MN-500 which takes place at 200 - 300 °C and results in the change of the HPS structure.

The best results were obtained for 1% Ru/MN-270. This catalyst demonstrates the highest hexitol yield and the lowest yield of other products. Most likely the high efficiency of this catalyst is due to combination of the high specific surface area, narrow pore size distribution,

and small, monodisperse Ru nanoparticles.

Table 1. Porosity data for the HPS samples and the catalysts

Sample	Surface area					
	Langmuir		BET		t-plot	
	S_L,[a] m^2/g	k_L[c]	S_{BET},[b] m^2/g	k_{BET}[c]	S_t[c], m^2/g	k_t[d]
MN-270	1500	0.9995	1420	0.99962	295[e] 1140[f]	0.99667
MN-100	840	0.9998	730	0.99954	200[e] 590[f]	0.99981
MN-500	650	0.9999	540	0.99943	150[e] 450[f]	0.99996
1% Ru/MN-270	1270	0.9994	1180	0.99957	250[e] 990[f]	0.99787
1% Ru/MN-100	890	0.9999	740	0.99938	195[e] 600[f]	0.99974
1% Ru/MN-500	120	0.9985	90	0.99994	80[e] 15[f]	0.99879

[a]S_L is the specific surface area (Langmuir model); [b]S_{BET} is the specific surface area (BET model); [c]S_t is the specific surface area (t-plot); [d]k_L, k_{BET}, k_t are the correlation coefficients; [e]specific surface area according to a t-plot model; [f]specific surface area of micropores;

To evaluate stability of this catalyst, after the completion of the reaction, the catalyst was separated and used again with fresh cellulose. The results show that the repeated use of the 1%Ru/MN-270 catalyst in three consecutive reaction cycles leads to only a slight decrease of its activity which can be explained by a loss of some amount of the catalyst during filtration. The analysis of the liquid phase by atomic absorption spectroscopy showed no Ru leaching.

4 Conclusions

Ru-containing catalysts based on HPS were studied in hydrolytic hydrogenation of cellulose. We demonstrated that only the catalysts based on non-functionalized MN-270 provide high efficiency and selectivity towards hexitols due to stability of the HPS framework resulting in high surface areas of the catalysts and well-defined Ru nanoparticles. The catalysts based on functional analogues of MN-270, i.e., MN-100 and MN-500, were practically inactive in this process.

The use of the 1.0% Ru/MN-270 catalyst allows achieving the total sorbitol and mannitol yield about 50% at the ~85% conversion that is comparable with the results obtained with more complex and expensive catalytic systems. Moreover, preliminary studies show that the temperature decrease and the increase of the process duration result in the increase of the hexitol yield up to 60 – 70 %. This catalyst is also highly stable in the repeated use making it promising for cellulosic biomass conversion to feedstock for chemical synthesis and industrial production of second-generation biofuel.

Keywords: pyridine, picolines, lutidines, zeolites, micro- and mesoporous aluminosilicates, multi-component reaction

1 Introduction

Pyridine and substituted pyridines are the important intermediates in the synthesis of pharmaceuticals, herbicides, metal corrosion inhibitors and surface-active agents. Industrially, pyridine and its derivatives are synthesized by condensation of aldehydes and ammonia over an amorphous aluminosilicate catalyst promoted by ThO_2, ZnO or CdO. The pyridine yield amounts 40-60%, and a significant amount of by-products is formed [1].

In this regard, at the Institute of Petrochemistry and Catalysis of the Russian Academy of Sciences conducted research is to develop a selective method for synthesis of pyridine over micro- and mesoporous aluminosilicates.

2 Experimental/methodology

We investigated the catalytic properties of microporous zeolites (HY, H-Beta, H-ZSM-12, H-ZSM-5), a micro-meso-macroporous zeolite HY-MMM and amorphous mesoporous aluminosilicates ASM (mesopores with a diameter of 2-7 nm) [2].

The zeolite catalysts were characterized by the X-Ray Phase (XRP) and X-Ray Diffraction (XRD) Studies, the Low Temperature Nitrogen Adsorption, and the Temperature Programmed Desorption of ammonia (TPD NH_3).

Mesoporous aluminosilicates with various chemical compositions have been prepared by sol-gel method and were characterized by nitrogen gas adsorption, transmission electron microscopy (TEM), small angle X-ray scattering (SAXS), and ^{29}Si and ^{27}Al magic angle spinning nuclear magnetic resonance (MAS NMR) [3-4]. The catalyst samples were calcined in the atmosphere of air for 3-4 hours at 540˚C.

The reaction of ethanol with formaldehyde and ammonia was conducted in a tubular, down-flow Pyrex reactor with 20 mm internal diameter at the temperature of 200-400˚C and the weight hourly space velocity (WHSV) within the range of 0.5-10 h^{-1}. The molar ratio of ethanol/formaldehyde/ammonia varies within the range of 1.0/0.4-1.1/1.5-5.0. The amount of the catalysts taken for every reaction was 0.4 g. The reaction mixture was fed from the top using a micro-pump. The product was collected at the bottom and cooled using ice-cold water.

The reaction products were analyzed by means of the gas-liquid chromatography (flame ionization detector, SE-30 column, l=25 m, the temperature of analysis 50-280˚C; the programmed heating gradient of 8˚C/min) and GC-MS (SPB-5 30 m × 0.25 mm column, the flow rate of the helium, temperature program adjustable between 40° to 300°C, the programmed heating gradient of 8˚C/min, the temperature of the ionization source is 200°C of ionization energy 70 eV).

The products were identified by comparing the mass spectra and chromatographic behavior of the separated and reference products (pyridine, picolines and lutidines).

- **Results and discussion**

We have develop a process the synthesis of pyridine and picolines by a reaction of ethanol with formaldehyde and ammonia over zeolite catalysts differed in their crystal structure, acidic properties and different porosity, and amorphous mesoporous aluminosilicates (ASM).

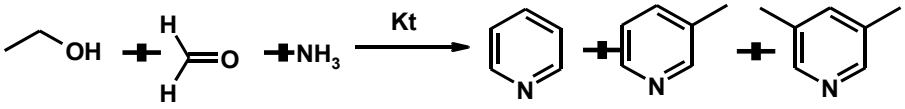

Fig. 1. Synthesis of pyridines from ethanol, formaldehyde and ammonia

We have found that the most active catalysts among microporous zeolites are H-Y and H-Beta. The conversion of ethanol are 60 and 55%, respectively (T = 400°C, w = 7 h^{-1}, mole ratio $C_2H_5OH:CH_2O:NH_3$ = 1.0:0.8:1.5).

Main reaction products in the presence of H-Beta and H-ZSM-5 zeolites are pyridine (50%) and picolines (40%), over H-Y and H-ZSM-12 zeolites - picolines (45-52%) and lutidines (19-25%).

It is shown, that the most active in the synthesis of pyridines is micro-meso-macroporous zeolite N-Y-MMM on which conversion of ethanol reaches 90%. The high activity zeolite HY-MMM due to the presence in its structure of meso- and macropores, improving diffusion reaction molecules and products reaction. In the present of zeolite H-Y-MMM as a part of reaction products predominant methylpyridine (48-54%).

Amorphous mesoporous aluminosilicates showed good catalytic activity in the reaction of ethanol, formaldehyde and ammonia is comparable to the activity of zeolite catalysts. Over sample aluminum silicate with the ratio of SiO_2/Al_2O_3 of 20 the conversion of ethanol are 50-70%. Main reaction products in the presence of ASM catalyst are 3-picolines (60%).

- **Conclusions**

Catalysts based on zeolites with a combined micro-meso-macroporous structure and mesoporous aluminosilicates showed high activity in the synthesis of pyridine and picolines (conversion of ethanol reaches 90% and 70%, respectively).

The composition of the reaction products can be controlled by changing the structural characteristics, porosity, acid properties, and varying the reaction conditions (temperature, weight hourly space velocity, the molar ratio of the reactants).

The selectivity of the pyridine formation reaches its maximum over microporous zeolites (49%) at 200-300˚C and 7 h^{-1}. The most selective formation of 3-picoline over micro-meso-macroporous zeolite H-Y-MMM and mesoporous aluminosilicate ASM (60%) at 300˚C, 7 h^{-1}.

Keywords: dehydrogenation, catalyst, composition of raw materials, coke formation, water feed, mathematical model

1 Introduction

The main stage of linear alkylbenzenes production (LAB) is dehydrogenation process of n-paraffins $C_{10} - C_{13}$. The formation of byproducts (diolefins, isoparaffins, cycloparaffins) occurs in this stage and it contributes to formation of coke on the dehydrogenation catalyst surface. Composition of raw materials has significant effect on the yield and quality of the LAB and accumulation rate of coke on the catalyst. It explains the importance of dehydrogenation process research in the case of processing of raw material various types whose components has different reactive capacity to the primary reaction [1–2].

The aim is to optimize the composition of raw materials and technological parameters of the process for producing olefins using experimental data from an industrial plant and computer odeling system [3–5].

2 Experimental

Influence of tridecane concentration of raw mixture on the technological parameters of dehydrogenation process of n-paraffins, duration of the catalyst operating cycle and yield of the main product were studied using the mathematical model developed dehydrogenation process. Maximum possible content of this component in the raw mixture and its optimal value in the initial mixture was determined.

The maximal production of main component is provided at the optimum content of C_{13} – components which reduces the recirculation ratio of mixture and the rate of coke deposition on the dehydrogenation catalyst. Recommendation for change of process parameters was developed.

3 Results and discussion

Using the mathematical model developed dehydrogenation process, the optimal modes of water feed to the dehydrogenation reactor at a molar ratio of reducing hydrogen / feedstock: decreasing the molar ratio of hydrogen / feedstock to 7/1 to 6/1 to compensate for the high rate of catalyst deactivation can be achieved by increasing the flow rate of water.

When the molar ratio H2 / hydrocarbon = 7 / 1rekomenduemy water flow 300 hours the catalyst is 4.5 liters / hr and 9.10 l / h on day 450-480 of the catalyst based on a predetermined concentration of 8.5% by weight of olefins. If a given concentration of olefins in the reactor product mixture is equal to 9.0-9.5 wt.%, The service life of the catalyst drop to 250-260 days at H2 / hydrocarbon = 6/1 to 350-380 days and at H2 / hydrocarbons = 7/1, it would require an adjustment mode the water supply to the reactor upwards.

4 Conclusions

It is shown that a change in the type of catalyst is necessary to adjust the recommendation

of water flow in the dehydrogenation reactor, as it is determined by the rate of coke formation reactions, which is different for different catalysts.

Keywords: photocatalysis, TiO_2, partial oxidation, glucose

1 Introduction

The search of alternative resources for the synthesis of chemicals currently produced from non-renewable sources has directed the activities of researchers towards the use of different raw materials such as biomass. Glucose, a major component of biomass, can be used as a model compound for the sustainable production of high value chemicals. To this aim catalytic processes at high pressure and temperature, pyrolysis, gasification or conversion under supercritical conditions have been object of intense research. In this framework heterogeneous photocatalysis can be considered as an alternative particularly because it is performed at ambient pressure and room temperature [1]. This work aims to convert glucose by a photocatalytic process in aqueous suspensions of different TiO_2 powders to obtain high added value products in soft and green conditions.

2 Experimental/methodology

Polycrystalline TiO_2 powders both commercial (Evonik P25, Merck and BDH) and home prepared have been used as photocatalysts for the glucose oxidation in aqueous suspension. Home prepared TiO_2 samples have been obtained from different Ti containing precursors. By using $TiCl_4$ three materials have been obtained, named HP, HP-R and HP-B; from $TiOSO_4$ and $Ti(OPr)_4$ the powders obtained were HPS-A and HP-IP-A, respectively. Bulk and surface characterizations were carried out in order to define the physicochemical features of the powders (See Table 1). The photoreactivity runs were carried out at room temperature and ambient pressure in a 800 mL open reactor irradiated in the UV region with an immersed 125 W medium pressure Hg lamp (Helios Italquartz, Italy). The initial aqueous glucose concentration was 1 mM. The amount of photocatalyst was enough to absorb all the photons emitted by the lamp. All of the runs lasted ca. 7 h. Samples were withdrawn at fixed intervals of time from the reacting suspension and the quantitative determination of glucose and its intermediate products were performed by HPLC analyses.

3 Results and discussion

Table 1 reports some physicochemical features of the commercial and home prepared TiO_2 powders. The home-prepared materials presented generally higher specific surface areas than the commercial ones and a lower crystallinity which did not prevent their photocatalytic activity. The degradation of glucose occurred by using all of the photocatalysts, although different conversion extent and distribution of intermediate products were observed, depending on the photocatalyst used. In Figure 1 it is reported the evolution of the substrate and the intermediate oxidation products during photocatalytic runs in the presence of TiO_2 Merck and TiO_2 HP photocatalysts. In the presence of the different powders not only the distribution of products but also the degradation rates changed.

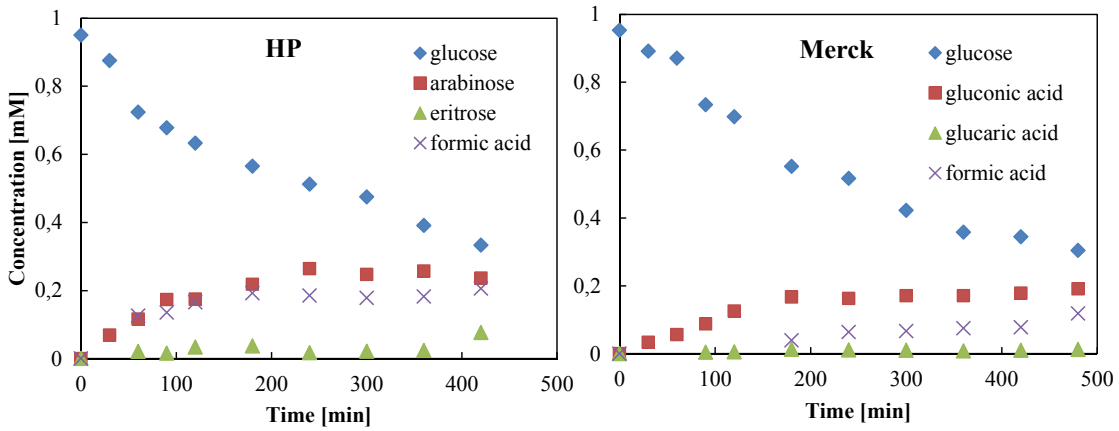

Figure 1. Evolution of glucose and their intermediate oxidation products versus irradiation time in the presence of TiO_2 HP and Merck.

The main glucose oxidation product was gluconic acid in the presence of the commercial TiO_2 Merck and BDH samples, whereas with Evonik P25 and all of the home prepared materials mainly arabinose was obtained along with eritrose, glyceraldehyde and formic acid. The isomerization of glucose into fructose was also observed. Table 2 resume some quantitative results.

Table 1. Physicochemical characterization of the TiO_2 photocatalysts

Photocatalyst	SSA (m^2/g)	Crystalline phase	Crystallinity (%)[a]	Crystallite size (nm)	Band gap (eV)

Keywords: catalytic cracking, dispersibility, difractograms, pore volume, hydrocracking

1 Introduction

At the present stage the process of light hydrocracking of heavy oil fractions has increased requirements for yield and quality of the desired products along with the stable activity of the catalysts used in combination process of light hydrocracking and catalytic cracking . Economic indicators of light hydrocracking are determined by the quality of the catalyst used .

2 Experimental/methodology

Based on the previously synthesized zeolite Ni-Al-Si- th catalyst, the highly efficient wide-porous catalyst was developed for the process of heavy feed stocks light hydrocracking .
The samples of zeolite Ni-Al-Si- th catalysts have been studied using EM techniques and X-ray DTA .

The pore volume, the effective average pore size and surface area of the synthesized zeolite Ni-Al-Si- catalyst are of 0.65 cm3 / g, 85 Å and 200 m2 / g , respectively, versus 0.42 cm3 / g, and 55 Å 300 m2 / g for the basic zeolite Ni-Al-Si- th catalyst.

3 Results and discussion

It was established that the modification of the porous structure of the zeolite-containing Ni-Al-Si- catalyst increases the dispersibility of the nickel in the range of 22-70 Å versus 60-210 Å and leads to a significant reduction of coke deposition (~ 3 -less) and therefore allows to get the light hydrocracking catalyst, keeping the stable activity after prolonged use. The catalyst activity is increased.

The difractograms reflect the significant decrease of height of the peak which corresponds both to metal nickel and nickel sulfide after recovery and regeneration, comparing to the parent sample . This indicates that the metallic nickel therein is in a higher dispersed state as compared to the initial sample .

Keywords: methylation, dimethyl carbonate, catalysts, tungsten, cobalt, manganese

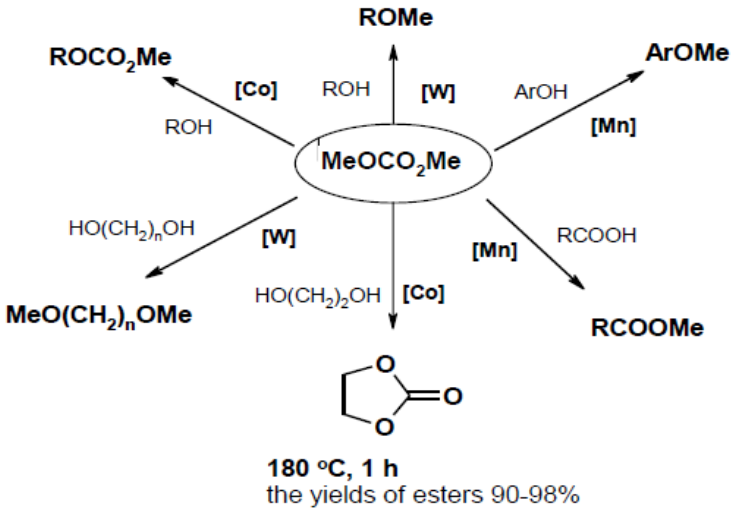
1 Introduction

According to the literature data, the stoichiometric amounts of Al2O3, MgO, K2CO3 and KF/Al2O3 were used to promote the methylation reaction of alcohols, phenols and acids with reagent «green chemistry» dimethyl carbonate (DMC) [1−5]. The methylation required harsh conditions (200−250 oC) and proceeded non-selectively; therefore it has not been of preparative interest.

2 Experimental/methodology

Herein we report compounds and complexes of tungsten, cobalt and manganese, which are effective catalysts for the methylation and carboxymethylation of alcohols, diols, and phenols, aliphatic and aromatic carboxylic acids with dimethyl carbonate (DMC). The reaction occurred in a stainless steel micro autoclave(V=17 ml) at 180 °C for one hour. The optimal ratio of the catalyst and the reactants was defined as [cat]: [ROH, ArOH, RCOOH]: [DMC] = 1−3:100:300−500, at which the yields of esters reached 90−98%.

3 Results and discussion



[Co] = $Co(acac)_2$, $Co(acac)_3$, $Co_2(CO)_8$; **[W]** = $W(CO)_6$;
[Mn] = $MnCl_2$, $Mn(OAc)_2$, $Mn(acac)_2$, $Mn_2(CO)_{10}$.

The best catalyst for methylation of alcohols and diols was W(CO)6. The methylation of phenols, aliphatic and aromatic carboxylic acids with DMC occurred in the presence of

compounds and complexes of manganese, namely, MnCl2, Mn(OAc)2, Mn(acac)3, and also Mn2(CO)10, which was the best. In the presence of Co2(CO)8, the carboxymethylation reaction of alcohols and diols with DMC was the major.

4 Conclusions

The advantages of homogeneous metal complex catalysts as compared to heterogeneous are the low consumption, shortening and quantitative yields.

Thus, as compared with the heterogeneous catalysts, the metal complex catalysts developed for the methylation of alcohols, diols, phenols and carboxylic acids, using DMC have a number of advantages: high reaction selectivity, shortening of the reaction, low catalyst consumption and the high yield of methyl esters.

Keywords: photocatalysis, nanoparticles, TiO_2, propane oxidation, UV light, selectivity

1 Introduction

The development of a selective direct route for partial oxidation of propane is of major industrial importance, as it would allow for an efficient use of this ubiquitous feedstock in important large-scale applications such as the area of polymer synthesis. Regarding the development of catalysts to affect such reactions, many of the reported approaches rely on thermal activation at elevated temperature. Photocatalysis at ambient temperature is a smart alternative for the conventional oxidation route. TiO_2 is a large-bandgap semiconductor with high photocatalytic activity. Extensive research eff$_2$orts have been reported to modify the properties of TiO_2 for selective photocatalysis applications [1]. Significant improvements in activity have been achieved by reducing the crystallite size, for example by impregnation of TiO_2 precursors on mesoporous materials such as MCM-41 [2], and SBA-15 [3]. The current study concerns the use of TUD-1, a form of mesoporous amorphous silica in which the physical and chemical properties of which can be systematically tuned during synthesis, as a support for TiO_2 nanoparticles. TiO_2 embedded in TUD-1 are shown to be more selective for propane oxidation than commercial TiO_2. It will also be demonstrated that the size tuning of TiO_2 nano-crystals in the range of 3-8 nm has a significant effect on the performance. Moreover, the effect of the illumination wavelength is discussed, which can be used to activate either isolated titanium sites Ti^{4+}, or the nano-particles of TiO_2. Finally, it will be presented that addition of small amount of Cr^{6+} (less than 1%) to TiO_2-TUD-1 influence the photocatalytic performance and the synergy between Cr^{6+} ions and TiO_2 nanoparticles will be discussed.

2 Experimental

One batch of TiO_2-TUD-1 with a Si/Ti ratio of 2.5 (Ti-40) was synthesized by the surfactant-free procedure described earlier [4]. After drying, the solid Ti-40 sample was divided into 4 equal amounts, which were hydrothermally treated in a Teflon-lined stainless steel autoclave to 450 K (at 5 K/min.) and incubated for different times (8-24 hours). Finally the samples were calcined at 873 K (1 K/min.) for 10 hours in air. The samples were labeled as Ti-40-xh, where x = the heating time in hours. One additional sample was prepared with the same Ti loading in addition to 1wt% of Cr^{6+}. The prepared samples were characterized by means of XRD, UV-Vis, elemental analysis, HR-TEM, and N_2 physisorption. The photocatalytic performance was evaluated in a high vacuum stainless steel cell with CaF_2 windows that allowed for simultaneous ultraviolet-light irradiation and FTIR spectroscopy in transmission. Ultraviolet light was obtained from a 200 W Hg-Xe arc, the excitation frequency was selected by means of a grating monochromator (single for photochemistry, bandpass 15 nm). The samples wafers were edge-supported in a copper sample holder incorporating a resistive heater and type K thermocouples. The cell was then loaded with 2.8 mbar of propane gas and 400 mbar of molecular oxygen (1 propane: 140 oxygen) and held at 300 K. The infrared spectra

of adsorbed species were monitored in-situ by an FTIR spectrophotometer.

3 Results and discussion

The diffuse-reflectance UV-VIS spectra of all the samples were similar. Two absorption maxima were resolved, centered at 220 nm (corresponds to isolated Ti^{4+} centres) and 330 nm (associated with solid TiO_2 particles). Morphological differences between the samples were evident from the N_2 sorption isotherms. All of the isotherms are of Type IV – an indication of meso-porosity. A quantitative analysis of these isotherms yields the specific surface area, pore volume, and pore size distribution (Figure 1). It was proposed previously [5] that TiO_2 nano-particles grow within the pores of the TUD-1 matrix. Therefore, tuning the pore size should influence the size of the TiO_2 inclusions. This is confirmed by HR-TEM images of the prepared samples.

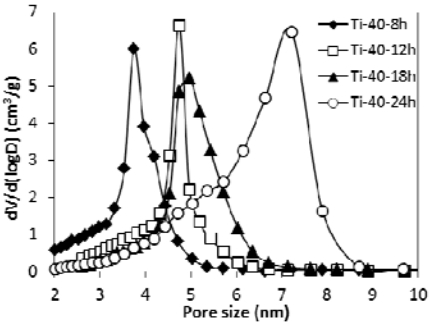

Fig.1. The pore size distrubution of the different Ti-40 samples.

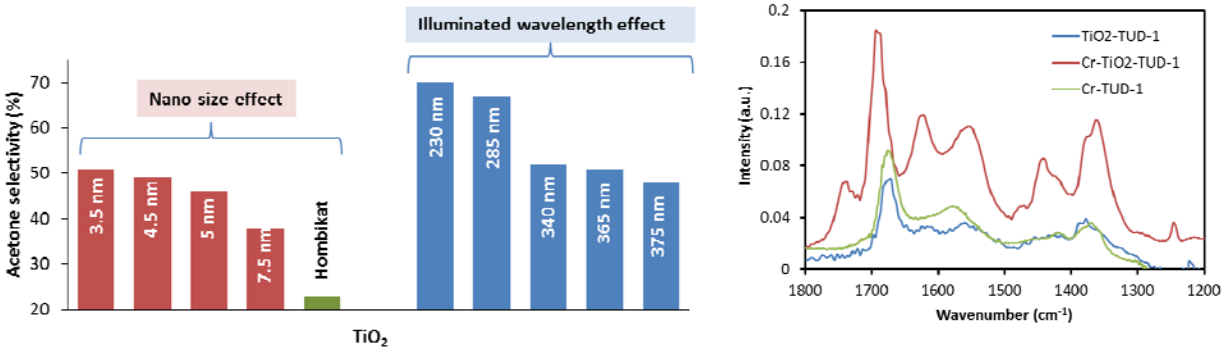

Fig. 2. Left panel: The acetone selectivity (%) obtained after 100minutes'reaction. Right Panel: The spectra of TiO_2-TUD-1 compared with Cr-TUD-1 and Cr-TiO_2-TUD-1 after 100 minutes' reaction.

A useful assay of photo-catalytic performance is the oxidation of propane to acetone (desired), carboxylates (undesired) and water. The prepared samples were evaluated under identical conditions, with 60 mW/ cm^2 of excitation at an ultraviolet wavelength of 335 nm. The total amount of products and the acetone selectivity were different. The initial reaction rates of Ti-40-12h, -18h, and -24h samples are identical and significantly greater than Ti-40-8h sample (3.5 nm). However, Ti-40-24h sample approached saturation faster than Ti-40-12h and -18h samples. For the smaller particles (i.e. Ti-40-8h) a slower rate is observed, but this rate is maintained over a prolonged period of time (i.e. up to 600 minutes). Acetone selectivity was decreased as a function of time (Figure 2) as a result of the over-oxidation reactions. The rate of the over-oxidation reaction over the Ti-40 samples is indeed different, acetone selectivity decreases slowly over a long time (600 minute) than the other samples, which decreased sharply in the first 200 minutes of the reaction in the other samples. Cr-TiO_2-TUD-1 showed a true synergy between Cr^{6+} and TiO_2 (Figure 2). The results will be dissected in details during the presentation.

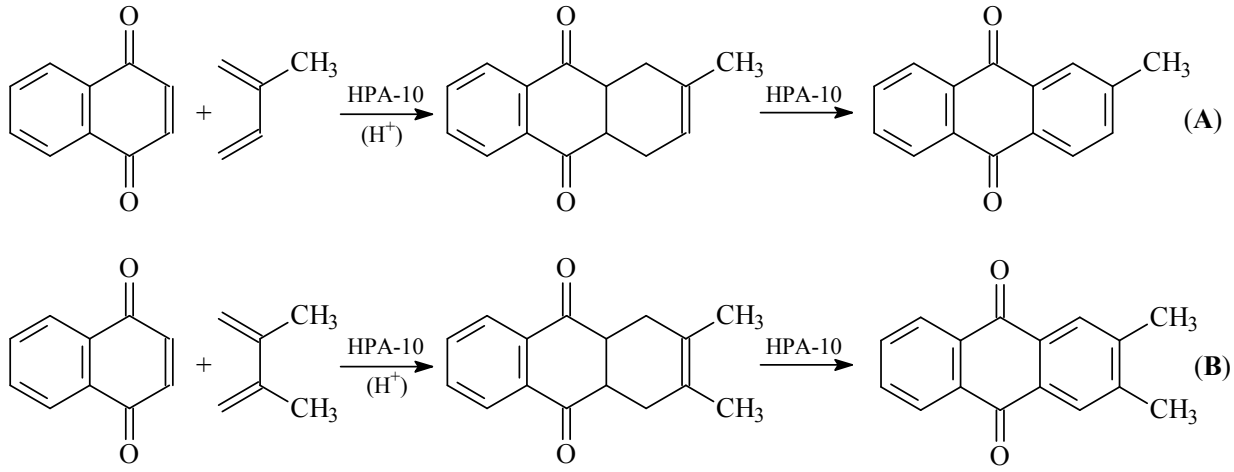
Keywords: substituted, anthraquinones, heteropoly, acid, catalyst, regeneration, multicycle, testing

1 Introduction

9,10-Anthraquinone (AQ) and its derivatives are the valuable products of organic synthesis. They are used in the production of dyes, hydrogen peroxide, and medical preparations and as catalysts for wood delignification [1].

Early [2-3] we developed one-pot processes for the preparation of substituted anthraquinones via diene synthesis in the presence of heteropoly acid $H_{17}P_3Mo_{16}V_{10}O_{89}$ (HPA-10) as a bifunctional catalyst, i.e., acidic catalyst for diene synthesis and catalyst for the oxidation of the obtained adduct. One-pot processes for the syntheses of 2-methylanthraquinone (2-MAQ) and 2,3-dimethylanthraquinone (2,3-DMAQ) are shown in schemes **A** and **B**.



2 Experimental

In the present work, we investigated the possibility of multicycle catalyst performance. In addition to the traditional regeneration of HPA-10 solution at temperatures 160−170 °C and PO_2 = 3−4 atm [4], we tested the feasibility of substituting low concentrations of nitric acid for the same purpose. Methods for regeneration of the catalyst were alternated (see Tables below).

Experimental data were obtained for two processes:

1) 2-methylanthraquinone (2-MAQ) synthesis from NQ and isoprene; and

2) 2,3-dimethylanthraquinone (2,3-ДМАQ) synthesis from NQ and 2,3-dimethyl-butadiene.

3 Results and discussion

Experimental results are presented in Tables 1 and 2.

Table 1. Multicycle synthesis of 2-MAQ via isoprene reaction with NQ in the presence of aqueous HPA-10.

Cycle Number	*E* of aqueous HPA-10 before reaction (1), V	2-MAQ yield, %	2-MAQ purity, %	Catalyst regeneration method
1	1.098	74	97	160 °C, PO_2=4 atm, 15 min
2	1.066	70	97	150 °C, PO_2=4 atm, 20 min
3	1.064	69	97	Boiling with 0.15 ml of concentrated HNO_3, 30 min
4	1.102	73	97	Boiling with 0.15 ml of concentrated HNO_3, 30 min
5	1.099	72.5	97	160 °C, PO_2=4 atm, 15 min
6	1.068	68	97	Boiling with 0.2 ml of concentrated HNO_3, 30 min
7	1.100	74	97	160 °C, PO_2=4 atm, 15 min

Table 2. Multicycle synthesis of 2,3-dimethylanthraquinone via NQ reaction with 2,3-dimethylbutadiene catalyzed by the HPA-10 solution.

Cycle Number	*E* of aqueous HPA-10 before reaction (1), V	2,3-DMAQ yield, %	2,3-DMAQ purity, %	Catalyst regeneration method
1	1.098	81	98	150 °C, PO_2=4 atm, 20 min
2	1.063	77	98	160 °C, PO_2=4 atm, 15 min
3	1.066	77	97.5	Boiling with 0.15 ml of concentrated HNO_3, 30 min
4	1.101	80.5	98	Boiling with 0.15 ml of concentrated HNO_3, 30 min
5	1.097	80	98.5	160 °C, PO_2=4 atm, 15 min
6	1.063	77	98	Boiling with 0.2 ml of concentrated HNO_3, 30 min
7	1.104	81	98	160 °C, PO_2=4 atm, 15 min

Conditions: 80 °C, 4 ml of 0.2 M HPA-10 solution, molar ratio HPA-10:NQ 0.5:1, volume ratio HPA solution:1,4-dioxane 1:1; 7 h; NQ conversion was ≥ 99.5%. *E* value is given with respect to NHE.

Analyzing the data of Tables 1 and 2, we concluded that 0.2 M HPA-10 solution with high stability performed as a bifunctional catalyst in the MAQ and **DMAQ** synthesis over 7 cycles, resulting in a product with 68-81 % yield and 97-98 % purity. HNO_3 apparently provided a more complete oxidation of reduced HPA-10 (i.e., which resulted in a higher *E* before the next cycle) than the regeneration by O_2 in an autoclave. After the regeneration using nitric acid, the oxidative capacity of the catalyst remained essentially the same as in the first cycle because after regeneration, the *E* values were close to that of the fresh HPA-10 solution used in the first cycle.

4 Conclusions

The HPA-10 solution remained homogeneous during all cycles, retained its productivity and gave no V-containing precipitates. The target products obtained with fresh and regenerated HPA-10 solutions were shown by comparison their IR-spectra to be identical. All side products remaining in the aqueous catalyst solutions after target reactions were completely oxidized to carbon dioxide and water in the course of regeneration. The complete recovery of the properties of the bifunctional catalyst after regeneration shows its technological usefulness.

Keywords: cellulose, hemicellulose, polyoxometalate, ruthenium, cesium, bifunctional catalysis

1 Introduction

Sorbitol and xylitol are valuable chemicals used, for example, in pharmaceuticals and food industry as sweeteners, which currently are produced from starch by biotechnical or catalytic methods. One-pot hydrolytic hydrogenation methods of formation of these polyols utilizing inedible polysaccharides like cellulose and hemicelluloses which are the components of lignocellulose biomass were developed many years ago [1]. However these methods are not widely used because of soluble mineral acids (catalysts of the hydrolysis) possessing corrosive effects.

Two sequential catalytic steps (hydrolysis and reduction) must be applied to obtain polyols from polysaccharides. Acidic catalyst must be applied for hydrolysis of polysaccharides to get sugars (glucose, xylose etc.). Reduction of monosaccharides to polyols proceeds over noble metals like ruthenium. Heteropoly acids (HPAs) and cesium salts of HPA have acidic catalytic centers. Thus bifunctional catalyst Ru/CsHPA having acidic and reductive centers could be proposed for polyols production using one-pot process of hydrolytic reduction of natural polymers like cellulose and hemicelluloses under soft conditions. HPAs are also known as catalysts for “green chemistry” because they are safety for environment.

The aim of the study was the development of the bifunctional ruthenium catalysts supported on the cesium salts of the heteropoly acids for the one-pot polysaccharides conversion to valuable polyols like sorbitol and xylitol.

2 Experimental

CsHPA salts were synthesized by mixing solutions of Cs_2CO_3 and respective HPA: $Cs_XH_{3-X}PW_{12}O_{40}$, $Cs_XH_{3-X}PMo_{12}O_{40}$ (x = 1.0, 1.5, 2.0, 2.5), $H_4PMo_{11}VO_{40}$, $H_4SiW_{12}O_{40}$ (x = 2.0, 2.5, 3.0 и 3.5). Ru/C and Ru/CsHPA were prepared via impregnation the support by Ru precursor $Ru(NO)(NO_3)_3$. The catalysts was characterized investigated by IR spectroscopy, N_2 absorption, XRD, AES-ICP, TEM (for Ru-containing samples only) and tasted in one-pot hydrolytic hydration of xylan and mechanically activated crystalline cellulose. The reaction was performed in the autoclave under hydrothermal conditions of 180 °C under Ar or H_2. The concentrations of products were measured by HPLC.

3 Results and discussion

IR spectroscopy and XRD of HPAs and CsPHAs show no changes of heteropoly anion structures before and after precipitation, that indicates the stability of HPA anion during catalyst preparation. According N_2 absorption data the surface area and Cs content increase simuteneously, and CsHPAs have a microporous structure. TEM analysis of Ru/C catalysts shows that ruthenium nanoparticles have average size equal to 2 nm for all the samples.

Preliminary oxidation of the carbon support by wet air increases the dispersion of Ru.

The investigations of stability of all CsHPAs under hydrothermal conditions show that solubility of salts decreases while Cs content increases. Cs salts of P-Mo-V HPA are unstable (solubilisation is 70 w/w%). $Cs_XH_{3-X}PW_{12}O_{40}$ (X - 2, 2.5) and $Cs_XH_{4-X}SiW_{12}O_{40}$ (X - 3, 3.5) are stable sufficiently for Ru to be impregnated.

At first, the most promising CsHPAs have been tested as the acid catalysts for the hydrolysis of cellulose under Ar. $Cs_XH_{3-X}PW_{12}O_{40}$ (X - 2, 2.5) and $Cs_XH_{4-X}SiW_{12}O_{40}$ (X - 3, 3.5) are shown to be the most active in the cellulose hydrolysis. The $Cs_3HSiW_{12}O_{40}$ reveals the highest activity.

The one-pot hydrolytic hydrogenation experiments with the most perspective CsHPA salt ($Cs_3HSiW_{12}O_{40}$) and 3%Ru/C have been performed to reveal the importance of acid and metal catalytic centres in the hydrolytic hydrogenation. $Cs_3HSiW_{12}O_{40}$ and 3%Ru/C tested separately do not show activity in hydrolytic hydrogenation of cellulose. While combination of these catalysts allows producing the sorbitol with the maximum yield 14.3%. Utilization of the bifunctional catalysts containing Ru nanoparticles supported on CsHPA: 3%Ru/$Cs_2HPW_{12}O_{40}$ and 3%Ru/$Cs_3HSiW_{12}O_{40}$ gives sorbitol with high yields (60-62%**)** and selectivity up to 88% (Table 1). Beside, the low yields of glucose, 5-HMF and mannitol were detected. These products are formed via another pathway of glucose reduction.

The hydrolytic hydrogenation of xylan to xylitol over Ru/CsHPAs has also been made to show the possibility of hemicelluloses transformations to polyols over such catalysts. The yield of xylite is also very high up to 70% (Table 1).

Table 1. Yields of the products of the cellulose hydrolytic hydrogenation. Reaction conditions: cellulose (*xylan*) 450 mg, catalyst 450 mg, V 45 mL, T 180 ºC, P_{H2} 7 MPa. * - xylan has been used as a substrate.

Catalyst	Y_{Σ}, %	t, h	Sorbitol/*Xylitol*		Mannitol/ *Lixytol*		Glucose/ *Xylose*		5-HMF	
			S, %	Y,%	S, %	Y,%	S,%	Y,%	S,%	Y,%
$Cs_3HSiW_{12}O_{40}$	19.9	2	0.0	0.0	0.0	0.0	72.4	14.4	21.1	4.2
3% Ru/C	9.1	2	8.8	0.8	38.5	3.5	5.5	0.5	39.6	3.6
3%Ru/C-$Cs_3HSiW_{12}O_{40}$	25.3	2	56.5	14.3	19.4	4.9	10.7	2.7	7.9	2.0
3%Ru/$Cs_2HPW_{12}O_{40}$	58.3	3	86.6	50.5	11.0	6.4	2.4	1.4	0.0	0.0
3%Ru/$Cs_3HSiW_{12}O_{40}$	70.7	5	87.8	62.1	6.4	4.5	1.4	1.0	3.4	2.6
*3%Ru/$Cs_2HPW_{12}O_{40}$	68.1	3	90.0	60.6	9.4	6.4	3.5	2.4	0.0	0.0
*3%Ru/$Cs_3HSiW_{12}O_{40}$	96.8	2	69.6	67.4	18.0	12.5	13.1	12.7	3.8	3.7

4 Conclusions

Cs salts of HPAs with different HPA structures and Cs content as well as Ru catalysts supported on carbon and CsHPAs were prepared. All the catalysts were characterized by the different analytical methods and tested for the stability in the hydrothermal conditions. The synthesized bifunctional Ru/CsHPA catalysts (where HPA was $Cs_2HPW_{12}O_{40}$ and $Cs_3HSiW_{12}O_{40}$) showed very high stability, activity and selectivity in the one-pot hydrolitic hydrogenation of polysaccharides (cellulose and xylan). High yields of sorbitol or xylitol up to 60 and 70% respectively were archived.

Keywords: cellulose, sibunit, oxidation, sulfonation, hydrolysis, 5-hydroximethylfurfural

1 Introduction

5-Hydroxymethylfurfural (5-HMF) is one of the most promising bio-based chemicals so-called "platform molecules". It could be used as a raw material in the production of food additives, plastics, pharmaceutics and biofuels [1]. 5-HMF is usually produced from starch and sucrose in the presence of enzymes or soluble mineral acids as a catalysts [2]. Utilization of an inedible cellulose as an alternative raw material, non-corrosive solid acid catalysts and one-pot design of the process could help to overcome the drawbacks of 5-HMF production methods. The carbon materials seem to be promising catalysts for cellulose depolymerization into valuable chemicals [3].

The aim of this work was a development of the solid acid catalysts based on graphite-like carbon Sibunit for the production of 5-HMF and glucose from cellulose and a elucidation of the mechanism of the catalytic action.

2 Experimental/methodology

The catalysts were prepared using sulfonation, oxidation and subsequent oxidation-sulfonation methods. The samples of sulfonatied Sibunit were made via treatment of carbon in fuming H_2SO_4 at 80-250 °C; the oxidized carbons were produced via oxidation by HNO_3 or wet air; oxidized-sulfonated catalysts were prepared form oxidized carbons by additional sulfonation at 200 °C. The catalysts were characterized by low-temperature N_2 absorption and titration with NaOH and tested in the one-pot hydrolysis-dehydration of a mechanically activated cellulose under hydrothermal conditions at 180 °C and 10 atm of Ar. The concentrations of products were measured by HPLC.

3 Results and discussion

Investigation of the prepared carbon catalysts by N_2 absorption shows that all the treatments lead to formation of the acidic species on the surface and simultaneous partial destroy of the carbon structure. However the sulfonation of Sibunit at the temperature above 200 °C was found to give considerable destruction of material, while the structural properties were not essentially changed at the temperatures less 200 °C. The amount of acidic groups on the surface of sulfonated carbon determined by titration increased with the increasing of the sulfonation temperature. The total amount of acidic species for the sulfonated carbons was 3-15 times higher than for the initial Sibunit. The maximal amounts were reached at the sulfonation temperatures 200 and 250 °C (1.0 and 2.7 mM/m^2). The total amount of acidic species for the oxidized samples was close and for oxidized-sulfonated ones 1.5-2 times higher than for the Sibunit sulfonated at 200 °C.

Catalytic tests of carbons showed high activity of sulfonated carbon catalysts in the cellulose hydrolysis-dehydration process. While pure carbon without sulfonate species was inactive.

HPLC analysis revealed glucose and 5-HMF as the main products. Moreover an accumulation of small amounts of cellobiose, mannose, fructose, levulinic and formic acids was detected. The maximum glucose and 5-HMF yields were reached over Sibunit sulfonated at 200 °C (46.0% and 21.5%, respectively). Oxidized and oxidized-sulfonated samples possessed the activity comparable to the activity of the catalysts sulfonated at 150 and 200 °C. The yields of 5-HMF and glucose were in the ranges of 17-20% and 28-42%, respectively. No difference in activity of oxidized and oxidized-sulfonated carbons was registered in spite of the total amount of surface species were different.

For elucidation of the mechanism of catalytic action and the role of catalysts the experiments with such intermediates as cellobiose, glucose, fructose and 5-HMF were carried out. Beside, a kinetics of substrate, intermediates and products in the presence of diluted H_2SO_4 as a catalyst and lower loading of the carbon catalyst were registered. The heterogeneous mechanism of the cellulose depolymerization was supposed base on the results of these experiments. The dissolving cellulose appeared to be a limiting step of the process while hydrolysis is the fast reaction. Rearrangement of glucose to fructose was also slow reaction. The irreversible dehydration of fructose was the most rapid step. Moreover there were different ways of glucose transformations (except glucose↔fructose→5-HMF).

Table 1. Yields of products in the cellulose hydrolysis-dehydration over carbon catalysts. Experiment conditions: cellulose 450 mg, catalyst 450 mg, volume 45 mL, stirring 1500 rpm, 180 °C, 1 MPa Ar.

4 Conclusions

The availability of 5-HMF and glucose production from cellulose with quite high yields using one-pot catalytic process of hydrolysis-dehydration over sulfonated and oxidized samples of graphite-like carabon Sibunit was shown. The sample of carbon treated by fuming H_2SO_4 at 200 °C seems to be very promising one. The kinetic study allowed to evaluate rate limiting stapes and suggest reaction pathways and the mechanism of catalytic action.

Keywords: macroinitiator, polyaddition reaction, diisocyanate, polyhedral, oligosilsesquioxane

1 Introduction

The influence of reaction conditions on the mechanism of 2,4-toluene diisocyanate (TDI) polyaddition to anionic macroinitiator, which is a block copolymer of propylene oxide and ethylene (PPEG), part of the hydroxyl groups substituted on potassium alcoholate, was studied,. The relevance of this work is the fact that this reaction is the basis of obtaining polymer film nanoporous materials.

In this research was used octaglycidyl polyhedral oligosilsesquioxane (gl-POSS). The role of POSS as stabilizers of active terminal polyisocyanate units which formed during the opening N=C bond and the formation of the linear N-substituted polyisocyanates (N-polyisocyanates) was studied. This effect was specified for wide range of epoxy-POSS concentration.

3 Experimental/methodology

Block copolymers of propylene oxide with ethylene oxide of the formulas $HO[CH_2CH_2O]_n[CH_2(CH_3)CH_2O]_m[CH_2CH_2O]_nOK$ where n ≈ 14, m ≈ 48, and the potassium alcoholat group content is 10.9% of the total number of functional groups (PPEG-4202) were synthesized as macroinitiators. The monomer was 2,4-toluene diisocyanate (TDI).

To create a branch nodes and stabilization of the end of the active centers of the polymer polyaddition were used octaglycidyl polyhedral oligosilsesquioxane (EP0409 glycidyl-POSS Cage Mixture, Hybrid Plastics).

The reaction medium for the synthesis of block copolymers was toluene, acetone or ethylacetate.

The macroinitiators were preliminarily dried via vacuuming at 90–100°C and a residual pressure of 0.07 kPa for 4 h. 2,4-toluylene diisocyanate was purified via vacuum distillation under a residual pressureof 0.07 kPa. The remaining reagents were purified and dried according to conventional procedures.

The syntheses of polymers from PPEG-4202, Gl-POSS and TDI were conducted on toluene, ethyl acetate, or acetone. A calculated amount of the isocyanate was introduced into a macroinitiator solution at 25°C under stirring. The reaction was conducted at 45°C under continuous stirring for 30 min. The total amount of there actants in the solution was 25%. The resulting solution of the polymer-forming system was cast into Petri dishes. Polymer film samples were formed at room temperature.

3 Results and discussion

Based on the structure of the isocyanate group, considering the existence of two types of linear polyisocyanate homopolymers, which may occur as a result of breaking the bonds N=C or C=O. In the first case the structure of the macromolecular chain has an N-substituted polyamide (N-polyisocyanates) structure, in the second - the structure of polyacetal (O polyisocyanates). It is known that in the absence of active centers stabilizers N-polyisocyanates cyclized to

isocyanurates (hexagons).

It was shown that the nature of the solvent, the presence of acidic compounds, ambient temperature and concentration of reactants influence on reaction path between TDI and PPEG. Thus, predominant formation of O-polyisocyanate units is observed when ethyl acetate containing a catalytic amount of acetic acid used as the reaction medium. If toluene or acetone used as a solvent, is completely consumed for TDI cyclization processes. When gl-POSS used as stabilizers and crosslinking compounds reaction is accompanied by the formation of N-polyisocyanate blocks.

The effective constants of reaction and activation energies were deduced. It is shown that the activation energy of O-polyisocyanates formation reaction is more than 80 kJ / mol, the activation energy of N- polyisocyanates formation reaction is 32 kJ / mol, and cyclization activation energy is 180 kJ / mol. These findings are consistent with published data and confirm the proposed reaction mechanisms of TDI.

4 Conclusions

The mechanism of disclosure of TDI isocyanate groups exposed anionic macroinitiators by using of acidic cocatalysts and polyhedral oligomeric silsesquioxanes was studied. The preferential formation of O-polyisocyanate blocks via using catalytic amounts of acetic acid was shown. Using the gl-POSS reaction is accompanied by the formation of N-polyisocyanate blocks. The kinetic parameters of the reactions were deduced.

Keywords: zeolites, butanol, dehydration, dealumination, butenes

1 Introduction

The increasing commercial production of bio-butanol makes it an interesting and emerging bio-based building block in view of the depletion and increasing costs of fossil feedstocks for the synthesis of butenes (through dehydration) that are widely used in polymers, oxygenated additives and rubbers... The dehydration of alcohols can be catalysed by acid sites, of which zeolites are the most promising. Shape selective effects of zeolites can give rise to high yields of butene isomers compared to other types of catalysts and differences in selectivity are found with the use of various zeolites. A lot of literature is available on ethanol dehydration over zeolites, whereas the research on butanol dehydration is still in its infancy[1,2].

2 Experimental/methodology

In this work, butanol dehydration was studied in a high throughput setup on the different zeolites (parent and acid treated samples) to determine the effect on the characteristics and reaction kinetics. Acid treatment is a common technique to dealuminate the zeolite lattice and remove non-framework alumina without the loss of zeolite type characteristics and to create mesopores[3,4]. Two different types of zeolites where chosen to compare the effects of zeolite topology as well.

Commercial zeolites (Zeolyst) were provided in ammonium form and were preliminary calcined at 550K for 8 hours to convert into the acid form. To investigate the effect of dealumination two different concentrations of hydrogen chloride were chosen keeping all other reaction conditions constant. 1.5 grams of zeolite were suspended in 150 ml of HCl solution of either 1M or 0.1M HCl concentration. The suspension was heated and stirred at 350 rpm until boiling point and kept under reflux during 2 hours. Afterwards the suspension was filtered and washed with deionised water until neutral pH and dried at 125°C.

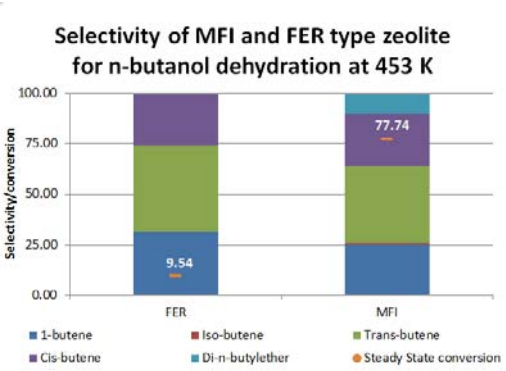
The assessment of the catalysts was performed in a high throughput setup equipped with 2 tubular reactors, under typical dehydration conditions. The catalyst was diluted with inert to ensure isothermicity of the catalyst bed. The feed consisted of n-butanol (Sigma Aldrich (99,4% pure)) and nitrogen (Air Liquide) as inert carrier. The product analysis is performed with a GC equipped with an FID-detector and PONA column. As internal standard methane is used. To fully understand the effect of the treatments a broad range of site times was tested under the same ?thermal? conditions. This approach provides an accurate investigation of the effect of the mesoporosity and acid strength without being influenced by the number of acid sites.

3 Results and discussion

All used catalysts were fully characterized by means of: NH_3-TPD, XRD, ICP, SEM/EDX and N_2 adsorption. A summary of these characteristics is given in table 1.

Table 1. Characteristics of tested zeolites for n-butanol dehydration

Sample	Si/Al_{bulk}	$Si/Al_{surface}$	$Conc_{brönsted}$ (mmol/g)	S_{Int} (m^2/g)	S_{ext} (m^2/g)	V_{Micro} (cm^3/g)	V_{tot} (cm^3/g)
MFI	16.4	17.34	0.36	376.4	123.5	0.114	0.255
MFI0.1	29	39.9	0.31	361.4	127.2	0.124	0.278
MFI1.0	26.5	21.7	0.33	392.1	193.1	0.132	0.308
FER	10	15	0.41	322.5	40.5	0.132	0.245



First dehydration tests on the non acid-treated commercial samples of MFI and FER show a difference in selectivities and conversion due to a difference in zeolite topology. Other characteristics were similar such as the Brönsted acid density and pore volumes. Both zeolites were tested under same site times (3.5 $mol.s/mol_{n\text{-}BuOH,o}$) at same reaction temperatures (160°C and $P_{n\text{-}BuOH,0}$: 15 kPa) and results are given in Figure 1.

4 Conclusions

In search to improve the stability, activity and selectivity of zeolite topologies for the dehydration reaction of n-butanol to butenes, the effects of dealumination of two types of zeolites were investigated. Treatment of the zeolites at two different concentrations of hydrogen chloride results in an increase in silica to alumina ratio due to the removal of framework and non-framework alumina. This also results in a slightly higher mesoporous material with higher specific area. When the acid concentrations reaches 1 M HCl we see a lower Si/Al ratio than for the treatment at lower concentrations. This could imply that not only aluminium is removed from the lattice but also silica. These improvements can result in higher resistance to deactivation caused by coke formation. Also effects in selectivity can be found due to changes in acidity strength and density.

Also noticeable differences are found with the change of zeolite topology regardless of the treatment. This supports the statement that structural differences in the zeolite lattices can be exploited to influence the activity and selectivities of n-butanol dehydration.

Keywords: oxidation, catalytic cracking, zeolite catalyst, thermal analysis

1 Introduction:

One of the most accessible directions of work intensification of catalytic cracking is to maintain a process in unconventional conditions – to existents of oxygen (Oxycracking) [1,2]. During researches [1,3] was found that the presence of an optimum amounts of oxygen increases the yield of light products from cracking products, in comparison with the traditional mode of carrying out the process, studied the effect the oxidative nature of the medium on the distribution of cracking products and the degree of conversion of raw materials. It's obviously that in evaluating the efficiency of oxidative catalytic cracking is a problem of deactivation of the catalyst.

This work is a continuation of these studies. It using thermal analysis studied the dynamics of accumulation and features of the formation of surface condensation products (CP) in condition oxidative catalytic cracking.

2 Experimental/methodology:

The proses of oxidative catalytic cracking was carried out in a flow reactor with a fixed bed industrial catalytic cracking zeolite catalyst OMNIKAT-340 at temperature 500ºC, atmospheric pressure, and volumetric velocity of feed 2 h^{-1}. The air supply to the reaction zone was 0.5% for raw materials. As a raw materials used vacuum qas oil (s.b.270 ° C – e.b.500°C).

The thermal behavior of zeolite-containing catalyst samples were studied by thermogravimetric and differential thermal analysis (TGA-DTA) installation for CD STA 429 company NETZSCH. For analysis was selected linearly linearly-polythermal heating the sample at a heating rate of 10°C /min in air´s atmosphere.

3 Results and discussion:

To determine the dynamics of coke deposits in the catalytic cracking of oxidative studies conducted derivatografic zeolite catalyst samples which differed in the length of time that the reaction medium: 15, 30, 45, 60 minutes (samples 1-4). For comparative analysis thermogram sample was removed for 15 minutes participating in the catalytic cracking process that use by traditional non oxidizing conditions (sample 5).

Discussing and analyzing the results, we can note the following:

- for all five samples in the temperature range of 25-310°C is characterized by a broad endothermic effect associated with the removal of the adsorbed pore water, accompanied by significant weight loss (5,5-15%). It should be noted that the minimum value of this index was noted for sample 5;
- on the differential curves of samples 1 to 4, after the removal of moisture, there are two exothermic peaks with maxima at 398 ... 407 ° C and 485 ... 504°C and the mass loss was 2.5-4 respectively and 10.5-12.5%. Noteworthy is that in contrast to the sample 1, the sample 5, which one the length of stay is a traditional non-oxidizing environment of

the reaction was 15 also minutes, characterized by single exothermic peak, whose maximum temperature is higher than the average of 40-125°C and reaches 525.5°C, which indicates a more condensed nature CP;

- analysis of the samples 2 and 3 indicates that part of the catalyst in the process during oxycracking within 15-45 minutes leads to a gradual increase in the degree of condensation and the number of CP. It specifies the offset of the two previously mentioned intense exothermic effects at higher temperatures pronounced total mass loss - up to 15-16.3 %. While the temperature maxima remained virtually unchanged;
- the highest number of CP contained is in the sample 4, which is explained by significantly longer cycle of his work in terms oxycracking (60 min). The degree of condensation of the CP it is very high, as evidenced by the end of their combustion temperature - 814.6°C. Despite the fact that the total weight loss of samples 2 and 4 have similar meanings, but CP formed on the surface of the former is less condensed, as evidenced by the lower end of their combustion temperature (624.7°C).

4 Conclusions:

Thus, our studies revealed distinct nature of CP, formed in the course of the traditional non-oxidative and oxidative catalytic cracking. Oxidative cracking of vacuum gas oil for 45 minutes formed two distinct phases surface CP: 1 - deposition of an amorphous type with a high hydrogen content; 2 - low coke density. Deleting the CP data observed in the temperature range 574 ... 675°C, which is lower than the regeneration temperature range of the traditional catalysts for catalytic cracking and shows promising oxycracking. It was also found that increasing the catalyst mileage oxycracking 60 minutes resulting in the formation of highly surface and graphitized structures, over which the burning temperature of 800°C, far exceeding the stability limit temperature of zeolite catalysts.

Effect of the Physico-Chemical Characteristics of the Various Mn-Based Oxide Catalysts on the Catalytic H_2O_2 Decomposition

Choi H.-Y., Jang J.H., Han G.B.*

Institute for Advanced Engineering, Yongin, Republic of Korea

* gbhan@iae.re.kr

Keywords: catalytic H_2O_2 decomposition, Mn-based catalyst, reaction, conditions, physic-chemical characteristics, catalytic activity

1 Introduction

Hydrogen peroxide has been utilized as an oxidizing agent in the waste water disposal facilities for the environmental remediation such as the bleaching and deodorization in the industry. The steam, oxygen and heat energy, which can be utilized in industry and other field and the reactant is a non-toxic and an environment-friendly, can be generated by the decomposition of H_2O_2. For these merits, the catalytic decomposition of H_2O_2 has been researched in view of the effect of the various oxide-based catalysts on the performance. The various metal oxide catalysts were prepared for the catalytic H_2O_2 decomposition and the effect of their characteristics on the performance was investigated in this study. The catalytic activity was compared through the variation of the temperature, pressure and reaction duration time during the catalytic H_2O_2 decomposition.

2 Experimental/methodology

The various catalysts were prepared by co-precipitation method using zirconyl nitrate ($ZrO(NO_3)_2 \cdot xH_2O$), manganese chloride ($MnCl_2 \cdot 4H_2O$), iron hydroxide ($Fe(OH)_3$), aluminium oxide (r-Al_2O_3), etc. and ammonia water (NH_4OH) as the precursors, support and precipitate, respectively. In the preparation procedure, the solid material obtained after the co-precipitation process was dried for 12 hr at 110 °C and was calcined for 4hr at 600 °C. The performance test of the various prepared catalyst was conducted using both fixed and batch type reactor.

3 Result and discussion

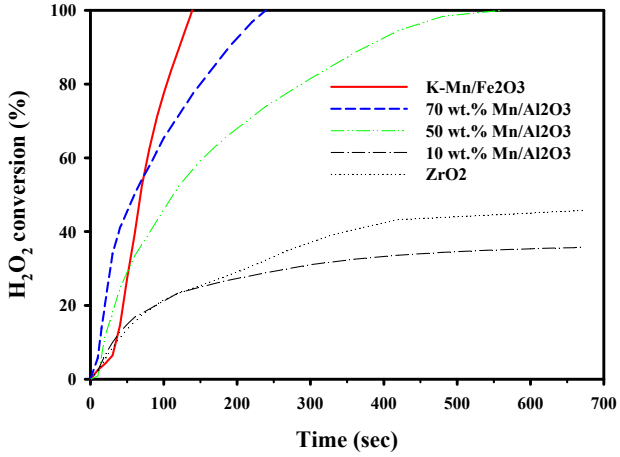

Fig. 1. H_2O_2 conversion in the catalytic H_2O_2 decomposition over Mn-based catalysts.

Fig. 1 shows the H_2O_2 conversion with the various catalysts in the catalytic H2O2 decomposition. The amount of catalyst and hydrogen peroxide were used 0.01 g and 40 ml, respectively. The conversion of H_2O_2 decomposed had a difference with the catalyst. The K-added Mn-based oxide catalyst had the highest activity with the reaction temperature and pressure among the various catalysts, simultaneously.

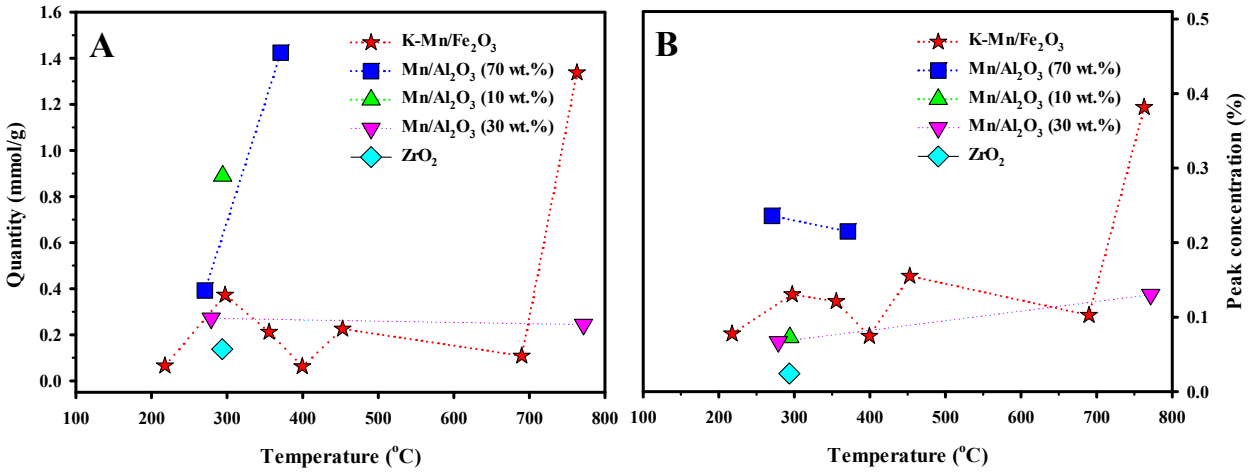

Fig. 2. Acidic properties of the various catalysts by NH_3-TPD.

Also, the physic-chemical properties of the catalysts were analyzed by SEM/EDX, XRD, XRF, NH_3-TPD. Fig. 2 shows the acidic properties with NH_3-TPD as a representative property of the various catalysts for the catalytic H_2O_2 decomposition. In this result, it was known that the strength and amount of the acidic sites of the various catalysts has an effect on the catalytic activity. Among the various catalysts, K-added Mn-based oxide catalyst had the most abundant acidic sites and strength and its activity was highest.

4 Conclusions

The relationship between the catalytic activity and the properties of the various catalysts for the catalytic H_2O_2 decomposition was investigated in this study. Consequently, it was known that the highest catalytic activity was obtained by using the K-added Mn-based oxide catalyst having the most abundant and strongest acidic sites in the catalytic H_2O_2 decomposition using the various catalysts.

Keywords: catalytic cracking heavy gasoil, ethylene, propylene, halloysite

1 Introduction

During the recent years the role of the catalytic cracking process assumes importance in the trend of obtaining the main feedstock to the polypropylene industry [1,2]. The investigations are carried out in most of the countries for increasing the yields of low molecular olefins, especially ethylene and propylene in the conducted deep catalytic cracking [3-6]. In the presented work has been investigated the thermocatalytic conversion process of heavy gasoil obtained from catalytic cracking process (CCHG) and its mixture with cotton oil at temperature range of 550-700°C.

2 Experimental/methodology

The catalytic conversion process of heavy gasoil and its mixture with 10% of cotton oil have been conducted in laboratory microdevice with the mass rate of 0,5-1 $hour^{-1}$ of feedstock supplying. Seokar-600 (I) and its mixture with halloysite (II) has been taken as a catalyst. The main catalyst has contained the amount of halloysite of 10% mas.

When the Seokar-600 /halloysite catalytic system is used the upper layer has been consisted of pure halloysites (approximately 5% of the height of catalyst layer), but the bottom layer of catalyst has been consisted of Seokar-600. The composition of hydrocarbon gas obtained from the catalytic cracking process of heavy gasoil and its mixture with cotton oil have been described in Table 1 and 2.

3 Results and discussion

Table 1. The hydrocrabons composition of gases obtained from the CCHG thermocatalytic conversion by using Seokar-600 (I) and its mixture with halloysite (II).

The composition of hydrocarbon gases,% wt.	**Catalysts**						
	I	**II**	**I**	**II**	**I**	**II**	**I**
	Temperature of process, °C						
	550		**600**		**650**		**700**
methane	1,4	1,8	3,2	4,0	7,6	7,2	7,8
ethane	1,0	0,9	1,2	1,4	2,0	1,4	2,1
ethylene	7,2	7,8	12,0	12,7	20,0	20,6	23,8
propane	1,9	2,1	0,95	1,1	1,4	1,2	1,6
propylene	11,8	12,4	14,6	15,3	14,7	15,2	17,1
butane	0,6	1,0	1,2	1,4	1,2	0,8	1,2
Σ butylenes	2,3	4,2	5,85	5,1	4,1	5,0	6,8
Total	26,2	30,2	39,0	41,0	51,0	51,4	60,4
Σolefin-	21,3	24,4	32,45	33,1	38,8	40,8	48,2

containing gases

The maximum yield of ethylene at 700°C in the presence of Seokar-600 and Seokar-600/halloysite mixture catalysts is accordingly of 23,8-24,4 %; but it is accordingly of 17,1-17,7 % mass in propylene. The increasing of the yield percent of olefins is observed when we add halloysite to the composition of Seokar-600 that used for all of the investigated temperatures.

The yield percent of either ethylene or propylene increases by increasing of temperature when vegetable oil of 10 % added to the composition of processed feedstock (Tabl.2).

Table 2. The composition of hydrocarbon gases obtained from the thermocatalytic conversion of CCHG fraction containing 10% vegetable oil by using Seokar-600 (I) and its mixture with halloysite (II)

The composition of hydrocarbon gases,% mass	**Catalysts**						
	I	**II**	**I**	**II**	**I**	**II**	**I**
	Temperature of process, °C						
	550		**600**		**650**		**700**
methane	1,4	2,0	3,6	4,1	7,8	8,2	8,4
ethane	1,0	1,1	1,5	1,2	2,3	1,6	2,3
ethylene	7,6	8,6	13,5	14,6	23,1	24,5	26,7
propane	2,3	2,0	2,0	1,4	1,6	1,4	1,8
propylene	12,6	13,1	15,7	16,0	16,1	16,7	18,0
butan	1,0	1,4	1,6	1,1	1,4	1,2	1,4
Σ butylenes	2,5	4,0	4,1	4,9	4,2	3,8	6,9
Total	28,4	32,2	42,0	43,3	55,1	57,4	65,5
Σolefin-containing gases	22,7	25,7	33,3	35,5	43,4	45,0	51,6

As it seen from Table 2, the maximum yield of ethylene at 700°C in the presence of Seokar-600 and Seokar-600/halloysite mixture catalysts is accordingly of 26,7-27,4, %; but it is accordingly of 18,0-18,8 % wt. for propylene.

The increase of 0,4-0,8; 1,5-0,9; 3,1-3,9; 2,9-3,0 % wt. in the yield of ethylene has been observed during the thermocatalytic conversion of CCHG at with adding 10% of cotton oil at a temperatures of 550-700°C in the presence of Seokar-600 and Seokar-600/halloysite mixture catalyst accordingly . This increase for propylene is accordingly of 0,8-0,7; 1,1-0,7; 1,4-1,5; 0,9-1,1 % wt.

Au-Cu^+ Synergy in $MgCuCr_2O_4$-Spinel Supported Gold Nanoparticles for Selective Oxidation of Alcohols and Olefins

Hensen E.J.M.*, Song W.

Eindhoven University of Technology, Inorganic Materials Chemistry Group, Schuit Institute of Catalysis, Eindhoven, The Netherlands

* e.j.m.hensen@tue.nl

Keywords: gold nanoparticle, spinel support, selective oxidation, reaction mechanism, DFT

1 Introduction

Supported gold nanoparticles are promising catalysts for a wide range of selective oxidation reactions. As the least reactive of all transition metals, several strategies are employed to render gold active and selective for such reactions. The nanosizing of gold and the use of supports are main approaches that help to activate dioxygen. In the present contribution, we will discuss the significant synergy between gold nanoparticles and a copper-doped $MgCr_2O_4$-spinel used as the support for the oxidation of ethanol to acetaldehyde [1] and propylene to acrolein [2].

2 Experimental/methodology

$Mg_{0.75}Cu_{0.25}Cr_2O_4$ (denoted as $MgCuCr_2O_4$) and $MgCr_2O_4$ were prepared by a coprecipitation-calcination method. Gold nanoparticles were loaded by homogeneous deposition-precipitation using urea. The gold loading was 1 wt%. The catalysts were calcined in air at 350 °C for 5 h. DFT with the PBE functional as implemented in the VASP code was employed to explore the reaction mechanism. A Hubbard *U* term was added to the PBE functional to properly treat electron localization. Spin-polarized DFT calculations were performed. The projector augmented wave method was used to describe the interaction between the ions and the electrons with the frozen-core approximation. The cut-off energy is 400 eV.

3 Results and discussion

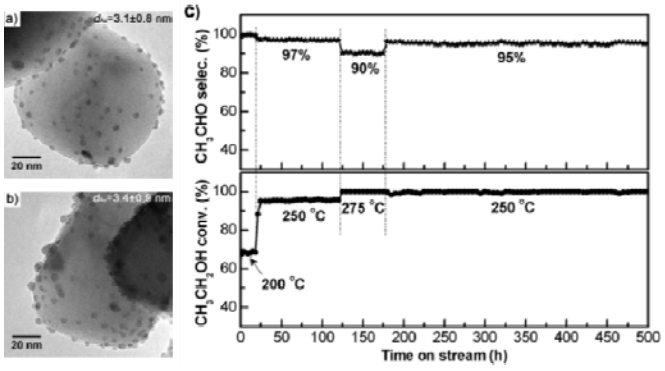

Fig. 1. TEM images of a) fresh $Au/MgCuCr_2O_4$ and b) spent $Au/MgCuCr_2O_4$ catalyst after 500 h on-stream; c) ethanol conversion and acetaldehyde selectivity (reaction conditions: catalyst 0.1 g, GHSV = 100,000 mL g_{cat}^{-1} h^{-1}, ethanol/O_2/He = 1/3/96).

The $Au/MgCuCr_2O_4$ catalyst is highly active and selective for the aerobic oxidation of ethanol to acetaldehyde (Fig. 1a and c; conversion 100%; yield ~95% at a space velocity of 100 L g_{cat}^{-1} h^{-1}). The catalyst is stable for at least 500 h and, during this time, the Au nanoparticles do not sinter (Fig. 1b). Extensive characterization by TEM, XPS and EXAFS shows that the synergy involves the close interaction between metallic and surface Cu^+ species stabilized in the support. $MgCuCr_2O_4$ is more stable than $MgCuAl_2O_4$, because in $MgCuAl_2O_4$ C Cu segregates into CuO. DFT calculations of the complete ethanol oxidation reaction mechanism explain the importance of the interface between the Au nanoparticles and the $MgCuCr_2O_4$-spinel [3].

$Au/MgCuCr_2O_4$ is also an active catalyst for the selective oxidation of propylene to acrolein

(selectivity close to 90%). The high selectivity agrees with the well-known notion that Au in interaction with Cu^{+} can selectively oxidize the allylic C-H bonds in propylene. An extensive DFT study of the reaction mechanism hints at the dynamic nature of gold atoms at the interface of the gold clusters with the support [2]. Adsorption of propylene leads to the formation of an isolated Au atom that strongly binds propylene. The reaction proceeds by activation of the allylic C-H bond by support O or adsorbed O_2 molecule (Fig.2). Detailed analysis of the electronic structures of the reaction intermediates in the catalytic cycle show that the critical role of Cu is the decrease of the desorption energy of acrolein.

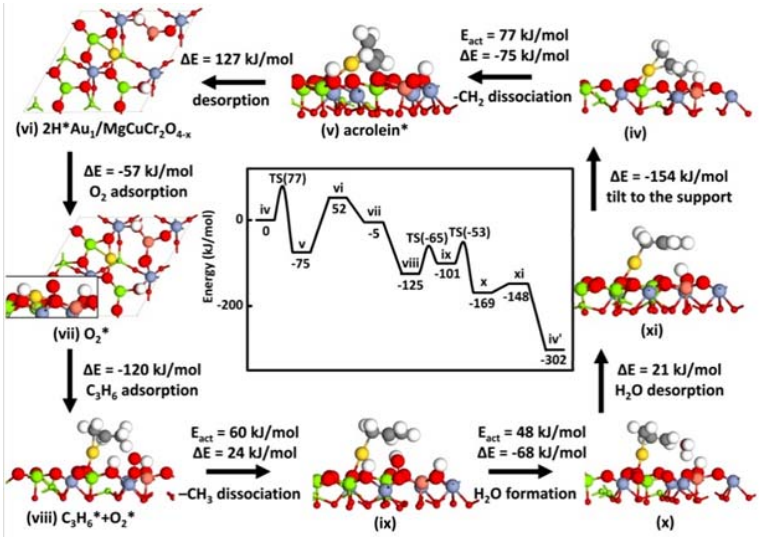

Fig. 2: Reaction energy diagram (middle) with elementary reaction steps for the oxidation of propylene to acrolein on the $Au_1/MgCuCr_2O_4$ model. Main reaction steps are: adsorbing propylene allylic C-H cleavage by support O or adsorbed O_2 species; C-O bond formation; second C-H bond cleavage to form acrolein; acrolein desorption.

4 Conclusions

Highly efficient, selective and stable oxidation of ethanol to acetaldehyde, propylene to acrolein by using $MgCuCr_2O_4$ spinel supported gold nanoparticles is reported. Density functional theory calculations provide a molecular level insight to the reaction mechanism and unravel the importance of Au-Cu synergy in both reactions.

Effects of Promotion Techniques on zsm-5 Activity in Conversion of Alcohols to Fuel Range Hydrocarbons

Isa Y.M.*

Durban University of Technology, Durban, South Africa

* YusufI@dut.ac.za

Keywords: zsm-5, alcohols, activity, promotion techniques, fuels, hydrocarbons

1 Introduction

Fermentation broth obtainable from organic materials is a potential source of ethanol [1]. The vision of using ethanol from fermentation as a universal feedstock for production of chemicals and fuels is surely one of the promising routes towards sustainable production. Bioethanol could be dehydrated to yield ethylene which could undergo a number of reactions that will produce priceless chemicals. The product distribution of ethanol conversion is majorly determined by the quality of ethanol, operating conditions as well as the catalyst employed in the process. While zeolites have been known to show good activity in ethanol conversion to fuel range hydrocarbons, other catalysts like cerium oxide are known to favour the production of hydrogen. The Fischer Tropsch process uses iron and cobalt catalysts for the production of different hydrocarbons [2]. The activity of these active components could also play a vital role in the transformation of ethanol to fuels and petrochemicals. This work investigates different techniques of promoting synthesized ZSM-5 zeolites with iron, cobalt and nickel as well as the efficiency of techniques with respect to catalyst activity and selectivity.

2 Experimental/methodology

A series of ZSM-5 catalysts were synthesized hydrothermally using aluminum salts and water glass as sources of alumina and silica respectively. The reagent composition was determined by the target ZSM-5 SiO_2/Al_2O_3. The pH of the batch mixture was kept below 10.8. The batches were further aged at different times (0-48 hrs.) and crystallization was done at different temperatures and times not exceeding 200°C and 96 hours respectively. The produced crystals were processed by filtration, calcination and protonation to synthesize the desired protonated form of the catalyst. A commercial zsm-5 was also purchased from Zeolyst for comparative studies with the in house catalyst.

Nitrates of cobalt and iron were used for promotion at different loadings (5%, 10% and 15%). Mechanical mixing, co-precipitation and incipient wetness impregnation were applied as promoting techniques to enhance catalyst performance. The synthesized catalysts were characterized using XRD, BET, XRF and SEM.

The catalyst activity was tested using a fixed bed reactor at different space velocities and temperatures in the range of 200-450°C. The feed used include ethanol and water mixtures of various composition, isopropanol and butanol. Other alcohols were investigated so as to have a better understanding of the most probable reaction path during ethanol conversion.

3 Results and discussion

Powder XRD patterns of the catalyst synthesized confirmed the presence of 2 theta values for the target ZSM-5 catalysts. Figure 1 shows the diffractogram of the synthesized zsm-5 catalyst. The presence of the zsm-5 characteristic peaks at 2 theta = 7-9° and 23-25° further confirm the successful synthesis of zsm-5. All the synthesized material had relative crystallinities of not less than 90% when compared to the commercial zsm-5 catalyst. The BET surface area and particle sizes are all seen to be a function of aging. The SEM analyses further confirmed that the zeolites formed were crystalline and had different morphologies depending on the technique used in incorporating the promoter and synthesis conditions. Figure 2 shows the micrograph of un-promoted zsm-5 with average particle size of 0.2μm. The incorporation of metals altered both the particle morphology as well as size.

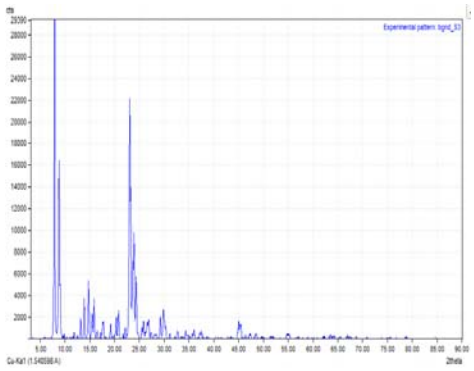

Figure 1. Diffractogram of synthesized zsm-5

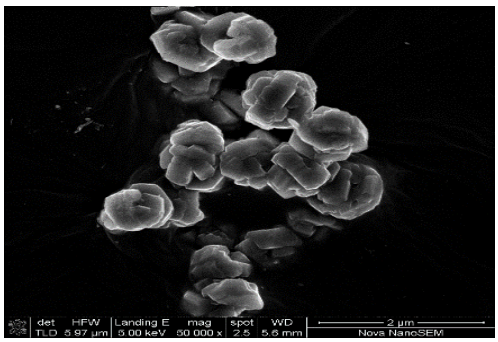

Figure 2: Micrograph of synthesized ZSM-5

All the catalysts showed 100% activity for ethanol and isopropanol conversion with liquid hydrocarbons forming a significant amount of the products. Loading of 5% iron oxide on the commercial catalyst by incipient wetness impregnation showed selectivity to gasoline range hydrocarbons of 72% in the liquid products whereas the in house catalyst showed a better selectivity of 98% during ethanol conversion. Co crystallization of both commercial and in house ZSM-5 showed different selectivity when compared to the unpromoted zsm-5. However, 5% loading of nickel showed the highest selectivity towards gasoline range hydrocarbons (99%) when ethanol was used as a feedstock. Conversion of isopropanol shows that promoting the ZSM-5 with both iron had more significant changes to hydrocarbon selectivity when compared to promotion with cobalt oxide. Promoting the in house zsm-5 with 5% Co did resulted in a selectivity towards gasoline of 63% which was slightly less than that obtained from the unpromoted commercial zsm-5.promoting with Iron under the same conditions shows 78% selectivity towards gasoline range hydrocarbons. In all three cases, the selectivity for diesel range hydrocarbons was less than 30%

4 Conclusions

ZSM-5 catalyst have been successfully synthesized and characterised, various promotion techniques and promoters used on zsm-5 catalysts showed that both the promotion techniques as well as promoting agents had a significant impact on the product distribution. It has been observed that ethanol as well as isopropanol could serve as potential sources of hydrocarbons in the fuel range. Finally the operating parameters greatly influence the product distribution of alcohols over zsm-5 catalysts.

Keywords: Fischer-Tropsch synthesis, cobalt, catalysts, nanocomposites, magnetism

1 Introduction

Innovative method of producing composite materials based on polymeric matrix IR-pyrolysis is offered in TIPS RAS. These materials are catalysts of Fischer-Tropsch synthesis which is second stage of refining processes of petroleum feedstocks in environmentally friendly components of motor fuels [1].

2 Experimental/methodology

For catalysts preparation following polymers: polyacrylonitrile (PAN), polybiphenyl amine (PDFA), polystyrene (PS), polyvinyl alcohol (PVA) and cellulose (CL) were used.

Catalysts were prepared in two stages: at first stage joint solution of polymer and salt was received, at second stage IR –pyrolysis of synthesized system was carried out.

Fischer-Tropsch synthesis was carried out in fixed bed reactor without pre-reduction stage. Magnetic characteristics of composites were measured on vibration magnetometer *in situ* [2].

Samples were also analyzed by X-ray «Geiger Flex» diffractometer («Rigaku»).

3 Results and discussion

All synthesized samples are active in synthesis of hydrocarbons from CO and H_2. Samples prepared by using PVA and PAN demonstrated maximum activity. CO conversion for these samples reach the value of 100%.

Liquid hydrocarbon productivity of contacts Co-PAN, Co-PDFA, Co-PVA is much than productivity of industrial analogs (to 2700 g/kgMe/hour).

Samples with greatest productivity value (Co-PDFA, Co-PAN, Co-PVA) were studied by magnetometric *in situ* method. Presence of Co ferromagnetic particles was shown by field dependences of nanocomposite materials. Also, according to magnetic characteristics metal's degree of reduction for sample before catalysis was determined.

It was determined by XRD method, that dominant phases for Co-PDFA, Co-PAN and Co-PVA samples are metal, metal along with oxide and oxide respectively.

These results correlate with magnetometric data.

4 Conclusions

It was established that composition (structure or nature) of a polymeric matrix has impact on nature of active centers, and, as a result, influences on Fischer-Tropsch synthesis indicators.

It was assumed that higher activity related with polyconjugated cyclic structure which formed during polymer pyrolysis.

The presence of cobalt and cobalt oxide phases which are responsible for active centers of different nature activities for Co-PDFA and Co-PAN samples was proved.

It was assumed that high catalytic activity of Co-PVA sample results from activation in syngas medium during Fischer-Tropsch synthesis.

Conceptual Design of the Catalytic H_2O_2 Decomposition Process for the Production of Dry Oxidizing Agent Used in the NO Oxidation

Jang J.H., Choi H.Y., Han G.B.*

Institute for Advanced Engineering, Yongin, Republic of Korea

* gbhan@iae.re.kr

Keywords: H_2O_2 catalytic decomposition, dry oxidizing agent, NO oxidation, conceptual design

1 Introduction

NOx is a major air pollutant produced by the combustion of fossil fuel. The many efforts have been conducted to improve the removal efficiency of NOx. The selective catalytic reduction (SCR) process has been known as a general and usual NOx treatment process[1-5]. However, SCR process has the disadvantage of the difficult installation, operation/maintenance cost to increase due to high operation temperature for the activity of used catalyst. Therefore, to develop the NOx treatment process having the low cost and high efficiency is necessary. Many technologies of the NOx treatment have been conducted and the NO oxidation using the various wet and dry oxidants was investigated to improve the NOx removal efficiency. The dry oxidant can be produced by the H_2O_2 decomposition and then iron, zirconium and some other transition metal-based oxide were used for the catalytic H_2O_2 decomposition. In this study, the catalytic process for H_2O_2 decomposition was investigated for the production of the dry oxidizing agent to use for the NO oxidation. The catalytic H_2O_2 decomposition over the various catalysts for the dry oxidant production and the combination with NO oxidation process using dry oxidant produced was investigated under the various reaction conditions (e.g., temperature, amount of catalysts, gas composition and space velocity).

2 Experimental/methodology

The experimental H2O2 decomposition system combined with NO oxidation was constructed to conduct for the production of the dry oxidizing agent and the NO conversion. In experimental set-up, the outside diameter and length of the reactor for the H_2O_2 decomposition was 1/2 inch and 50 cm, respectively, and the outlet of the H_2O_2 decomposition process was combined with the inlet of NO oxidation process. The outside diameter of reactor for the NO oxidation process was 1/2 inch. The amount of the catalyst packed was about 0.5 g and the operation temperature was about 150 ℃. The basic reaction conditions were shown in the table 1.

Table 1. Basic reaction conditions.

Factor	Value
Catalysts	
Temperature	70 - 200 ℃
Space Velocity	5,000 - 30,000 ㎤/g-cat.·h
[H2O2]/[NO]	1.0 - 3.5
NO concentration	1,000 – 5,000 ppm

3 Results and discussion

Fig. 1 shows the H2O2 decomposition efficiency depending on the different catalysts for the dry oxidant production by H2O2 decomposition. The reaction temperature for the catalytic H2O2 decomposition was 150 ℃. The catalysts having the highest activity for H_2O_2 decomposition were K-Mn/Fe2O3 and Na-Mn/Fe_2O_3 catalysts.

Fig. 2 shows the NO conversion with the dry oxidant in the NO oxidation process combined with the catalytic H_2O_2 decomposition over the various catalysts. It was known that the NO conversion reached about 100% when the catalyst used in the H_2O_2 decomposition process were K-Mn/Fe_2O_3, Na-Mn/Fe_2O_3.

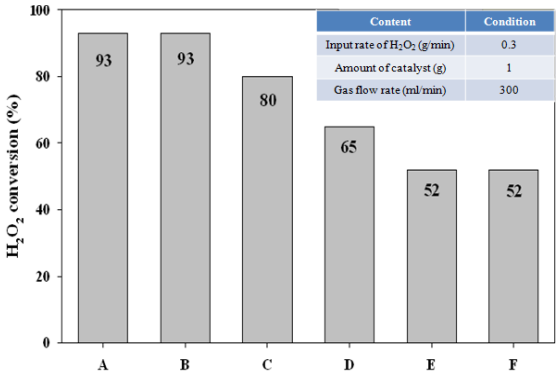

Fig. 1. H2O2 decomposition efficiency depending on the catalyst type for the dry oxidant production (A: K-Mn/Fe2O3 (70%), B: Na-Mn/Fe2O3 (70%), C: Mn/Al2O3 (30%), D: Mn/Al2O3 (10%), E: Fe2O3, F: S-ZrO2).

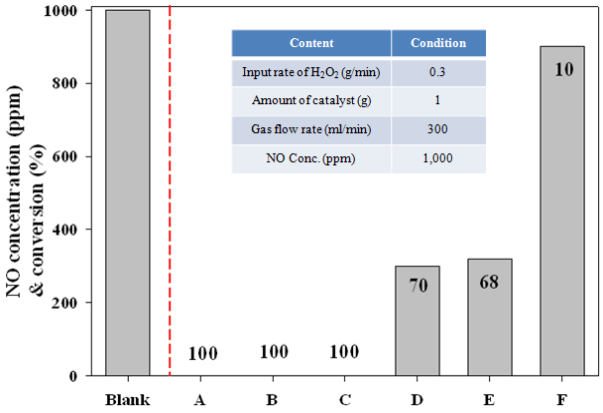

Fig. 2. NO conversion using the dry oxidant produce by H2O2 decomposition according to the catalyst type.(A: K-Mn/Fe2O3 (70%), B: Na-Mn/Fe2O3 (70%), C: Mn/Al2O3 (30%), D: Mn/Al2O3 (10%), E: Fe2O3, F: ZrO2, value: NO conversion).

4 Conclusions

In this study, H_2O_2 decomposition and NO oxidation processes were combined and operated for the dry oxidant production and NO oxidation to improve the NOx treatment efficiency. Under the optimized operation conditions, the H_2O_2 decomposition efficiency was about 93% in the H2O2 decomposition process over KMnO4-based catalyst and then, simultaneously, the NO conversion reached about 100% in the NO oxidation process.

Keywords: glycerol, acetylation, triacetin, catalyst

1 Introduction

In the recent years, biodiesel has gained significant attention as renewable and sustainable transportation fuel. Glycerol is inevitably produced by 10 wt% in total biodiesel production which resulted in a large surplus of low value glycerol in the market. Glycerol esterification with acetic acid (acetylation) is one of the processes to valorize glycerol to useful chemicals such as monoacetin (MAG) and diacetin (DAG) that have applications in cryogenics and polymers. Triacetin (TAG) can act as cold flow improver and viscosity reducer for biodiesel [1]. Glycerol acetylation is usually performed in batch operation using homogeneous catalysts like H_2SO_4, p-toluenesulfonic acid or heterogeneous acidic catalysts such as heteropolyacids [2], ion exchange resins like Amberlysts [3], etc. However, the solid catalysts get deactivated due to leaching of active species. On the other side, it would be attractive to transform liquid phase batch processes to continuous flow processes, as this has several advantages, especially in the view of their implementation in industry. Surprisingly, very few reports are currently available on continuous flow glycerol acetylation [4]. In the present work, several silica-based catalysts (SiO_2-MO_x in molar ratio of 30:1) were prepared, characterized and evaluated in the gas phase acetylation of glycerol for their catalytic activity.

2 Experimental

The SiO_2-MO_x catalysts (MO_x = TiO_2, MgO, ZrO_2, SrO and Sc_2O_3 using precursor ammonium titanyl oxalate (ATO), magnesium acetate, zirconium oxychloride, strontium nitrate, and scandium nitrate, respectively, were prepared by the sol-gel method. In a typical procedure, SiO_2-TiO_2 catalyst was synthesized by dissolving 5.7 g of ATO in 30 g of distilled water. This solution was added to the aqueous solution of 120 g of TEOS (tetraethyl orthosilicate precursor for SiO_2) and conc. HCl (0.4 ml). Under stirring, aqueous ammonium acetate (buffer) solution was added to the above solution to form transparent yellow coloured gel, which was further aged for 12 h at 70 °C. To this gel, 110 g of aqueous ammonia solution (3wt%) were added and the sample was again aged for 12 h at 70 °C, further dried and calcined at 500 °C. Similarly, catalysts with MgO, ZrO_2, SrO and Sc_2O_3 were prepared.

3 Results and discussion

The prepared catalysts were studied with physico-chemical methods to evaluate the specific amount of acid sites as well as textural and structural properties (BET, Pyridine IR, XRD and others). XRD-patterns didn't show any peaks, i.e. all the catalysts were found to be X-ray amorphous. BET surface areas, pore volumes and pore diameters of SiT30 and SiMg30 are close to SiO_2. Other samples showed an increase in BET surface area. SiZr30 catalyst with highest surface area showed strongly intense Lewis acid sites, whereas all other catalysts

showed significantly less intense Lewis acid sites.

Table 1. Physico-chemical and acidic properties of the catalysts

Catalysts	BET surface area (m^2/g)	Pore Volume (cm^3/g)	Pore diameter (nm)	Band Intensity (L-Py) at 250 °C (a.u.)
SiO_2	395	0.92	9.8	0
SiTi30	404	0.81	8.7	0.46
SiMg30	375	0.85	9.1	0.42
SiZr30	572	0.60	3.7	1.64
SiSc30	451	0.75	6.3	0.45
SiSr30	275	0.86	11.3	0.06

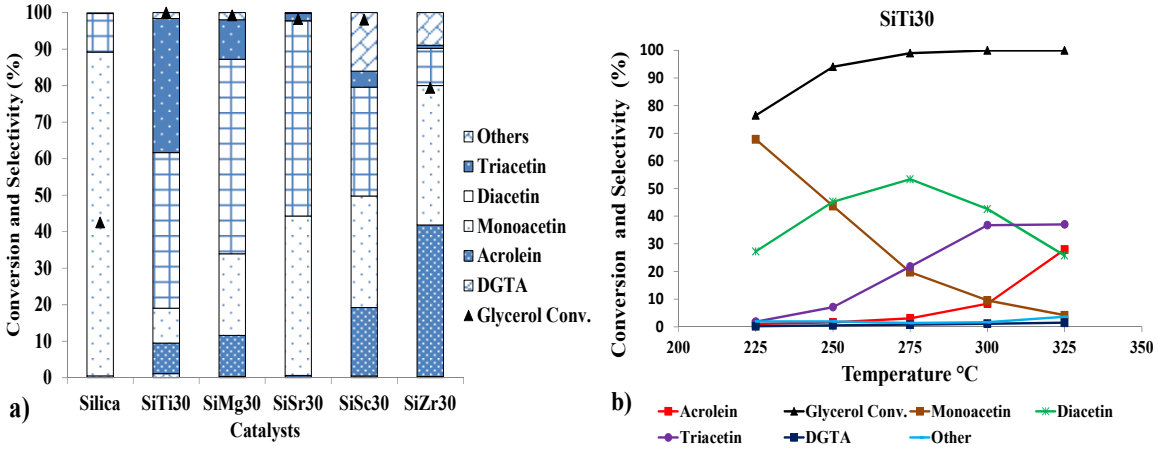

Fig. 1 a) Screening of catalysts (acetic acid/glycerol = 6, 0.6 g of catalyst, T = 300 °C, GHSV = 1707 h^{-1}). b) Effect of temperature on catalytic performance of SiTi30 (acetic acid/glycerol = 6, 0.6 g of catalyst, GHSV = 1707 h^{-1}) (DGTA = diglycerol tetraacetate).

All catalysts except the pure support showed high activity (almost 100% glycerol conversion) at 300 °C. Interestingly, SiTi30 showed high selectivity for triacetin (36.8%), whereas SiZr30 showed comparatively high selectivity for acrolein (41.5%), possibly due to its outstanding acidity (*c.f.* Fig. 1a). The curve for SiTi30 shows that acrolein selectivity rises with temperature (28% at 325 °C, Fig. 1b). The formation of diglycerol tetraacetate (DGTA) oligomer as by-product was observed, as previously also reported for batch runs [3].

4 Conclusions

Among the prepared catalysts, SiTi30 showed the best catalytic performance with complete conversion of glycerol and 37% selectivity for triacetin. SiZr30 is selective towards acrolein (41.5%). It seems that an optimum amount of Lewis acid sites is responsible for high activity and selectivity for acetins.

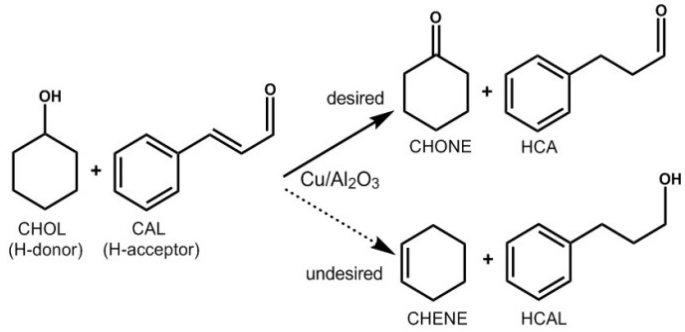
Keywords: cyclohexanol, cyclohexanone, cinnamaldehyde, hydrocinnamaldehyde, coupling reaction

1 Introduction

Coupling of industrially important dehydrogenation and hydrogenation reactions in gas phase over a single catalyst bed have several advantages such as operational simplicity, good energy efficiency, enhanced conversion and eco-friendly process [1]. Interestingly, the in-situ released hydrogen from the dehydrogenation step can be effectively utilized in the hydrogenation of second reactant in such a way that this approach not only completely eliminates the supply of external hydrogen in the reactant feed mixture for hydrogenation but also provides an opportunity to combine and perform two reactions simultaneously in one step under one set of reaction conditions. Only a few reports are available on this type of coupling process which involves a catalytic hydrogen transfer [e.g. 2-3]. The present study is the first attempt of combining dehydrogenation of cyclohexanol (CHOL) and hydrogenation of cinnamaldehyde (CAL) in one step to produce cyclohexanone (CHONE) and hydrocinnamaldehyde (HCA) using a single reactor over Cu/Al_2O_3 catalysts (Scheme 1). The target products have high commercial significance; cyclohexanone is used for the manufacture of caprolactam in nylon-textiles and hydrocinnamaldehyde is an intermediate in the synthesis of anti-viral pharmaceuticals, particularly HIV protease inhibitors. However, cyclohexene (CHENE) and hydrocinnamyl alcohol (HCAL) are the by-products of this combined reaction.



Scheme 1. Coupling of cyclohexanol dehydrogenation and cinnamaldehyde hydrogenation in one-step.

2 Experimental

Commercial γ-Al_2O_3 (Sudchemie, BET surface area 223 m^2/g) was used as a support for preparing the present Cu/γ-Al_2O_3 catalysts with varying Cu loadings (2.5 to 10 wt%) by impregnation method. These catalysts were characterized by XRD, TPR, XPS, ICP, TEM etc. The catalytic tests were carried out in a fixed bed reactor at atmospheric pressure under N_2 flow in the temperature range of 250 to 325 °C. About 2 g of the catalyst was used for catalytic tests. Prior to testing, the catalyst was reduced under H_2 flow at 280 °C for 3 h. The products were collected in an ice-cold trap for every 30 min and analysed by off-line GC equipped with FID using AT-5 capillary column.

3 Results and discussion

The BET surface area values decrease gradually from 221 to 185 m^2/g, as the copper loading increases from 2.5 to 10 wt%. XRD showed that the reflections corresponding to CuO phase could only be seen in the catalysts with higher Cu loading (>5 wt% Cu). Similarly, the XRD patterns of reduced catalysts revealed the presence of metallic Cu^0 phase in the catalysts having >5 wt% Cu content. From XPS analysis it was observed that the chemical state of copper was Cu^{2+} for calcined catalysts and for reduced catalysts it is in between Cu^+ or Cu^0. TPR patterns of Cu/Al_2O_3 catalysts exhibited two types of reduction peaks in the temperature range of 150 to 300 °C. The peaks corresponding to lower temperature are due to the reduction of highly dispersed CuO species and high temperature peaks may be due to the reduction of bulk CuO particles. TEM analysis of reduced catalysts shows high dispersion of smaller copper particles. Fig. 1 depicts the influence of Cu loading on the catalytic activity and selectivity for coupling process. With increase in the copper loading from 2.5 to 7.5 wt%, the cyclohexanol conversion increased from 36 to 70% and then decreased to 51% while the conversion of cinnamaldehyde increased from 19 to 64% and then decreased to 50%. Similarly, selectivity of cyclohexanone and hydrocinnmaldehyde also increased in a similar fashion with Cu loading (i.e. from 75 to 93% and then levelled off). Besides, various important reaction parameters such as temperature, space velocity (GHSV), mole ratio and flow rate of reactants were also optimized. For instance, with increase in the mole ratio of cyclohexanol and cinnamaldehyde to 2 : 1, nearly 100% conversion of cinnamaldehyde and 80% cyclohexanol conversion with 90% selectivity of cyclohexanone and 80% selectivity of hydrocinnamaldehyde could be obtained. However, the catalyst displays gradual deactivation due to coking. As a result, after 8 hours-on-stream over 7.5wt% Cu catalyst, the conversion of cyclohexanol decreased from 80 to 67% while conversion of cinnamaldehyde decreased from ~100 to 88%. However, the selectivity of cyclohexanone was decreased from 92 to 80% while the hydrocinnamaldehyde selectivity remains more or less constant at 85%.

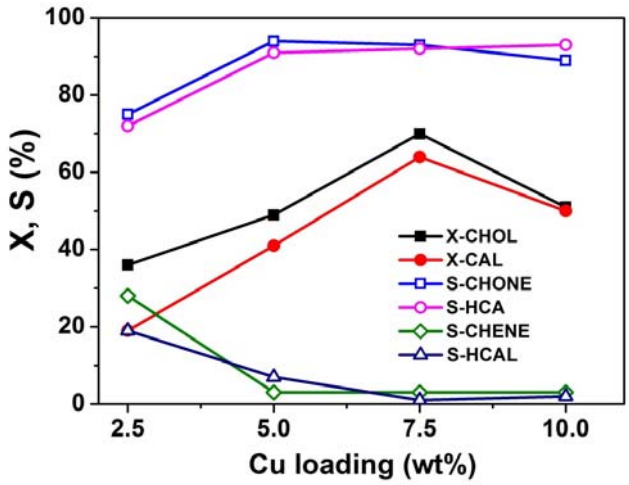


Fig. 1. Influence of Cu loading on coupling of cyclohexanol and cinnamaldehyde over $Cu/\gamma\text{-}Al_2O_3$ catalysts (T=275 °C, V_{cat}=1.4 ml, Total flow=3.7 l/h, GHSV=2690 h^{-1}, CHOL : CAL : N_2=1 : 1 : 40)

4 Conclusions

Cu/Al_2O_3 catalysts demonstrate overwhelming performance towards novel coupling of cyclohexanol dehydrogenation and cinnamaldehyde hydrogenation reaction. Results revealed that the Cu loading has strong influence on the catalytic performance. Among all, 7.5wt% Cu/Al_2O_3 exhibited the best performance plus significantly high yields of cyclohexanone (70%) and hydrocinnamaldehyde (80%) could be successfully achieved for the first time.

1 Introduction

One of the effective ways to improve the properties of special bitumen is their chemical and physical modification. When selecting the source raw material, the results of the earlier studies were taken into consideration [1], proving that the oxypolymerization ends at the stage of bitumen obtaining. Therefore, the raw material for special bitumen production is the flux oil of naphthene-aromatic sub-structure - Karabashsky NBZ (KNBZ) and paraffin-naphthene substructure - Elkhovsky NPU (ENPU) OJSC "Tatneft" (Table 1).

Table 1. Physical-chemical properties of flux oil

Indices	Flux oil		
	Karabashsky NBZ	Elkhovsky NPU	Mordovo-Karmalsky NB
Density, kg/m^3	0,9686	0,9878	0,9985
Relative viscosity, RV_{80},	22,96	51,76	80,0
Content, %mass.:			
- CAB	18,25	28,23	55,8
- sulphur	0,492	0,887	5,2
- paraffins	< 2,0	15,0	15,0
Asphaltenes/resin	0,64	0,45	0,47

2 Experimental

The investigations of structural-dynamical properties of flux oil by impulse NMR show high inhomogeneity of chemical group composition of resinous-asphalthene materials (RAM) in the flux oil of ENPU (Fig.1) due to high content of paraffin HC (Table 1), corresponding to high content of phase A – 75%mass. and low frequency of core precessions of the phases under study. Formerly it was found out, that the structural dynamical analysis (SDA) of oil disperse systems has the phases A, B and C, which are conventionally classified as oil, resins and asphaltenes respectively, due to their different content and molecular mobility.

3 Results and discussion

In the course of investigations of BIM, based on special bitumens of ENPU (both with MBM and without it - bitumens 1 and 2), it was determined an inverse proportion of covering strength on rheological characteristics of BIM. Therefore, MBM usage in oxidation of ENPU flux oil significantly increases the hardness (Fig. 3), and it is characterized by multiply less values of dynamic viscosity and shearing stress of BIM, what proves the existence of BIM structural net, formed by their micelle structure. It was revealed, that the dissolution rate of bitumen-1 in aromatic solvent is higher than the one of bitumen-2.

The studied samples shall be divided into two groups in the content and composition of paraffin structures. So, the bitumens with Tsoft equal to 85 and 1000C the total content of methylene and methyl groups is lower, and the branching of paraffin structures is higher, than in the bitumens with Tsoft equal to 103 (bitumen-2) and 1240C. Alongside with that, bitumen-1 has low content of aromatic structures; its asphaltenes are more condensed and less oxidized, than the ones of bitumen-2.

The change of asphaltene structure in special bitumens promotes their high chemical homogeneity with resin components due to the mutual diffusion of phases B and C (Fig. 1).

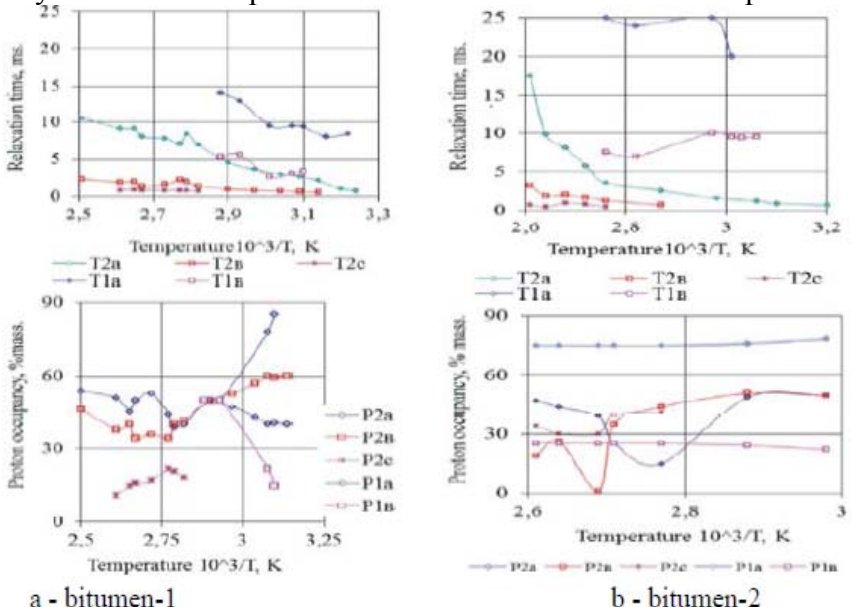

Fig. 1. The results of the analysis of structural-dynamical states of special bitumens of Elkhovsky NPU

4 Conclusions

The results of the investigations, taking into consideration the data, obtained by impulse NMR, infrared spectroscopy and physical-mechanical analysis show that the BIM are plastified due to the asphaltenes, which have the properties of "heavy" resins, because of oxidative polymerization of MBM and flux oil components of ENPU.

Keywords: wave technology, microwave radiation, the wave non-linear mechanics

1 Introduction

Traditional methods of intensification of chemical and technological processes of oil refining are energy intensive and often reached effect's value does not cover the costs. In this regard, there is the task to use modern high technologies, ensuring the achievement of the required effect without the high material and energy costs, among which most promising and effective are the wave technologies. The aim of this study was to investigate the effect of wave impacts on the speed and depth of chemical processes. We would like to draw attention on the technologies which use wave methods of impacting oil refining chemical-technological processes are applied for enhancement of physical-chemical properties and fractional composition of oil and oil products. The increase in the light hydrocarbon fraction molecules oscillation amplitude during oil fraction distillation, contributes to weakening of intermolecular interactions, separation of these molecules from supermolecular structure solvation shells and transfer to a vapor phase, which results in increase in the yield of light fractions. The decrease in such amplitude may be used in crystallization of various solutions or melts in order to obtain optimal system properties. The use of wave exposure methods is an efficient means for intensification of oil refining chemical and technological processes [1].

2 Experimental

The main effect of acoustical treatment of oil stocks and its products is connected with the action of audible and ultrasonic frequency band elastic oscillations on the substance and progress of various reactions and processes due to cavitation, acoustic pressure and acoustic wind.

The action of a 2450 MHz electromagnetic field on the substance makes polar or polarizable molecules or ions orient in accordance with the field pulsation. Due to phase discordance between the field fluctuations and dipole rotation, the radiation energy turns into molecular motion energy and the entire volume of the substance is heated from the inside as opposed to conventional heating of surface by heat transmission.

A particular rise of exploratory activity in the use of microwaves in organic chemistry was in 1989 after publication of two articles written by French authors who used household microwave ovens for heating reaction mixtures and despite some technical difficulties observed a significant reduction in the period of Diels-Alder reactions, Claisen reactions, etherificafion, oxidation etc. at equal target product outputs.

3 Results and discussion

The use of microwave irradiation (MIR) contributes to a considerable acceleration of petrochemical processes, increases selectivity and yield of products and improves ecological characteristics of industrial processes.

The essence of wave methods of oil stock and products treatment lies in molecule energizing (molecule activation) aimed at inducing their transformation in a positive direction by exposure to various physical fields on intramolecular, molecular and intermolecular bonds. The molecule energizing (molecule activation) means energizing by an electromagnetic radiator, which radiated frequencies are resonant with frequencies of oil stock and products molecule.

Oil is an extremely complex mixture of various classes of carbons and heteroatom compounds in complex intermolecular bonds, which form a disperse system with a complicated internal structure; therefore a wide oil vibrational spectrum range is expected. In means that in order to ensure target influence on oil components it is necessary to choose the object of such influence. In this regard, a quantum-chemical analysis of the Carbon-Carbon bond (C-C) and Carbon-Hydrogen bond (C-H), implemented at atomic level (not at molecular), is of a significant interest (Syunyaev, et al., 1990).This analysis is all the more important as thermodeconstructive, thermocatalytic and many other means of influence on oil stock are based on stimulating, breaking and formation of such bonds.

4 Conclusions

The use of wave exposure methods is an efficient means for intensification of oil refining chemical and technological processes.

Keywords: paraffin-asphalt associates, physical-chemical modification, oxidative polymerization

1 Introduction

The results of our previous studies [1] evidencing that oxidative polymerization is accomplished at the stage of construction bitumen synthesis were taken into account during selection of raw material sources. As the result, tars of naphthene-aromatic (Karabash Oil-Bitumen Plant (KOBP)) and paraffin-naphthene bases (Elkhovskiy Petroleum Refining Plant (EPRP) OAO "Tatneft") served as the raw material for production of special bitumen.

2 Experimental

A choice of a co-product of wood processing (CWP) as a modifying agent of bitumen is related with high convergence mechanism of reciprocal transformations of their components in high-temperature oxidation. CWP contains unsaturated acids, which reduce the release of asphaltenes in oxidative polymerization together with petroleum acids. The choice of the multicomponent bifunctional modifier (MBM)-a component of polymer oils production (CPOP) as the main raw material is stipulated by its high capacity to chemical structuring due to the formation of esters better film-forming ability. Oil dispersed systems according to the structural-dynamic analysis (SDA) contain the phases A, B and C, which due to their different concentration and molecular mobility are conventionally referred to oils, resins and asphaltenes, respectively.

3 Results and discussion

Based on the naphthene-aromatic composition and small content of paraffinic hydrocarbons, KOBP tar is the most convenient raw material for the production of BIM, what is confirmed by studies of structural-dynamic (Fig. 1) and physical-mechanical properties of the final products.

It was found that manganese dioxide (MD) at 240°C and above forms salts with the organic acid which are soluble in bitumen medium and as a result catalyzing the oxidation. It was identified that the maximum reduction in the time of material presence in the reaction zone reveals at the introduction of the three-component modifier with simultaneous increase of bitumen-1 output (special bitumen EPRP, modified MBM, T = 100°C) by 17% m and the formation of degradation products reduces by 15-17%. It is known that the inhibitors capable to slowing of polymerization are destroyed at 250°C and the presence of MD and CPOP. Low physical and mechanical properties of BIM based on bitumen-3 (special bitumen KOBP, modified MBM) can be explained by the high content of carbenes and carboids 0.81% and structural features of phases A (90%) and B, in which phase A has a negative impact on the film-forming ability of BIM.

Our studies of BIM based on special bitumen EPRP (both with MBM and without-bitumen-1 and -2) have identified inverse proportional dependence between hardness of C and the

rheological characteristics of BIM. Thus, the implementation of MBM in the oxidation of tar EPRP promotes a significant increase in the hardness (Fig. 3) and characterizes by lower dynamic viscosity and shear tension of BIM, what is an evidence of a spatial lattice structure in BIM formed by their micelle structure. It was found that the resolution rate of bitumen-1 in an aromatic solvent is higher than for bitumen-2.

Abnormally of high physical-mechanical (Fig. 2) and low rheological properties of BIM obtained from bitumen-1 containing up to 41% of asphaltenes (Table 2) compared with GOST 5631-79 with asphaltene content up to 39% can be explained by the chemical structure of the disperse system components (Fig. 3a), high chemical homogeneity of phases B and C, the frequency of precession of the nuclei and the content of phase B. This phenomenon according to IR spectroscopy is confirmed by a comparative analysis of the structural-group composition of bitumens and separated asphaltenes (Tables 3 and 4). In this case, bitumen with Tm equal to 85, 100 and 124°C belong to the same type of oxidizing material, i.e. tar EPRP together with additives of different oxidation.

Changes of the structure of asphaltenes in special bitumens promote their high chemical homogeneity with the components of resins due to reciprocal diffusion of phases B and C.

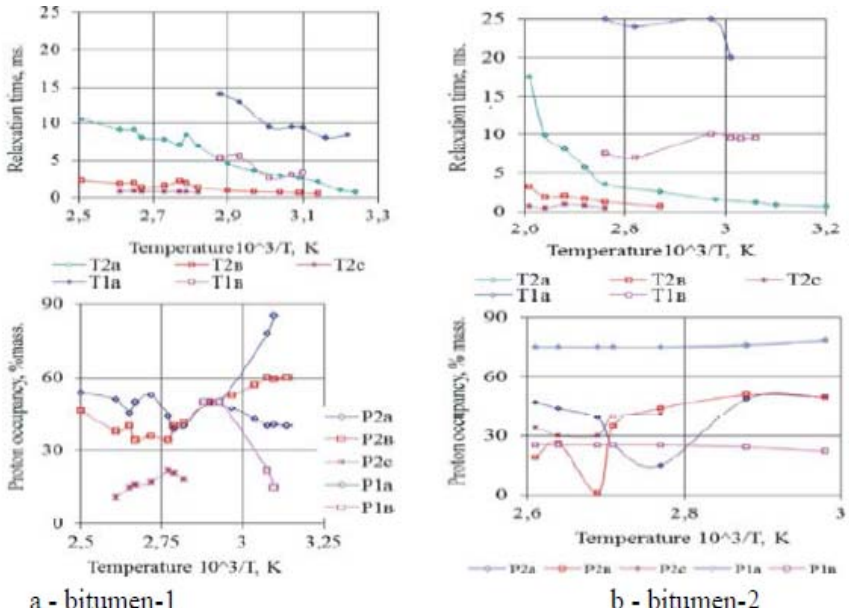

Fig. 1. Dependences of the spin-spin relaxation time and hydrogen proton occupancies in phases a, b and c on temperature.

4 Conclusions

In our studies, we have determined using impulse NMR, IR spectroscopy and physical-mechanical analysis that BIM are plasticized due to asphaltenes possess the properties of the "heavy" resins as a result of oxidative polymerization of MBM components and tar EPRP that BIM the fact that.

Ways of Regeneration of Highly Effective Catalysts Based on Mo-V-P Heteropoly Acid Solutions

Zhizhina E.G.*, Gogin L.L., Pai Z.P.

Boreskov Institute of Catalysis, SB RAS, Novosibirsk, Russia

* zhizh@catalysis.ru

Keywords: heteropoly, acid catalyst, regeneration, multicycle, testing

1 Introduction

Mo-V-phosphates are polyoxometalates, which are widely used nowadays. Free Mo-V-P heteropoly acids (HPA) and their salts belong to the same class of compounds. Most of these acids have Keggin composition $H_{3+x}PMo_{12-x}V_xO_{40}$ (HPA-x). They contain easily reducible V^V, and by its expense such compounds have rather high redox potential *E* and are quite strong oxidizers. This allows their use in homogeneous and heterogeneous catalysis. In particular, in homogeneous catalytic oxidation processes involving O_2 HPA-x are used as *reversible oxidizers*. Oxidation reactions of substrates (Su) in the presence of the HPA-x solutions are usually performed in two stages, (1) and (2), in different reactors. The sum of these stages is a catalytic reaction (3), the oxidation of substrate by O_2. Stages (1) and (2) constitute the catalytic cycle of reaction (3) [1].

$$^m/_2\ Su + {}^m/_2\ H_2O + HPA\text{-}x \longrightarrow {}^m/_2\ SuO + H_mHPA\text{-}x \quad (1)$$

$$H_mHPA\text{-}x + {}^m/_4\ O_2 \longrightarrow HPA\text{-}x + {}^m/_2\ H_2O \quad (2)$$

$$Su + {}^1/_2\ O_2 \longrightarrow SuO \quad (3)$$

The individual performance of stages (1) and (2) shows the high selectivity (to 99 %) of target reaction (1). Because the reduced catalyst solutions (H_mHPA-x, where m is the number of electrons accepted by HPA-x) are complex equilibrium mixtures of HP anions with various integers **m** (including m = 0) and cations VO^{2+} and VO_2^+, the average reduction degree of such solutions **m** is equal to $[V^{IV}]$ / $[H_mHPA\text{-}x]$. Here $[V^{IV}]$ is the total concentration of V^{IV}, and $[H_mHPA\text{-}x]$ is the total concentration of HP anions. The latter is equal to the initial [HPA-x].
In the catalyst regeneration, according to reaction (2), V^{IV} in HP anions is oxidized to V^V, and the reduction degree of HPA-x decreases. Therefore, in the catalytic process (3) HPA-x is a *reversible* acting oxidizer (i.e., a catalyst), in which vanadium atoms undergo redox transformations: $V^V \rightarrow V^{IV} \rightarrow V^V$. The catalyst productivity, or its oxidative capacity (the amount of Su oxidized in the single cycle by 1 L of the catalyst solution), depends on $[V^V]$ before reaction (1). Therefore, in many testing catalyst cycles according to schemes (1) + (2), a maximum catalyst regeneration is required to provide the highest $[V^V]$ in the HPA-x solution and, thus, the maximum possible amount of substrate that is oxidized in the following cycle. Stage (2) is a *common* and *key* step of the catalytic processes (3).

2 Experimental

The HPA-x catalyst solution regeneration is usually performed at temperatures 150−170 °C and P_{O_2} =3−4 atm [2]. Note that not only oxygen may be used for regeneration. In principle, it is possible to reoxidize strongly reduced HPA-x solution by the 30 % H_2O_2 solution. We have used this method in the development of process of vitamin K_3 synthesis [3]. This oxidizer is really good, since it environmentally harmless. However, H_mHPA-x oxidation in this case is not complete, since vanadium ions appear to catalyze H_2O_2 decomposition into oxygen and water.

Therefore, the oxidative capacity of the HPA-x solution after regeneration by H_2O_2 will be essentially reduced starting from the second cycle. Moreover, organic admixtures present in the catalyst solution after reaction (1) are not completely oxidized during such regeneration, and, thus, will accumulate from cycle to cycle, reducing *E* before target reaction (1) and catalyst productivity in whole.

We have also tried to use the concentrated HNO_3 for the HPA-x solution regeneration [4]. Though this oxidizer is not good regarding environment, it may be used in small amounts under certain conditions as assistant during the oxidation by air oxygen. In the case of HNO_3 assistance catalyst regeneration may be performed under atmospheric pressure. In case if there is organic residue from the previous cycle, it is completely oxidized to carbon dioxide and water by the nitric acid admixture during catalyst regeneration before the next cycle.

3 Results and discussion

In our studies [1-4] we have shown that catalysts based on the HPA-x solutions completely restore their properties during regeneration which can be carried out in various ways.

For example, recently we investigated the possibility of multicycle HPA-10 ($H_{17}P_3Mo_{16}V_{10}O_{89}$) performance as a bifunctional (acidic and oxidation) catalyst in the synthesis of 2,3-dimethylanthraquinone (7 cycles). In addition to the regeneration of the HPA solution by O_2 at 150−160 °C, we tested the feasibility of its substitution by low concentrations of nitric acid for the same purpose. Methods for regeneration of the catalyst were alternated.

Table 1. Multicycle synthesis of 2,3-dimethylanthraquinone (2,3-DMAQ) via NQ reaction with 2,3-dimethylbutadiene catalyzed by the HPA-10 solution.

Cycle number	E_{cat} before reaction (1), V	2,3-DMAQ yield, %	2,3-DMAQ purity, %	Catalyst regeneration method
1	1.098	81	98	150 °C, P_{O_2}= 4 atm, 20 min
2	1.063	77	98	160 °C, P_{O_2}= 4 atm, 15 min
3	1.066	77	97.5	Boiling, HNO_3 (0.15 ml), 30 min
4	1.101	80.5	98	Boiling, HNO_3 (0.15 ml), 30 min
5	1.097	80	98.5	160 °C, P_{O_2}= 4 atm, 15 min
6	1.063	77	98	Boiling, HNO_3 (0.2 ml), 30 min
7	1.104	81	98	160 °C, P_{O_2}= 4 atm, 15 min

Conditions: 80 °C, 4 ml of 0.2 M HPA-10 solution, molar ratio HPA-10:NQ 0.5:1, volume ratio HPA solution:1,4-dioxane 1:1; 7 h; NQ conversion ≥ 99.5%. E_{cat} values are given with respect to NHE.

HNO_3 apparently provided a more complete oxidation of reduced HPA-10 (i.e., higher E_{cat} before the next cycle) than the regeneration by O_2 in an autoclave. After the regeneration using HNO_3, the oxidative capacity of the catalyst remained essentially the same as in the first cycle because after regeneration the E_{cat} values were close to that of the fresh HPA-10 solution used in the first cycle.

4 Conclusions

The HPA solution remained homogeneous during many cycles, retained its productivity and gave no V-containing precipitates. The complete recovery of the properties of the HPA-x catalyst after regeneration shows its technological usefulness in various oxidation processes.

Synthesis of a Novel Anthracene Based Schiff Base-Copper(II) Complex as a Potential Catalyst

Kocak A.[1*], Malkondu S.[1], Turhan D.[1], Kocak N.[2]

1 - Selcuk University, Science Faculty, Department of Chemistry, Konya, Turkey
2 - Necmettin Erbakan University, Deparment of Science Education, Faculty of Education, Konya, Turkey

* akocak@selcuk.edu.tr

Keywords: schiff base-copper(II), antracene, synthesis, excimer

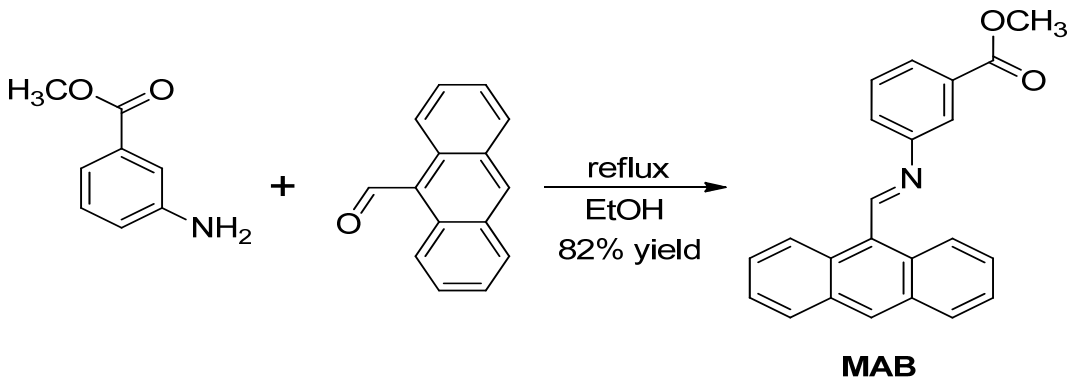
1 Introduction

Schiff base metal complexes have been studied widely due to their several chemical and physical properties and their wide range of applications in numerous scientific areas [1]. These types of complexes have been prudently explored in recent years and such studies have been the subject of many papers and reviews. Schiff base ligands are easily synthesized and form complexes with almost all metal ions. Many Schiff base complexes show excellent catalytic activity in various reactions at high temperature and in the presence of moisture. Many of them are centered on the catalytic activity of Schiff base metal complexes in a large number of homogeneous and heterogeneous reactions such as oxidation, epoxidation, hydroxylation, aldol condensation, polymerization and hydrogenation reactions [2-4].

Considering wide catalytic properties of Schiff base complexes, we have designed a simple methyl anthracenylimine benzoate (**MAB**) derivative, which has the ability to form self-assembled anthracenyl excimer species with a specific metal ion.

2 Experimental/methodology

NMR spectra were recorded at room temperature on a Varian 400 MHz spectrometer in DMSO-d6 or CDCl3. Chemical shifts are expressed in δ units. IR spectra were obtained on a Perkin Elmer Spectrum 100 FTIR spectrometer. UV-vis spectra were measured with a Perkin Elmer Lambda 25 spectrometer. The fluorescence spectra were measured on a Perkin Elmer LS 55 spectrometer in 1 cm quartz cells with slit 6 nm. Excitation wavelength of MAB is of 388 nm. High resolution mass spectra were recorded on a Bruker Daltonics MicroToF II mass spectrometer. All starting materials and reagents used were of standard analytical grade from Aldrich and Merck used without further purification. The stock solutions of metal ions in MeCN were prepared from their perchlorate salts.



Scheme 1. Synthetic route to **MAB**

MAB was readily synthesized by the route outlined in Scheme 1. Methyl 3-aminobenzoate

was prepared starting from benzoic acid. Fischer esterification of benzoic acid afforded methyl benzoate in quantitative yield. The nitration of methyl benzoate with a mixture of HNO_3/H_2SO_4 provided methyl 3-nitrobenzoate in good yield. Reduction of methyl 3-nitrobenzoate with Fe powder/AcOH gave methyl 3-aminobenzoate, the condensation reaction of which with 9-anthracene carboxaldehyde provided **MAB** in 82% yield. The structures of the intermediates and final product were verified by ^{1}H NMR, ^{13}C NMR and FT-IR spectroscopy and HRMS.

3 Results and discussion

The complexing ability of **MAB** toward a wide range of metal ions (Li^+, Na^+, Cs^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Ag^+, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, Al^{3+} and Fe^{3+}) has been investigated by fluorescence spectroscopy (λ_{ex} = 388 nm) in MeCN at 20 ^oC (Figure 1). In the absence of any metal ion, **MAB** shows a very weak emission at 439 nm in MeCN due to the highly efficient PET (photoinduced electron transfer) process between the methyl 3-aminobenzoate receptor moiety and the anthracene fluorophore. Among the nineteen metal ions, only Cu^{2+} was found to give a distinct spectral change. The addition of Cu^{2+} (5.0 equiv) induces two new emission bands, a weak monomer emission band centred at 471 nm and a strong excimer emission band centred at 594 nm, indicating strong complex formation with Cu^{2+} ions. Under similar conditions, the other tested metal ions had very little effect on the emission. The value of the sensing index (I_{594}/I_{439}) for **MAB** to Cu^{2+} is 14.8 whereas it is less than 0.4 for the other metal ions. Therefore, **MAB** shows high selectivity toward Cu^{2+} over other competing metal ions.

4 Conclusions

In conlusion, a novel anthracene-based, highly selective fluorescent receptor has been synthesized through simple synthetic route, and its sensing ability for a wide range of metal ions (Li^+, Na^+, Cs^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Ag^+, Zn^{2+}, Cd^{2+}, Hg^{2+}, Al^{3+} and Pb^{2+}) has been explored. **MAB** exhibits high selectivity and sensitivity for Cu^{2+} in the presence of various metal ions with a significant emission enhancement via unique copper(II)-directed static excimer formation. The basis of the excimer formation has been investigated and found to be a static in nature from a survey of the excitation and absorption spectra. The results demonstrate that disassociation of the excimer species to monomers is caused by the temperature and solvent fraction. This dissociation process enables **MAB** to be used as a temperature and solvent sensor. The Job's plot and mole-ratio curves reveal a 1:2 (M:L) stoichiometry. **MAB** exhibits a high sensing index value of 14.8 for Cu^{2+} ions. The detection limit is sufficiently low to determine micromolar levels of Cu^{2+} ions. The present study is a good example of a receptor in which the rational conversion of excimer species to monomers can be monitored distinctly. The copper complex of **MAB** will be further explored as catalyst in some organic reactions.

Determination of Pt-Catalyst Efficiency of Reforming Process for Different Industrial Plants

Koksharov A.G.*, Ivanchina E.D.

Tomsk Polytechnic University, Tomsk, Russia

* antonkg@tpu.ru

Keywords: catalytic reforming, Pt-catalyst, rate, constant mathematical model, non-stationary kinetic model

1 Introduction

One of the main goals of the reforming process is to increase the aromatics concentration. In addition to the target reactions dehydrocyclization of paraffins and dehydrogenation of cyclohexanes also some undesirable reactions that decrease the liquid yield (light hydrocarbon gas formation by hydrocracking) always occur to some extent. Rates of the individual reactions depend on the catalyst selectivity and process conditions. Using the obtained values of the rate constants of chemical reactions and non-stationary kinetic model we calculated the main indicators of the catalytic process in industrial units L-35-11/600 and LCh-35-11/1000, under different operating conditions of the catalyst RG-682.

2 Experimental/methodology

We use non-stationary mathematical model is a system of differential equations to the extent that the use of the inner surface of the catalyst pellet (η) and coke formation.
The mathematical model of catalytic reforming:

$$\begin{cases} G_c \dfrac{\partial C_i}{\partial Z} + G_c \dfrac{\partial C_i}{\partial V} = \sum_j k_j \cdot C_i \cdot \eta_j, \\ G_c \dfrac{\partial T}{\partial Z} + G_c \dfrac{\partial T}{\partial V} = \dfrac{1}{\rho \cdot C_p^{mix}} \sum_j \Delta H \cdot k_j \cdot C_i \cdot \eta_j. \end{cases}$$

The initial conditions:

$$Z = 0 \quad T = T_{en} \quad C_i = C_i^{en};$$
$$V = 0 \quad T = T_{en} \quad C_i = C_i^{en}.$$

Where Ci - a concentration of i-th component, mol/m3; T – temperature; Z – a raw material volume, m³; i - number of components in the mixture; j - number of reactions; kj - rate constant j-th reaction; ΔH - the thermal effect of the j-th reaction J/mol; ρ - density, kg/m3; V - a volume of the catalyst layer,m3; G - a raw material flow rate, m3/h.

Accounting for non-stationary model made it possible to calculate the values of the rate constants of reactions (Table. 1).

Table 1- rate constants of chemical reaction for the catalyst (in relative units, one adopted for the hydrocracking reaction rate)

Reaction	RG-682	
	L-35-11/600	LCh-35-11/1000
hydrocracking of n-P	0,53	0,28
n-P → izo-P	0,23	0,14
izo-P → n-P	0,08	0,16
n-P → N-6	0,31	0,31

hydrocracking of izo-P	1,00	0,48
izo-P → N-6	0,27	0,38
N-5 → izo-P	0,23	0,16

3 Results and discussion

The catalyst has different rate constants for the reactions dehydrocyclization, isomerization, and hydrocracking of paraffins, thus affecting the performance of the catalysts and the resulting yield.

The results of the calculation of the yield in industrial units L-35-11/600 and LCh-35-11/1000 using a catalyst of the brand RG-682 are shown in Figure 1.

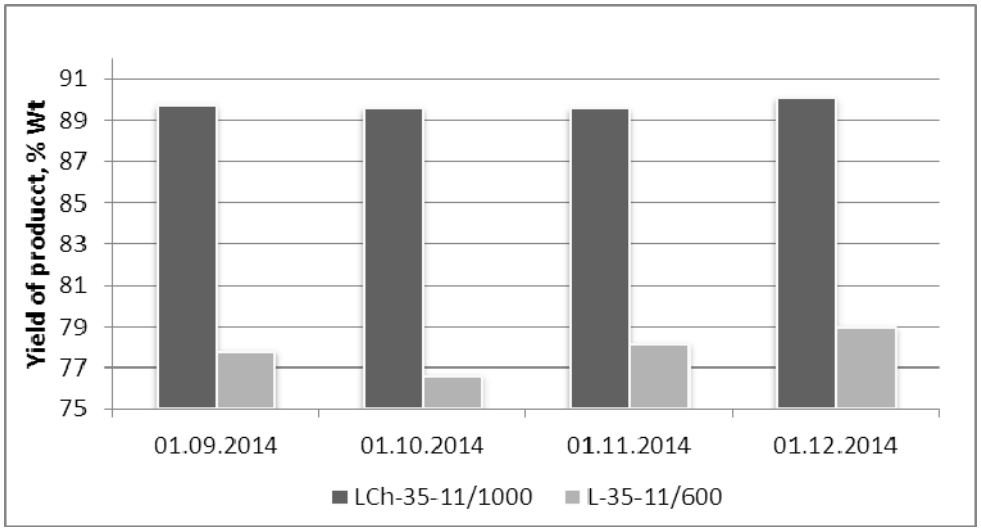

Fig.1. Calculation of yield on units L-35-11/600 and LCh-35-11/1000.

Technological parameters of the unit LCh-35-11/1000 provided low activity of the catalyst in spite of this, it possible to obtain the yield in the range of 89-90% by weight.

5 Conclusions

1. Using non-stationary mathematical model derived rate constants of chemical reactions on the catalyst RG-682 at its operation in various the reforming units.
2. Calculations yield of the objective product at the L-35-11/600 and LCh-35-11/1000.

New Chiral Catalysts of Nitroaldol Condensation

Konev V.N.*, Khlebnikova T.B., Malysheva L.V., Pai Z.P.

Boreskov Institute of Catalysis, Department of Catalytic Processes of Fine Chemical Synthesis, Novosibirsk, Russia

* Konevv@catalysis.ru

Keywords: chiral, catalysts, diterpenes, levopimaric, acid

1 Introduction

Nitroaldol condensation (the Henry reaction) is an efficient method of carbon-carbon bond formation between the nucleophilic part of the nitroalkane and the electrophilic center of the aldehyde or ketone. Thus, the Henry reaction can be considered as a convenient way for 1,2-amino alcohols and α-hydroxy acids producing. Asymmetric version of the nitroaldol condensation is carried out with the use of metal complexes containing chiral ligand.

Complexes of copper (I) and (II) with nitrogen-containing ligands are efficient catalysts of Henry reaction used for preparation of nitroalcohols from nitroalkanes and aldehydes. The work presented in the paper is devoted to the development ofthe synthesis of the new chiral copper catalysts for nitroaldol condensation containing tetradentate ligands derived from natural terpenes.

2 Results and discussion

Synthesis of chiral nitrogen-containing compounds is based on the transformations of natural optically pure levopimaric acid contained in rosin produced by coniferous trees. In our earlier work we developed procedures of the P-, N-containing ligands synthesis starting from tricyclic diterpenes, levopimaric and dehydroabietic acid[1].

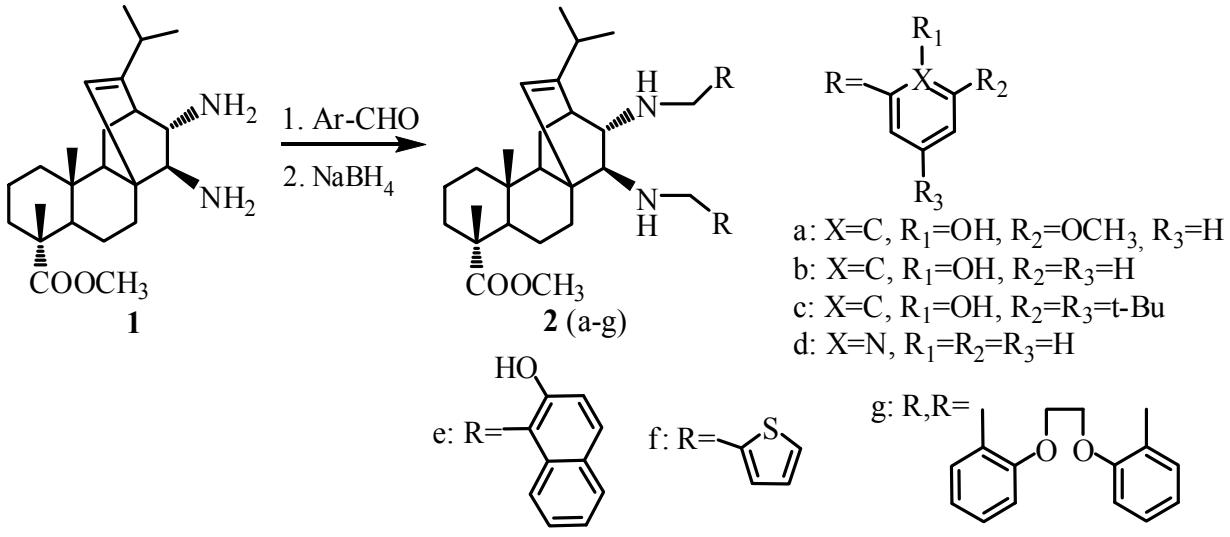

Fig. 1. The structure of the synthesized ligands

The key step in the synthesis of diterpene nitrogen-containing derivatives is the productionof trans-1,2-diamine (**1**) from fumaropimaric acid methyl ester [2]. This transformation is based on a synthetic possibilities of Curtius reaction. The new optically pure

Schiff bases were synthesized by the interaction of trans-1,2-diamine (**1)** with various aldehydes. Diastereomerically pure diamines (**2 a-g**) were synthesized by the sodium borohydride reduction of the corresponding Schiff bases. The structures of the obtained compounds is confirmed by IR, NMR, mass-spectrometry analysis.

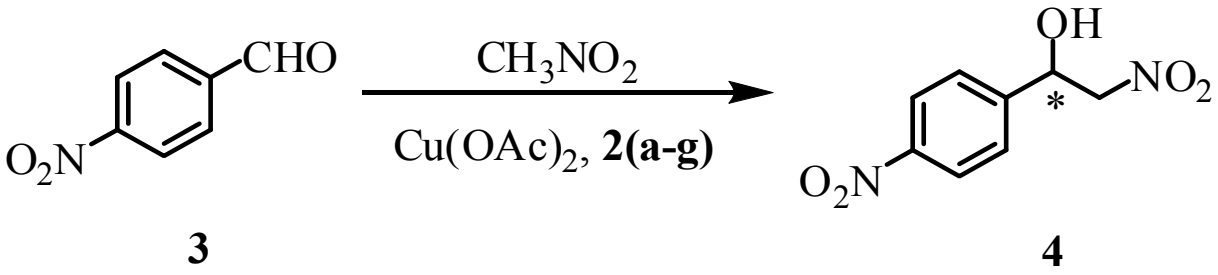

Fig. 2. Asymmetric nitroaldol condensation

Study of asymmetric induction of obtained chiral copper catalysts with tetradentate ligands **2 (a-g)** was carried out in the reaction of 4-nitrobenzaldehyde with nitromethane. Racemic mixtures of nitroalcohols were formed in the nitroaldol reaction carried out in the presence of complexes with ligands (**2 c, d, f, g**). Copper complex with ligand **2b** showed the highest activity, at that nitroalcohol **4** was formed in 98% yield and the 60% ee optical purity. The study of other derivatives of benzaldehyde showed that the aldehydes containing acceptor groups in the benzene ring are more reactive. Yields of chiral alcohols for various nitro benzaldehyde derivatives are 45 - 99%, with an enantiomeric purity of the products being from 30 to 60% ee.

3 Conclusions

Thus, we have developed and synthesized the novel chiral copper complexes with nitrogen-containing ligands, which catalyze the reaction of nitromethane with aldehydes to give nitroalcohol in yields of 45-99% and optical purity of 60% ee.

Keywords: n-octanol oxidation, silver catalysts, support, modification

1 Introduction

Selective alcohol oxidation is one of the key transformations in organic synthesis and in industrial practice. Conventional methods were based in the use of stoichiometric oxidants, which produce great amounts of undesirable subproducts. This drives the efforts made to adapt it to green chemistry principles [1], by implementing processes based on catalysis and non-toxic oxidants. Platinum group metals (PGM) have been used for this reaction, but they are costly (and possibly short supply in the future), which is a major barrier to worldwide spread of green chemical processes. Au nanoparticles (NPs) show similar or higher catalytic activity giving a new strategy to design PGM-free catalysts. One may expect that silver, as a group IB metal but less expensive than gold, could be a good alternative for designing of PGM-free catalysts for this reaction. Ag catalysts are industrially used for gas phase selective oxidation processes (ethylene epoxidation) but are much less studied for liquid-phase process.

Among all types of alcohols, unbranched primary alkanols show the lowest reactivity for selective oxidation, and very often *n*-octanol is tested as a model molecule for these [2]. Few works report catalytic oxidation of *n*-octanol on Ag-based catalysts, but in vapour phase [3]. For this reason, we selected this reaction to assess the feasibility of new "green" processes of alcohol selective oxidation using silver catalysts under very mild conditions and with clean oxidants.

This work is aimed to development of Ag-based heterogeneous catalysts for liquid phase selective oxidation of *n*-octanol. Modification of the support with transition metal additives with electron donor (La, Mg) and electron acceptor (Fe, Ce) properties was used as a tool for transforming and stabilizing silver species. Thus, the effect of support modification on the catalytic performance the active species of silver has been investigated.

2 Experimental

Titania Degussa P25 was used as base support. Support modifiers (M = Ce, La, Fe or Mg) were deposited on titania by impregnation with aqueous nitrate solution (molar ratio Ti/M = 40). Ag (nominal loading 2.3 wt. %) was deposited from $AgNO_3$ solution by deposition-precipitation with NaOH. Catalysts precursors were centrifuged and washed twice, and dried under vacuum at 80°C for 2 h, and the resulting samples were used with no further calcination treatment. Catalysts were characterized with S_{BET}, FTIR CO, XPS and HRTEM.

Catalytic tests for *n*-octanol oxidation were conducted at 80 ºC and atmospheric pressure for 6 h, using 0.1 M *n*-octanol in *n*-heptane with no base added, a molar ratio *n*-octanol/metal =100, and 30 mL/min O_2. Reactants and products were periodically analyzed by GC.

3 Results and discussion

The BET area of the support TiO_2 was reduced by modification with all modifiers: some 20% with La, Ce and Fe and 50% with Mg. However, further Ag deposition did not modified it, excepting for the unmodified TiO_2, giving similar values for all catalysts (ca. 45 m^2/g) but that with Mg (ca. 30 m^2/g). Analytical Ag content was ca. 2 wt. % for all catalysts. However the modification of the support had a strong effect on catalytic performance.

Under the conditions tested, Ag/TiO_2 catalyst showed relatively low activity (2.5% conversion with 90% octanal selectivity after 6 h). Support modification with La had no effect but that with Ce, Mg and Fe increased conversion by a factor or 5, 3 and 2.5 times, respectively. This allows grouping roughly the catalysts into two groups: A) active (Ag on Ce, Mg and Fe modified titania) and LA) little active (Ag on TiO_2 or $LaTiO_2$).

By analogy with Au catalysts [4], it was hypothesized that the active sites of silver catalysts in the selective alcohol oxidation are partly charged metal clusters $Ag_n^{\delta+}$. In fact, FTIR of CO adsorption, showed one peak at 2162 cm^{-1}, that can be assigned to $Ag_n^{\delta+}$ charged clusters, for all the active catalysts samples, in good agreement with catalytic properties. HRTEM data of active samples showed that average Ag particle sizes (7, 3 and 1 nm for Ce, Mg and Fe containing supports, respectively) parallels the order of their catalytic activity. XPS data of the most active Ce modified sample showed binding energies E_b (Ag $3d_{5/2}$) = 366.0 eV and E_b (Ce $3d_{5/2}$) = 882.0 eV, due to decoration of Ag particles with CeO_2, and E_b (O 1s) = 529.4 eV and E_b (C 1s) = 283.3 eV, respectively. Thus, XPS data demonstrate that carbonaceous deposits contain not only carbon, but consist of oxygenated carbon structures. Fe and Mg modified samples showed E_b (Ag $3d_{5/2}$) = 368.3 eV, which corresponds to Ag^0, while E_b (Fe 2p) = 711.7 eV and E_b (Mg 2p) = 51.2 eV are characteristic for oxides with reduced content of oxygen. Main carbon species for samples modified by Fe and Mg oxides are related with elementary amorphous carbon or small graphite particles (E_b (C1s) are from 284.9 to 285.1 eV).

At a variance, HRTEM and FTIR CO data of the less active catalysts did not show any Ag species formed neither $Ag_n^{\delta+}$. Their XPS characterization showed E_b (Ag $3d_{5/2}$) = 367.8 eV and E_b (O1s) = 530.0 eV both corresponding to Ag_2O, which explains the low activity of these samples. Main carbon species for these samples are also related to elementary amorphous carbon or small graphite particles.

Comparison of catalytic and spectroscopic data showed that partly charged metal clusters $Ag_n^{\delta+}$ are probable active sites of silver catalysts in the studied process. Additions of support modifying Ce, Fe and Mg oxides influence structural and electronic properties of Ag-based catalysts and stabilize these active species.

4 Conclusions

Titania supported silver catalysts shows little activity for liquid phase oxidation of octanol under the mild (and demanding) conditions tested. However, Ag catalysts activity can be increased markedly through the appropriate support modification. Partly charged metal clusters and $Ag_n^{\delta+}$ are the most probable active sites for this reaction. As a consequence, Ag catalysts supported on modified with Ce, Fe and Mg oxides titania can be a promising alternative system for *n*-octanol oxidation. Further studies are being conducted to further promoting their activity and compare it to gold based catalysts [5].

Highly Active and Recyclable Metal Oxide Catalysts for Prins Condensation of Bio-Renewable Feedstocks

Costa V.[1], Bayahia H.[2], Kozhevnikova E.[2], Gusevskaya E.[1], Kozhevnikov I.[2*]

1 - Universidade Federal de Minas Gerais, Belo Horizonte, Brazil
2 - University of Liverpool, Liverpool, UK

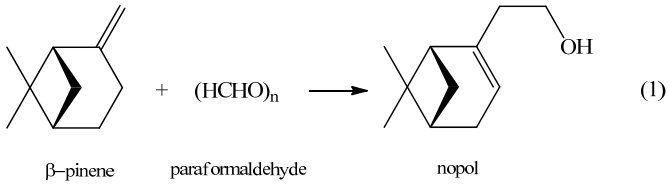
Keywords: Prins condensation, formaldehyde, beta-pinene, metal oxides, renewable feedstock

1 Introduction

Terpenes are important renewable feedstock for the perfumery, food and pharmaceutical industries. The development of sustainable chemical processes utilizing renewable raw materials with the use of environmentally benign heterogeneous catalysis is a major challenge for academia and industry [1].

Nopol is an optically active bicyclic primary alcohol used in the agrochemical industry to produce pesticides and also in soap fragrances, detergents and other household products due to its balsamic odor [2]. Nopol is generally produced by Prins condensation of β-pinene and paraformaldehyde (eq. 1) using homogeneous acid catalysts. These methods, however, suffer from severe reaction conditions, low yields and unwanted side products.

We now report that certain metal oxides such as Nb_2O_5, Cr_2O_3 and especially Zn(II)-Cr(III) mixed oxide are highly efficient and recyclable heterogeneous catalysts for Prins condensation (1). To our knowledge, little research on the use of metal oxides as the catalysts for Prins reaction has been reported so far.



(1)

2 Experimental

Experimental details on catalyst preparation and characterization (BET, XRD, Py-FTIR and NH_3 adsorption microcalorimetry) are given elsewhere [3]. Prins condensation was carried out in a glass reactor equipped with a magnetic stirrer and a reflux condenser. In a typical run, the reactor was charged with β-pinene (5 mmol), paraformaldehyde (10–30 mmol HCHO), acetonitrile solvent (5–10 mL) and a catalyst (0.1–0.5 g) and placed in an oil bath heated to 80 ^oC. The reaction was followed by gas chromatography (GC) by taking aliquots of the reaction mixture at appropriate time intervals and using dodecane as a GC standard [3].

3 Results and discussion

Fig. 1 shows the time course for reaction (1) in the presence of supported 20%Zn-Cr(1:6)/SiO_2 catalyst and bulk Nb_2O_5, Cr_2O_3 and Zn-Cr (1:6) oxides. It can be seen that the reaction is almost complete in 2 h, followed by a rather slow increase in conversion afterwards. Nb_2O_5 is the most active amongst these catalysts giving 100% β-pinene conversion in 4 h. However, it is less selective than Cr_2O_3 and Zn-Cr. In terms of the nopol yield, Zn-Cr (1:6) is the best (97%), followed by 20%Zn-Cr(1:6)/SiO_2 (94%), Cr_2O_3 (92%) and Nb_2O_5 (88%) in 10 h reaction time. After reaction, the oxide catalysts were easy to recover by filtration and reused. The Zn-Cr oxide is on a par with the best heterogeneous catalysts reported so far ([3] and

references therein). On top of that, it has the advantage of being a robust material which is easy to prepare and handle.

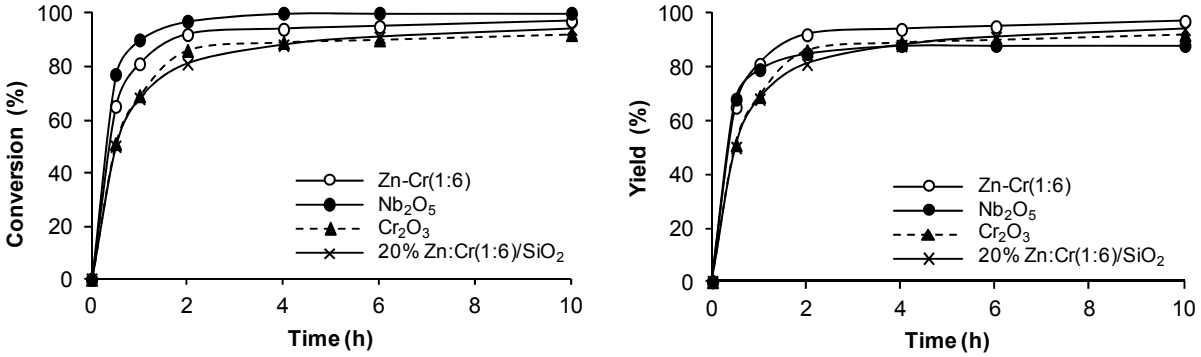


Fig.1. Conversion of β-pinene (left) and nopol yield (right) vs. time (80 ºC, 0.50 g catalyst, 5.0 mmol β-pinene, 30 mmol paraformaldehyde, 5.0 mL acetonitrile). Catalyst pre-treatment: Cr_2O_3 and Zn-Cr (1:6) were calcined at 300 ºC in N_2 for 5 h, 20%Zn-Cr(1:6)/SiO_2 at 400 ºC/N_2/5 h and Nb_2O_5 at 110 ºC/air/3 h.

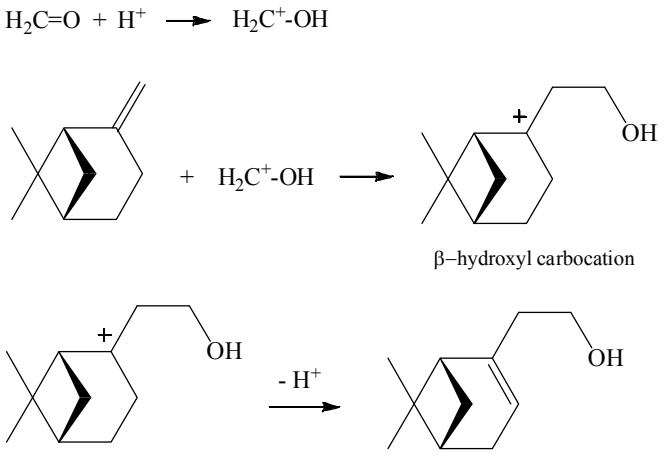

A plausible mechanism of nopol synthesis by Prins condensation (1) involves protonation of the aldehyde followed by attack on the methylene group of β-pinene to form β-hydroxyl carbocation intermediate, which undergoes proton elimination to yield nopol. The reaction therefore involves both protonation and deprotonation and is thus subject to acid and base catalysis. The acid properties of Nb_2O_5 and Zn-Cr mixed oxide were characterised by FTIR spectroscopy of adsorbed pyridine and ammonia adsorption microcalorimetry. An appropriate combination of acid-base properties of the Zn-Cr oxide is thought to be responsible for its high efficiency.

4 Conclusions

We have demonstrated that the metal oxides such as Nb_2O_5, Cr_2O_3 and especially Zn-Cr (1:6) mixed oxide are highly active and recyclable heterogeneous catalysts for Prins condensation providing a clean, high-yielding route for the synthesis of nopol by the condensation of β-pinene with paraformaldehyde. The results obtained show that metal oxides are promising environmentally benign catalysts for Prins condensation of bio-renewable feedstocks.

Keywords: multi-walled carbon nanotubes, aerogels, bimetallic catalysts

1 Introduction

Aerogels of multi-walled carbon nanotubes (MWCNTs) combine unique mechanical, thermal and electrical properties of nanotubes with specific characteristics of aerogels [1]. This material as well as MWCNT forests [2] can be more promising than conventional MWCNT powder for such applications as EMI and acoustic shielding, gas sensors and substrates for biological objects. Usually MWCNT aerogel synthesis includes MWCNT-based gel formation supplied by specific cross-linking agents and following supercritical drying [3-4]. However, One-step MWCNT aerogel production during the synthesis of nanotubes is to be more cost-efficient. Catalyst sputtering during MWCNT growth [5] and additional reactive ion etching of catalyst during synthesis of MWCNT forest [6] led to aerogel formation. In the present work, we report one-step MWCNT aerogel production via catalytic CVD technique under conditions close to industrial nanotube synthesis (T~1000 K, P~ 1 atm).

2 Experimental/methodology

The catalysts used consist of nanosized mixed metal oxides of Fe,Co Ca or Mg. Fe-Co alloy is an active component of this catalysts [7]. An activation of preformed [8] catalyst was carried out in the same conditions as following MWCNT growth (i.e. *in situ*; 670^{o}C, C_2H_4/Ar , 1:1, 400 sccm). Ethylene decomposition on the catalyst surface led to Fe, Co species reduction followed by alloy formation with subsequent nanotube nucleation and growth [9]. Catalyst structural changes and MWCNT aerogel morphology were observed with HRTEM (JEM-2010) and SEM (JSM6460LV). N_2 adsorption isotherms (77 K) were determined with ASAP-2400 (Micromeritics). Electric and magnetic polarizabilities of MWCNT aerogels were measured by open microwave resonator with a measuring hole in one of the mirrors (8-12 GHz).

3 Results and discussion

In situ activation of the preformed catalyst results in the formation of multiple nanosized active centers on the surface support particle (fig. 1B). This self-assembling system provides multi-center growth of MWCNTs. Following tangling of the MWCNTs results in the formation sponge-like and rigid structure of aerogel (fig. 1 C,D). Due to intensive MWCNT growth, a volume of resulting material significantly increases in comparison with the initial catalysts. This leads to the formation of aerogels with density of 0.03-0.08 g/cm^3. Any shape of MWCNT aerogels is possible to obtain by using different geometry of preformed catalyst (balls, cylinders etc.) (fig.2A). Pores of size >120 nm occupy >95% of MWCNT aerogel volume whereas smaller pores take up <2%. MWCNT aerogels showed polarizability intermediate to that of metal conductors and dielectrics with values close to metals while having a substantially lower weight (fig.2B).

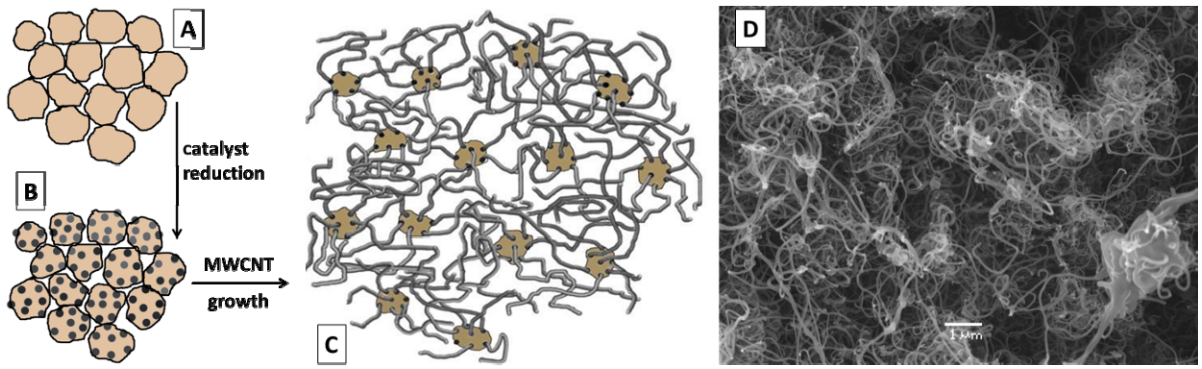

Fig. 1. A-C: A scheme for the formation of the MWCNT aerogel structure; **D:** Typical SEM microphotography of the internal structure of the MWCNT aerogel.

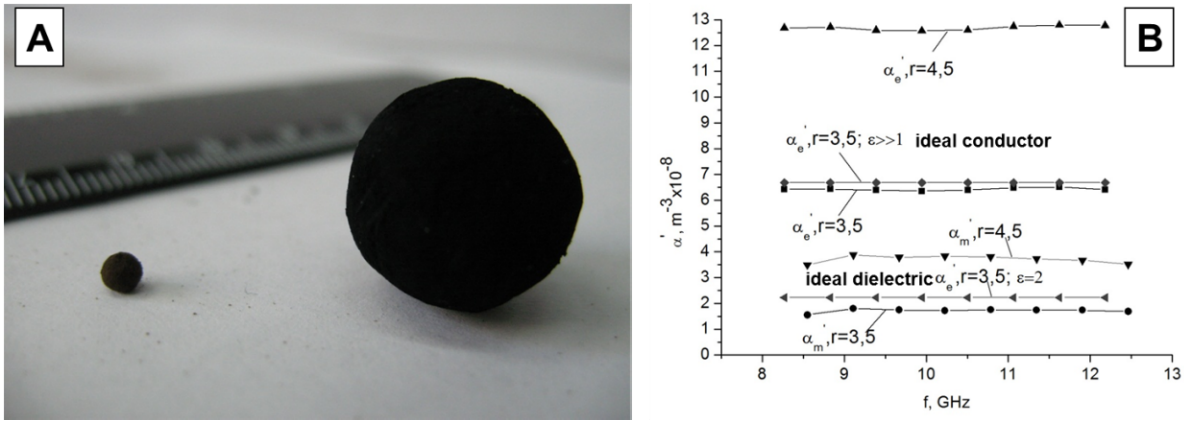

Fig. 2. A: Preformed catalyst (brown sphere on the left) and the MWCNT aerogel produced from it; **B:** Frequency dependence of real part of electrical (a'_e) and magnetic polarizabilities (a'_m) in comparison with a'_e of ideal conductor (r=3.5; ε>>1) and ideal dielectric (r=3.5; ε=2).

4 Conclusions

A new cost-efficient technique for one-step *in situ* MWCNT aerogel production under conditions close to industrial nanotube synthesis was developed. Such properties of the aerogels as S_{BET}, pore size distribution, density, conductivity and shape can be varied in a wide range. *In situ* produced MWCNT aerogels demonstrate high electrical conductivity (several S/cm), remain stable in different solvents and hold more than 2500 their weight. Due to high polarizability, MWCNT can be employed as low weight reflecting coatings. Macroporous and rigid structure combined with high surface area allow MWCNT aerogel to be promising support material for a different compounds including biological and supramolecular species.

Carbon Nanomaterials in 1,2-Dichloroethane Dechlorination and Aliphatic Alcohols Conversion. The Role of Surface Chemistry and Carbon Matrix Structure

Tveritinova E.A., Zhitnev Yu.N., Kulakova I.I..*, Savilov S.V., Maslakov K.I., Lunin V.V.

Lomonosov Moscow State University, Moscow, Russia

* inna-kulakova@yandex.ru

Keywords: carbon nanomaterials, dechlorination, 1,2-dichloroethane, conversion of alcohols

1 Introduction

The problems of environmental protection require the creation of new environmentally friendly catalysts, what must be thermally persistent, easily recycled and resistant to aggressive media. These requirements are met by carbon nanomaterials, which have a regular porous structure with a low content of micropores, the developed surface with a large number of functional groups which are important for the catalysis. They exhibit catalytic activity in processes such as oxidative dehydrogenation of ethylbenzene and light alkane [1], dehydration and dehydrogenation of aliphatic alcohols [2]. The aim of this work was to identify the catalytic activity of carbon nanomaterials with the different structure of their carbon matrix in conversion of 1,2-dichloroethane and C2-C4 alcohols.

2 Experimental

The following carbon nanomaterials we used as catalysts: detonation nanodiamond (ND), carbon nanoflakes (UNFs), including doped with nitrogen (UNFs-N), carbon nanotubes (CNTs), These materials are formed by carbon atoms in state sp^3-, sp^2 -, and curved sp^2 - hybridization, respectively. The composition of the surface functional groups of these materials was due to the conditions of cleaning after synthesis.

The surface and structure of the carbon materials were characterized using different methods: BET, DTA, SEM, TEM, XPS, XRD, TPR, diffuse reflectance IR spectroscopy.

The catalytic properties of the materials are studied using the pulsed microcatalytic method. We have studied the dichloroethane dechlorination and the conversion of all alcohols C2-C4: ethanol, 1- propanol, 2-propanol, 1- butanol, 2-butanol and t-butanol in the presence of selected nanocarbon catalysts.

3 Results and discussion

Catalytic activity in 1.2-dichloroethane conversion was exhibited only by ND, and the selectivity to ethylene was almost 100%. Regeneration of the deactivated ND-catalysts with hydrogen not only restored their activity, but also increased it. Because other carbon nanomaterials did not showed catalytic properties in the process of 1,2-dichloroethane dechlorination, we concluded that the key role in catalysis plays a "diamond" structure of ND and hydrogen groups on its surface.

In the conversion of aliphatic C2-C4 alcohols CNTs and ND showed catalytic activity in various degrees, while UNFs were inactived. The conversion of secondary alcohols (2-propanol and 2- butanol) on CNTs occurs with predominant formation of the dehydration products (propene,1- butene and 2- butene) with a selectivity of ~90%, whereas the main products of conversion on ND are dehydrogenation products (acetone and butanone). This allowed us to

conclude that the Lewis acid centers play a key role in the catalysis on the surface of the CNTs, while the basic oxygen-containing centers on the ND surface responsible for the catalysis on it.

The conversion of t-butanol on CNTs starts almost at room temperature, reaches 100% at 160^0C and proceeds with 100% selectivity to isobutene. In the case of ND the conversion of t-butanol in isobuten reaches 75% only at 300^0 C. These experimental data confirm participation in the conversion of aliphatic alcohols on the CNTs surface oxygen-containing Lewis sites and unsaturated surface C=C bonds. Catalytic centers in the conversion of aliphatic alcohols on ND are only oxygen-containing surface groups (e.g., carbonyl, carboxyl, etc.) UNFs-N, containing 10% nitrogen, exhibit catalytic activity only in the conversion of primary alcohols, and products dehydrogenization are mainly formed. This nanocarbon material was inert in the conversion of 2-propanol and 2-butanol, that allows to judge about the participation only of nucleophilic nitrogen-containing groups in the conversion of alcohols.

4 Conclusion

Metal-free carbon nanomaterials due to their unique structure and composition of surface functional groups, thermal stability and resistance to aggressive environments, as well as relatively low cost can compete with traditional metal containing and oxide catalysts. These catalysts one can consider as novel class of catalysts with large potential for industrial application.

Synthesis of CO and H_2 Conversion Nanoheterogeneous Catalysts in Disperse Systems

Kulikova M.V., Karpacheva G.P., Khadzhiev S.N.*

A.V.Topchiev Institute of Petrochemical Synthesis, RAS, Moscow, Russia

* m_krylova@ips.ac.ru

Keywords: nanoheterogeneous catalysts, Fischer-Tropsch synthesis, methanol synthesis

1 Introduction

Development of a heterogeneous catalysis is directed on creation of catalysts with most regular structure, on the directed formation on support surface of special clusters or nanodsized particles of active component now.

Along with it catalysis in disperse phase providing synthesis of catalyst nanosized particles in liquid or solid dispersion medium intensively develops.

Results of last period researches on synthesis of ultrafine and nanosized particles of CO and H2 conversion catalysts suspended in liquid hydrocarbon medium or distributed in solid organic matrix are given in report.

2 Experimental/methodology

Synthesis of nanoheterogeneous contacts were carried out by various methods in disperses media, including using organic matrix method.

Catalytic tests were carried out in fixed bed and slurry phase reactors.

3 Results and discussion

At synthesis of nanoheterogeneous contacts in liquid hydrocarbon medium nanosize stable suspensions with a size of particles no more than 50 nm were obtained. The disperse phase in such disperse systems isn't inclined to sedimentation that does them perspective for industrial realization in liquid-phase slurry -reactors.

Nanosized Fe and Co contacts prepared by method of precursor decomposition in dispersive medium are highly effective in Fischer-Tropsch synthesis. Their activity in CO conversion and liquid products specific productivity in two and more times exceeds this indicator for the catalysts which are traditionally used in slurry-reactors.

Ultrafine Cu-Zn catalysts prepared similarly allow carrying out synthesis of methanol with activity on CO conversion, equal 37% per pass, and selectivity to 98%. And change of the direction of reaction towards formation of dimethyl ether by introduction to catalyst of dehydrating component is possible.

At synthesis of nanoheterogeneous contacts distributed in solid organic matrix methods for obtaining of polymercontaining composite materials are used. Initial organic matrixes represent polyconjugated systems decomposing to carbon during formation of the catalyst. Thus particles of 10-20 nm in size metal are formed from salts immobilized on polymers.

4 Conclusions

Synthesized nanosized particles show high activity and selectivity in CO and H_2 conversion which is carried out in fixed bed or liquid-phase reactors. So, Fe and Co catalysts of this type have demonstrated extremely high activity in Fischer-Tropsch synthesis. In fixed bed reactor at

CO conversion close to 100% specific productivity by liquid products next larger than at traditional catalysts is observed.

1 Introduction

The polymerization of olefins by single-site catalysts has experienced a phenomenal growth in the last decades. Numerous highly active single-site homogeneous catalysts based on metals across the transition series have been reported. Among them metal complexes with OO-type ligands (especially where ligand structure contain both phenol and alcohol hydroxyls) are indeed unique. In recent studies, we have found the ability of lithium and magnesium compounds to promote the catalytic process due to the products of secondary coordination.

Herein, we report the synthesis of tetranuclear titanium complexes, stabilized by saligenin-type ligand – 4-bromo-2-(hydroxymethyl)-6-methoxy-phenol and their utility as polymerization catalysts.

1 Experimental/methodology

All manipulations of air-sensitive materials were performed with rigorous exclusion of oxygen and moisture in oven-dried Schlenk glassware on a dual manifold Schlenk line, interfaced to a high-vacuum line. X-ray diffraction data for the single crystals of **3** were collected using a "Bruker SMART APEX DUO" CCD diffractometer, for the single crystals of **4** – using "Bruker SMART APEX II" diffractometer. Polymerization of ethylene was performed in a 100 mL reactor (Parr Instrument Co.) equipped with a magnetic stirrer and inlets for loading components of catalytic systems and ethylene at a total ethylene and toluene vapors pressure of 0.7 atm.

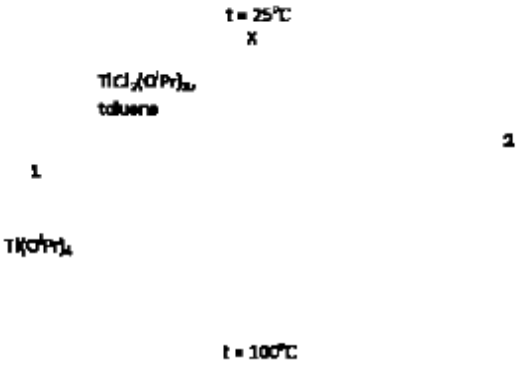
3 Results and discussion

Ligand **1** was synthesised by bromination of o-vanillin with subsequent reduction with $NaBH_4$. The ligand was treated with $TiCl_2(OiPr)_2$, but the formation of the desired product **2** wasn't occur. NMR indicated the formation of a set of complexes.

Carrying out the reaction under more severe conditions was accompanied by chemical modification of the ligand - alcoholic hydroxyl was substituted by chlorine, and compound **3** was obtained (scheme 1).

By the reaction of the ligand **1** with titanium tetraisopropoxide compound **4** has been obtained. The molecular structures of the complexes **3**, **4** are shown in Figure 1.

Pre-catalysts **3-4** were completely inactive in presence of MAO, Me_3Al or Et_2AlCl, but been activated by binary co-catalyst Et_2AlCl-Bu_2Mg, exhibited moderate to high activities toward ethylene polymerization, giving high molecular weight polymers with broad molecular weight distributions. Catalytic activity of compounds **3-4** is 2570-3000 kg of PE (mol of Ti atm)$^{-1}$ h^{-1}. The molecular mass of the polymers is 4.2 10^5-5.8 10^5; PDI – 2.4-2.8, respectively.



Scheme 1. Synthesis of titanium (+4) complexes based on ligand **1**.

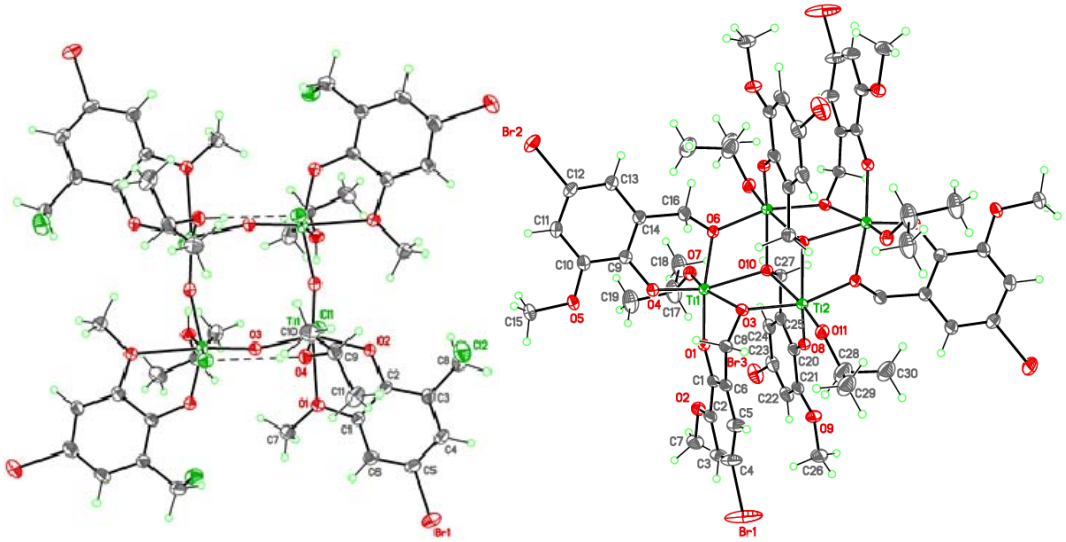


Fig. 1. The molecular structure of the complexes **3**, **4**. Atoms are represented as thermal ellipsoids (P = 50%). The hydrogen atoms are not shown.

4 Conclusions

A series of novel tetranuclear titanium complexes (**3-4**) bearing $[O,O,O]^{2-}$-type ligand (**1**) were synthesized in high yields.

We speculate that observed ability of magnesium chloride (which appears in the catalytic system as the result of the interaction of $MgBu_2$ with $2AlEt_2Cl$) to promote the catalytic process is due to the products of secondary coordination.

Further modification of these systems to enhance their catalytic performance is underway and will be reported in due course.

Keywords: aspen-wood, catalytic conversion, ethanol, zeolites

1 Introduction

In recent decades, much attention has been focused on the production of chemicals from renewable lignocellulosic biomass as an alternative to fossil fuels. Thermal conversion of biomass in supercritical aliphatic alcohols is a perspective method for obtaining low-boiling hydrocarbons. Supercritical fluids are finding an increasing application in chemical processing of plant biopolymers because they have a high diffusing capacity and low viscosity. The use of solid acid catalysts including zeolite allows to intensify the transformations of various types of lignocellulosic biomass, as well as its major components – cellulose, hemicelluloses and lignin to low molecular mass organic products.

We have previously demonstrated that the intensive pre-treatment in a activator mill AGO-2 reduces the degree of polymerization and crystallinity of aspen wood and increases its reactivity in acid hydrolysis.

The aim of this work was to study the transformations of mechanically activated aspen wood in sub- and supercritical ethanol in the presence of zeolites with different silicate module.

2 Experimental

The sample of aspen wood, which was used in this study contained (in % wt. on dry wood): 46.3 – cellulose; 20.4 – lignin; 24.1 – hemicellulose; 3.6 – soluble substances; 5.2 – extractives; 0.5 – ash. The dried wood was mechanically activated by treatment in a tensile energy planetary activator mill (AGO-2) at the acceleration of grinding bodies 600 $m \cdot s^{-2}$ during 30 min. The high silica zeolites in H-form (H-HSZ) with a molar ratio SiO_2/Al_2O_3 = 30–100 were used.

Thermal conversion of wood in ethanol was carried out in a rotary autoclave at 270 and 350 °C. These temperatures were chosen based on the results of the preliminary study of wood thermal conversion by thermogravimetric method. They correspond to two maxima of the mass loss on the DTG curve. Operating pressure in the autoclave was varied in the range of 4.0–20.0 MPa. The soluble in ethanol products was analyzed by GC-MS. The content of sugars in the water-soluble products was determined by GC. Samples of mechanically activated aspen wood and solid residues of its thermal dissolution in ethanol were investigated by IR, XRD and chemical analysis methods.

3 Results and discussion

It was established that during the conversion of mechanically activated aspen wood in ethanol medium the increase of pressure in an autoclave from 4.0 to 20.8 MPa leads to the increase of the degree of wood conversion into liquid and gaseous products from 56 and

67 wt.% to 95.5 and 76.0 wt.% at a process temperatures of 270 °C and 350 °C, respectively.

At the process temperature 270 °C in subcritical conditions, the yield of products extracted with ethanol reached to 55.2 wt.%. They mainly consist of fraction boiling up to 180 °C (60 wt. %). The growth of pressure increased the yield of products extracted by ethanol to 76.2 wt.%. Simultaneously the yield of fraction boiling above 180 °C was substantially increased. Our studies have shown that all the basic components of wood: cellulose, hemicelluloses and lignin are transformed under these conditions. Hemicelluloses was the most reactive component, while cellulose was the most stable. The growth of the pressure increases the conversion of all wood components. The degree of hemicelluloses conversion reached 100 wt.% at pressure of 15.2 MPa. At a higher pressure (20.0 Mpa) the conversion of lignin was more than 70 wt.% and cellulose – 67 wt.%.

Solid residue of aspen wood thermal conversion at 350 °C consists of coke and ash. Possibly, at this temperature, the two competing processes are occurred: the decomposition of wood components with formation of products soluble in ethanol and their secondary conversions into coke. The growth of the pressure increases the density of ethanol vapor, preventing the interaction of obtained products with the formation of coke.

The use of zeolite catalysts increases the yield of light fraction of liquid products and reduces the yield of the fraction boiling above 180 °C. The highest yield of light fraction (59.9 wt.%) was obtained in the presence of catalyst H-HSZ – 30 with Si/Al ratio 30 at the process temperature 350 °C (Fig).

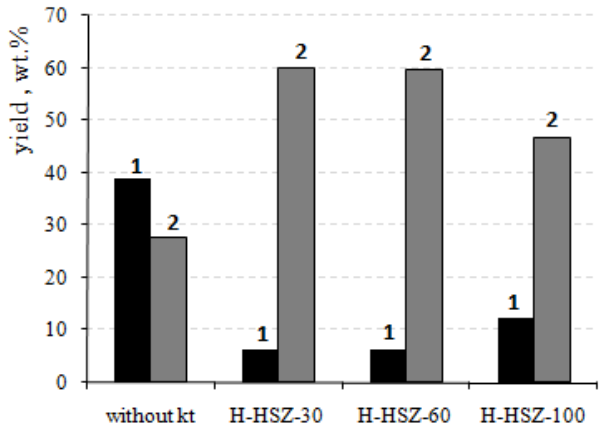

Fig. Influence of catalysts on the yield of liquid products of aspen wood thermal conversion in ethanol at 350 °C, 18 MPa: 1 – fraction b.p. > 180 °C, 2 – fraction b.p. < 180 °C

According to GC-MS data the obtained liquid products consist of several groups of substances. They are formed from ethanol, from wood components and by interaction of products of wood and ethanol conversions. Zeolite catalysts decreased the content of phenol and furfural derivatives in liquid products. While the content of the ethyl esters, especially ethyl levulinate was increased significantly in the presence of catalysts.

4 Conclusions

It was shown that the increase of pressure of mechanically activated aspen wood conversion in ethanol from 4.0 to 20.8 MPa significantly increases its conversion degree (up to 95.5 and 76.0 wt.% at a temperatures of 350 °C and 270 °C, respectively).

The use of zeolites as catalysts in this process increased the yield of liquid fraction boiling up to 180 °C by 1.7–2.2 times and reduced the yield of the fraction boiling above 180 °C by 3.2–6.3 times at a process temperature of 350 °C and pressure of 18.0 MPa.

Keywords: TiO_2 template, bio-inspired, photocatalyst

1 Introduction

Naturally occurring biological systems with complex structures, textures, and geometries can serve as efficient templates for the design and production of novel catalytic materials with extraordinary surface morphologies, shapes, and compositions [1-3]. These sacrificial biotemplates allow the synthesis of unique catalysts with complex and unprecedented hierarchical pore structures. In this contribution, we used a *Lycopodium clavatum* (LC) spore as a bio-template to synthesise a buckyball-shaped TiO_2 photocatalytic architecture with an unusual surface morphology which is not feasible to be attained by conventional bottom-up synthetic strategies. Photocatalytic degradation of Rhodamine B by UVA illumination was utilized to demonstrate the photocatalytic functionality of these bio-inspired buckyball-shaped TiO_2 structures, whose catalytic performance can be optimized by varying the relative precursor concentrations and calcination temperature.

2 Experimental

A template-assisted synthetic strategy was employed to obtain micron-sized buckyball-like TiO_2 architectures. Bio-template was coated with an inorganic TiO_2 thin film *via* sol-gel technique [3] to replicate the fine-structural details of the underlying biomaterial. Successful TiO_2 coating was performed by mixing the precursor (*i.e.*, titanium (IV) isopropoxide or TIP) with ethanol using different TIP:ethanol volume ratios (3:2, 2:1, 3:1; v/v; respectively). Calcination process was performed to remove the original biotemplate and to control the crystallinity of the TiO_2 overlayer. The photocatalytic activity of the obtained micron-sized buckyball-like TiO_2 architectures under UVA irradiation was evaluated by using the discoloration rate of Rhodamine B (RhB) dye solutions [4].

3 Results and discussion

A typical SEM image of the LC biotemplate after titanium (IV) isopropoxide deposition at 25 ^oC is presented in Figures 1a and 1b demonstrating the presence of the TiO_2-coated overlayer on the biotemplate which is also verified *via* EDX measurements. Even after calcination at elevated temperatures (*e.g.* > 800 ^oC) buckyball-shaped TiO_2 structures preserve their structural details (Figure 1c). Photocatalytic RhB degradation performance of the micron-sized buckyball-like TiO_2 architectures was examined under UVA irradiation by obtaining the apparent first-order rate constants (k′) as a function of calcination temperature and TIP loading in the precursor solution which in turn, allow the fine-tuning of the grain size and crystal structure of the TiO_2 overlayer. Bio-inspired buckyball-shaped TiO_2 structure with a TIP:EtOH loading of 2:1, v/v and calcined at 800 ^oC yielded the highest k′ value among all of the investigated micron-sized buckyball-like TiO_2 architectures. The crystallographic structure of the outermost layer for this highly efficient catalyst was composed of ~ 50 wt.% anatase and 50 wt.% rutile.

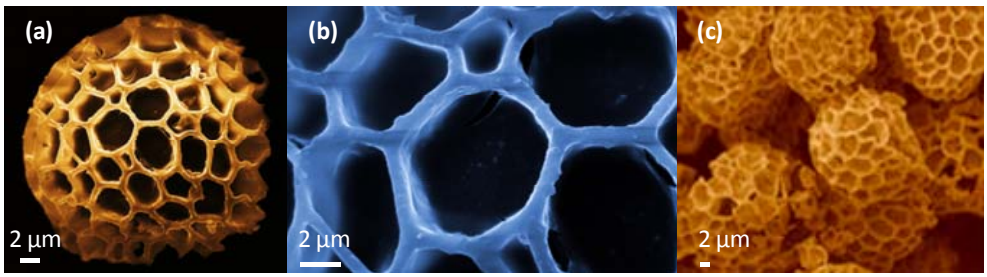

Fig. 1. SEM images of the buckyball-shaped TiO_2 photocatalytic structures.

4 Conclusions

In the current study, bio-inspired buckball-shaped TiO_2 structures were synthesized using a sacrificial template-assisted sol-gel method. We showed that by simply altering the titanium (IV) isopropoxide:ethanol volume ratio in the synthesis mixture, as well as the calcination temperature, one could fine-tune the crystal structure and the surface composition of the buckyball-like TiO_2 overlayer. It was also illustrated that the unique surface morphology and the pore structures of the LC biotemplates could be successfully transferred to the inorganic TiO_2 overlayer by effective removal of the biological scaffold. Moreover, we demonstrated the catalytic functionality of these micron-sized buckyball-like TiO_2 architectures in the photocatalytic degradation of Rhodamine B dye.

KMo Alumina Supported Catalysts for the Synthesis of Methylmercaptan from Syngas and H_2S: New Insight into the Nature of the Active Phase

Cordova A.[1], Lamonier C.[1*], Blanchard P.[1], Lancelot C.[1], Frémy G.[2]

Keywords: potassium, molybdenum catalysts, sulfide catalyst, methylmercaptan, XPS

1 Introduction

Nowadays methylmercaptan (CH_3SH) is an industrially chemical of major importance used as raw material mainly for the production of valuable organosulfur compounds such as methionine, an amino acid used as poultry feed supplement [1]. Methylmercaptan is currently manufactured at industrial scale by the reaction of methanol with hydrogen sulfide [2]. This route needs a multiple-step pathway for the synthesis of methanol, which results in raised costs of production. The development of a new route using a simple feedstock (syngas/hydrogen sulfide) is then increasingly attractive for industrial application. The production of methylmercaptan from the one-step reaction of syngas and hydrogen sulfide has been studied since 1980s. Its production at laboratory scale is usually carried out using K-Mo based catalysts with alumina [3] or silica as carriers [4]. Looking at the earlier works concerning the synthesis of methylmercaptan, most of the researches have been focused in the development of efficient catalytic systems and the determination of the reaction mechanisms starting from $CO/H_2/H_2S$ or $COS(CS_2)/H_2$ reactants [5]. Concerning active phase determination, a Mo^{6+}-S_x-K^+ phase was first proposed as active phase using $CO/H_2/H_2S$ mixture [6] but the exact nature remains unclear. In this work, the nature of the active phase has been studied as well as the improvement of catalytic performances.

2 Experimental/methodology

Mo and various K(Na)Mo catalysts with fixed metal amounts (8.1 Mo wt%, 6.6 K wt.%) were prepared by incipient wetness impregnation method using ammonium heptamolydate, (AHM), potassium nitrate, $K(Na)_2MoO_4$ and K_2MoS_4 solutions impregnated on alumina support. The catalysts performance was evaluated in a fixed-bed flow reactor under reaction conditions of 10 bars, temperature range 280-300-320 °C, feed gas composition $CO/H_2/H_2S$ = 1/2/1 (v/v) and GHSV = 1333 h^{-1}. Reactants and products were analyzed by on-line GC. Prior to testing, the catalysts were activated in-situ by sulfidation. Before activation, catalysts were characterized by elemental analysis (ICP), BET, XRD, Raman spectroscopy and XPS. An extensive study of Mo sulfided catalysts was performed by XPS and TEM.

3 Results and discussion

In K_2MoO_4 and K_2MoS_4-based catalysts, the preservation of the impregnated species was observed by Raman and XPS. These species precipitate inside the porosity during their incorporation, leading to crystallized species whereas a good dispersion of Mo species was observed using AHM based solutions. The catalytic results showed that the simultaneous presence of Mo and K in the catalytic system allowed to achieve higher CO conversion and

CH_3SH selectivity and a decrease in CO_2 selectivity, highlighting the favorable influence of the coexistence of both metals in the catalytic system. The incorporation of K and Mo coming from a unique precursor was beneficial when considering catalysts time and costs preparation.

A careful XPS analysis of potassium containing sulfide catalysts (fig 1.) brings out the presence of a new molybdenum sulfide phase with an unusual Mo3d (K-Mo^{4+}(S)) binding energy coexisting with classical 2H-MoS_2 (Mo^{4+}(S)). Taking into account literature data on intercalated Li_xMoS_2 material, this phase is assumed to be a potassium intercalated phase K_xMoS_2 in which potassium can stabilize the unusual 1T-MoS_2 phase with octahedral coordination of Mo. It is proposed for the first time for supported catalysts.

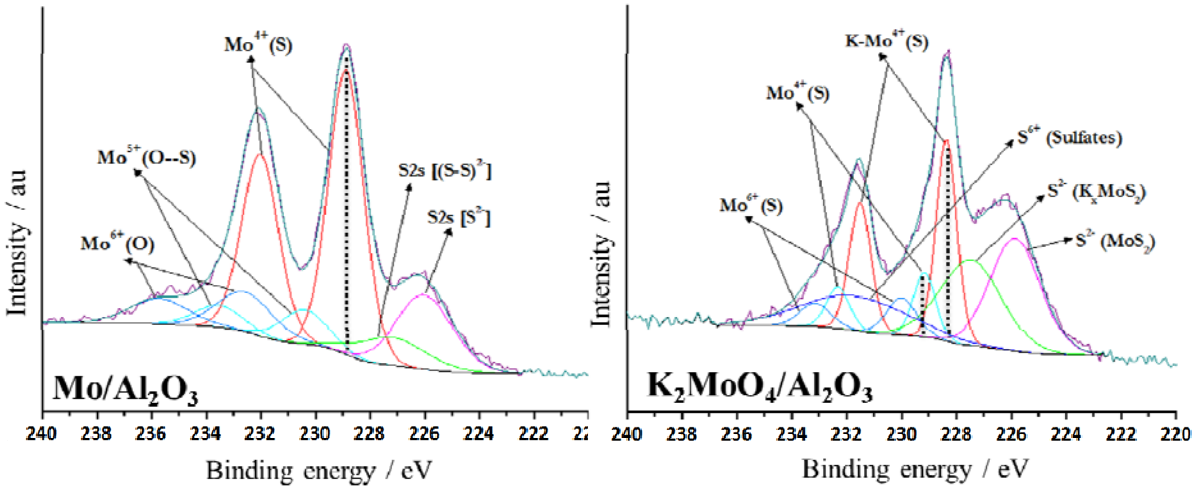

Fig 1. Mo3d XPS spectra for Mo/Al_2O_3 and K_2MoO_4/Al_2O_3 sulfide catalysts

Moreover a good correlation has been obtained between the relative amount of intercalated K_xMoS_2 and CO conversion as well as CH_3SH productivity taking into account the quantity of molybdenum detected by XPS. The study by HRTEM of these samples suggested that intercalation of K on MoS_2 phase has an effect over the slab length and stacking degree of MoS_2 layers.

4 Conclusions

The presence of an intercalated K_xMoS_2 has been shown for the first time in supported KMo sulfide catalysts. By correlating the amount of this phase with the catalytic performances, we observed that the higher the amount of K_xMoS_2 in the catalyst, the higher the CO conversion and CH_3SH productivity in the reaction of syngas with hydrogen sulfide. Based on these statements intercalated K_xMoS_2 is proposed as the active phase in the reaction of thiolation of syngas. Catalytic performances can be improved by changing the support and increasing the Mo loading.

Investigation of Palladium Catalysts Supported on Highly Porous Cellular Metal Carriers

Laskin A.*, Kirgizov A., Ilyasov I., Lamberov A.

Kazan (Volga region) Federal University, Kazan, Russia

* artemka166@mail.ru

Keywords: selective hydrogenation, highly porous cellular metal support

1 Introduction

Industrial purification of ethylene and propylene processes for further polymerization carried out by selective hydrogenation in the gas phase in the reactors with irregular granular catalyst bed. Catalyst is a palladium, dispersed on the alumina surface, in the form of spheres, cylinders or other geometries, which characterized by insufficient heat- and mass transfer in the catalyst bed. Poor thermal conductivity of the inorganic carrier causes the formation of local overheating in the granular bed, which leads to a change in physical properties (density, viscosity) of the hydrocarbon stream with an increase its uneven distribution over the cross section of the reactor and the subsequent deterioration in the running of the catalyst. Formation of local overheating with increasing temperature of the recommended technological regime also cause reactions of deep hydrogenation of acetylene and diene hydrocarbons to alkanes and oligomerization processes, leading to a decrease in the selectivity of the main components and the rapid deactivation of the catalyst, respectively. Large grain diameter of catalyst, usually more than 3 - 2 mm, is not provide good mass transfer of the starting components and reaction products resulting from diffusion limitations associated with the location of the active component in a depth granules. This leads to inefficient use of the active component and the deep side reactions hydrogenation of acetylene and diene to the alkane hydrocarbons with decreased catalyst activity and selectivity. Reducing the size of the grains of the catalyst to reduce the adverse effects of diffusion limitations with the increasing availability of the active component to the reacting molecules causes the growth of hydraulic resistance with disabilities improve productivity of industrial reactors.

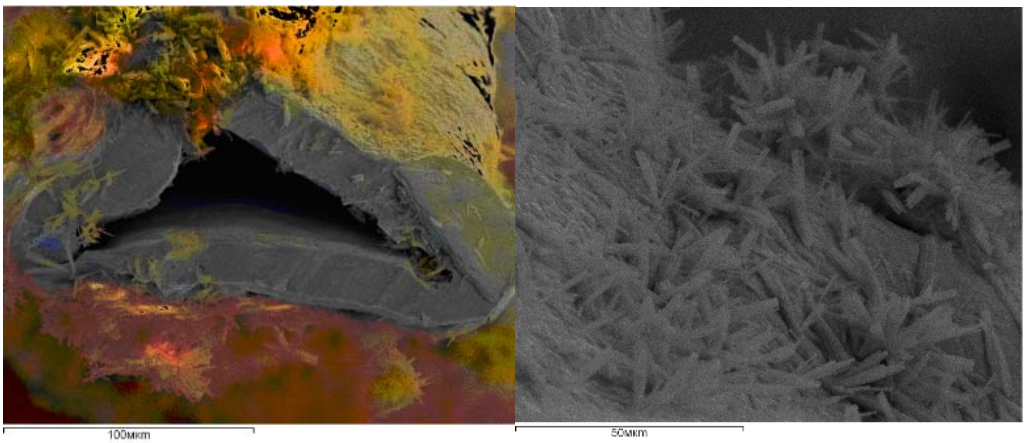
2 Experimental/methodology

Traditional alumina carrier was obtained by calcining boehmite extrudates in air at 550 ° C (2 h). On nickel HPCM obtained elktrochemically deposition metal coated with aluminum hydroxide by reacting with nitric acid. Calcining the resultant composite is further led to the formation of secondary aluminum oxide layer. Catalysts were prepared by impregnating the respective adsorption of carriers benzene solution of palladium acetylacetonate, followed by drying at 100 ° C and calcination at 300 ° C for 2 hours. The concentration of active component in the finished catalyst was 0.5 weight%.

The surface area (BET), volume, pore size and pore size distribution (BJH) of carriers was determined by nitrogen sorption (Autosorb iQ, Quantachrome, USA) -195,7 ° C. X-ray diffraction of carriers (XRD) was carried out on diffractometer XRD 7000S (Shimadzu) using a long-wave radiation CuK_α (λ = 1,54187Å). Image scanning electron microscopy (SEM) were recorded on MERLIN by Carl Zeiss Microscopy. IR spectra were obtained at a temperature of - 83 ° C in the Fourier spectrometer Bruker Vertex 70. Temperature program reduction (TPV) samples and dispersion of palladium measured by CO chemisorption was performed on an automated chemisorption analyzer AutoChem 2950 HP (Micromeritics, USA).

3 Results and discussion

A highly porous cellular composite material based on nickel (HPCM) is a reticulate structure with a honeycomb cell size of 2 mm, a width of the webs formed by nickel of 200 micron, which is fixed γ-Al_2O_3 layer thickness of 20 microns (Fig.1).



a b

Fig. 1. SEM picture: a - jumper HPCM, b - the surface of the composite HPCM

Alumina produced on the surface of Ni-HPCM is different in morphology and texture characteristics of γ-Al_2O_3, synthesized without the substrate, which is associated with a variety of textural and morphological properties of their precursors - aluminum hydroxides. Specific surface area for γ-Al_2O_3/Ni-HPCM is 319 m^2/g, total pore volume is 0.135 cm^3/g, and for γ-Al_2O_3 is S = 108 m^2/g, pore volume is 0.29 cm^3/g.

Various methods for the synthesis of oxide structures are responsible for the differences in the characteristics of the acid sites of the two carriers, that confirmed by data TPD of ammonia. Subsequent application of a palladium salt on γ-Al_2O_3/Ni-HPCM and conventional γ-Al_2O_3 according to IR spectroscopy of adsorbed carbon monoxide lead to the formation of palladium particles, varying in diameter and charge state. For palladium particles supported on γ-Al_2O_3/Ni-HPCM characterised more uniform particle size distribution and the electronic states (d_{av} = 4.6 nm, D = 24,5 %), than for the conventional alumina (d_{av} = 2.8 nm, D = 39,5 %). Greater interaction force inflicted Pd precursor to the surface acid sites of conventional alumina support γ-modification compared to γ-Al_2O_3/Ni-HPCM systems, determine the high dispersion of the active component and a wide range of charge state confirm TPR results in hydrogen.

Smaller values of selectivity conversion of acetylene hydrocarbons for catalysts based on conventional γ-Al_2O_3 compared with samples of γ-Al_2O_3/ Ni-HPCM due to the presence of large crystallites of palladium and the metal particles are characterized by the presence of surface atoms of the active component with low electron density on the valent orbitals.

4 Conclusions

In order to assess the possibility of use as a highly porous medium permeable to the cellular material coated on its surface alumina hydrogenation catalyst investigated the effect of the texture, and morphologic characteristics to its acidic properties and catalytic properties of palladium particles deposited by the reaction of hydrogenation of acetylene hydrocarbons. The formation of a narrow range of charge states of palladium particles deposited by surface atoms that are characterized by a high electron density on the valent orbitals catalysts Ni-based HPCM, determines a higher selectivity of the conversion of acetylene hydrocarbons (S = 78,3%) as compared with the conventional catalyst (S = 42,6%), was synthesized using γ-Al_2O_3.

Aqueous Phase Hydro-deoxygenation of Glycerol towards One-step Production of "Green" Propene

Lemonidou A.A.[1,2*], Zacharopoulou V.[1], Vasiliadou E.S.[1]

1 - Department of Chemical Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece
2 - Chemical Process & Energy Resources Institute, CERTH, Thessaloniki, Greece

* alemonidou@cheng.auth.gr

Keywords: green propene, biomass conversion, molybdenum, oxides, glycerol, hydro-deoxygenation

1 Introduction

The demand for propene, a valuable olefin, has increased significantly over the past years, especially for the production of plastics (polypropylene). The majority of olefins are produced via steam cracking, one of the most energy-consuming industrial processes, resulting in particularly high CO_2 emissions. In addition to the arising environmental concerns, the finite natural resources address the significance of innovative procedures, utilizing renewable and sustainable resources, as raw materials. [1] Over the past decade, biomass has received considerable attention, as technological advances enable the development of inventive processes for the production of valuable bio-chemicals and bio-fuels, substituting the finite natural resources. Glycerol, one of the 12 top building block chemicals derived from biomass, is a readily available, low-cost molecule that can be upgraded to high added-value products; the production of lower hydrocarbons from glycerol has recently been explored, promising catalytic glycerol conversion to alkanes and alkenes, such as ethane and propane. [2] Complete glycerol de-oxygenation, along with the formation of a C=C bond in a one-step process, is a challenging path; complete oxygen removal could lead to propene formation, linked with a succeeding notable increase in product value. Within this context, a novel "green" propene production method has been developed using biomass-derived feedstock: propene can be selectively formed via one-step glycerol hydro-deoxygenation reaction (HDO), over Mo-based catalysts. [3]

2 Experimental/methodology

Mo (20.8% wt) and Fe-Mo catalysts (Mo: 19.3 & Fe: 2.7 % wt), supported on commercial carbons, were synthesized by combining wet impregnation and co-precipitation methods [2]. Samples were characterized using BET, XRD and TPD NH_3 techniques. Prior to their evaluation, catalysts were pre-reduced at 500ºC, under H_2 flow. Glycerol HDO experiments were conducted in a batch reactor; the typical reaction conditions were: 300°C temperature, 8.0 MPa H_2 pressure, 2.0 w/w % aq. glycerol solution and 2h reaction time. Products of both gas and liquid phase were analyzed offline, using Gas Chromatography (GC).

3 Results and discussion

This research subject focuses on the investigation of the various parameters affecting the catalytic performance of glycerol conversion to propene via HDO reactions; this novel research subject has not yet been thoroughly explored in the open literature. Hence, the present work is an initial attempt to cope with the above-mentioned issues and comprehend the intricate reaction pathways. Propene can be effectively produced through glycerol HDO; reaction product distribution confirms that propene is the main reaction product (100% selectivity in the gas phase), with overall selectivity values up to 75.0%, after a six-hour reaction (88.8% glycerol conversion). [3]

The partially reduced MoO_2 is considered the active phase of the reaction providing bi-

functional properties (metallic-acidic function) and thus, enhancing consecutive dehydration-hydrogenation stages. In order to investigate the various HDO reaction steps, experiments were performed using all the major liquid products of the reaction as a feed: 2-propenol, 2-propanol, 1-propanol, propanal, propylene glycol and 1,3-propanediol. 2-Propenol, as well as 2-propanol, reacts selectively towards propene formation. Propylene glycol is primarily converted to propanal, as well as to propanols, while 1,3-propanediol and propanal to 1-propanol. The reactant activity order, based on propylene formation rate, is the following: 2-propenol>>2-propanol>propylene glycol>>1-propanol>1,3-propanediol>propanal. According to product distribution of the above-mentioned experiments, successive dehydration-hydrogenation stages are proposed; following the key reaction path, glycerol can be initially dehydrated to acrolein and then the latter can be hydrogenated to 2-propenol (reduction of the carbonyl group), which is finally converted to propene (loss of oxygen while preserving the C=C double bond) through a dehydration/ hydrogenation stage (Figure 1). Alcohol dehydration is a parallel, secondary step towards the formation of the desired product, substantiated by the significant 2-propanol conversion to propene.

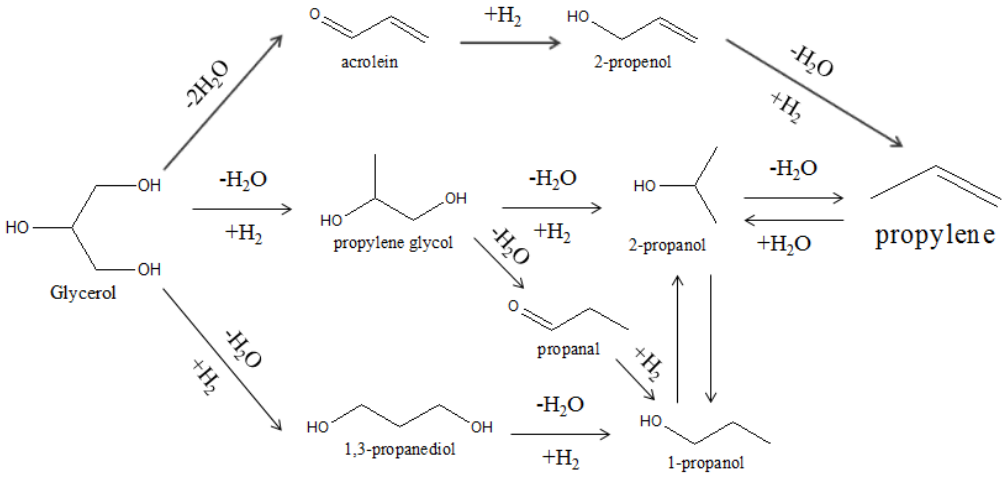

Fig. 1. Glycerol Hydro-deoxygenation Reaction Pathways

4 Conclusions

Glycerol HDO towards propene formation is a novel, alternative and environmentally-friendly chemical process, promising substantial contribution into meeting the increasing demand for propene, worldwide. Catalytic results of this study validate that this innovative method can lead to propylene production via HDO reactions, using biomass-derived feedstock. Propene is primarily produced via the acrolein-2-propenol route via sequential dehydration/ hydrogenation steps.

1 Introduction

CO_2 is the main global warming potential (GWP) greenhouse gas with 50~60%. Direct influence on environmental and green-house effects has become an important issue for environmental protection all over the world [1]. The direct synthesis of dimethyl carbonate (DMC) from CH_3OH and CO_2 has attracted considerable attention. DMC has been used as a green chemical and an alternative to corrosive and toxic reagent. Therefore, the direct synthesis of DMC is an effective way to solve environmental pollution [2]. Due to its high mixing octane number (105), excellent compatibility with hydro-carbonates and high amount of O_2 in the molecule (3 times than methyl-tert-butyl ether) can reduce the emission of off-gas after adding it to gasoline/petroleum. DMC becomes an important additive of gasoline/fuel oil due to its many advantages nowadays [3].

2 Experimental

In order to eliminate the mineral impurities, the commercial activated carbon (AC) was first treated with H_2SO_4 aqueous solution. Cu–Ni/AC catalyst with the metal loading were prepared by an incipient wetness impregnation in which $Cu(NO_3)_2 \cdot 3H_2O$ and $Ni(NO_3)_2 \cdot 6H_2O$ were impregnated on supports. The V-Cu-Ni/AC catalyst was prepared by co-impregnation using aqueous solutions containing NH_4VO_3. After the co-impregnation, the mixtures were stirred at ambient temperature, ultrasonicated, and aged, followed by drying at 90°C. The fully dried product was crushed carefully in an agate mortar to give the catalyst precursors, which were then calcined at 500°C in a N_2 flow, and further reduced in a H_2 flow at 500°C.

3 Results and discussion

Figure 1 shows the XRD patterns of Cu–Ni/AC and V-Cu-Ni/AC catalysts with different V contents. For all catalysts, the broad and weak peaks at around 2h = 23° were attributed to the characteristic diffraction of AC. The intensity and the width of C dispersion characteristic peak varied versus different contents of V. Two peaks at around 2h = 43° and 50° were assigned to be the diffraction of Cu-Ni alloy, while a peak located at 2h = 75 degree was believed to be due to the Ni species. New diffraction peaks were detected at 2h = 24.2°, 26.6°, 32.9°, 53.7° due to the increase of V content. The dispersion of active metal particles on the surface of the support is crucial to enhance the catalytic activity. As further disclosed in FE-SEM of Fig. 1 for the V-Cu-Ni/AC catalyst, the brighter gray portions corresponded to AC support, whereas the darker dots were the catalyst particles. It was evident that the active metal particles were well dispersed on the surface of the catalyst support. The primary particle size estimated from the FE-SEM micrographs were observed in the range of 10-40 nm.

Figure 2 shows the NH_3-TPD profiles of Cu-Ni/AC catalysts with V contents. It was found that desorption peak area of the Cu-Ni/AC catalyst was higher than those of V-Cu-Ni/AC

catalysts. Moreover, desorption peak areas of V-Cu-Ni/AC catalysts decreased obviously. These results indicated that V addition resulted in a decrease of surface acidity of catalyst.

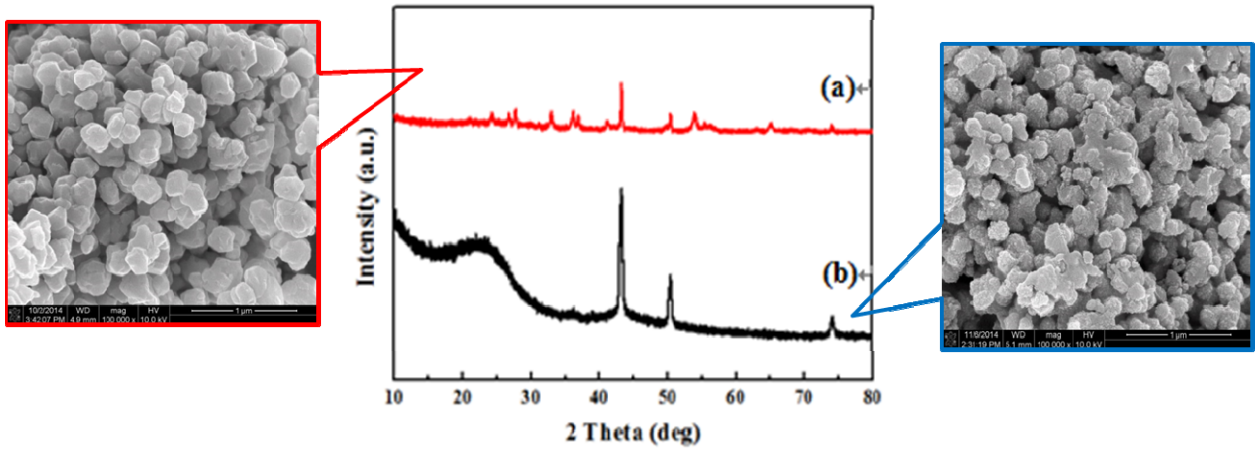

Fig. 1. XRD patterns of (a) V-Cu-Ni/AC and (b) Cu-Ni/AC.

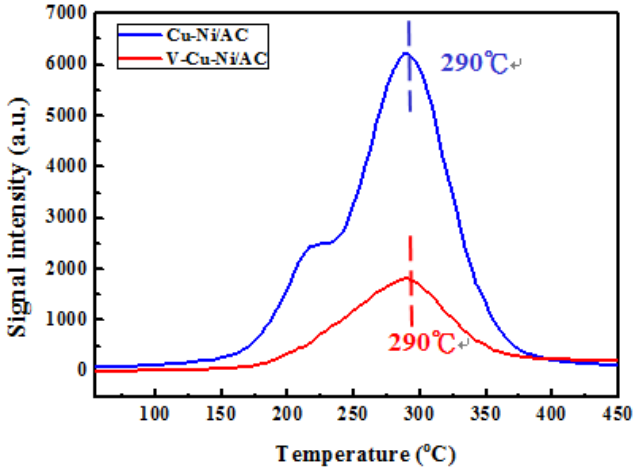

catalyst	reaction results	
	methanol conversion (%)	DMC yield (%)/mmol
Cu-Ni/AC	6.44	5.62
V-Cu-Ni/AC	7.76	6.98

Fig. 2. NH_3-TPD curves of Cu-Ni/AC and V-Cu-Ni/AC.

4 Conclusions

The particle sizes and aggregation effect increased and appeared after adding V_2O_5. The particle size of Cu-Ni/AC and V-Cu-Ni/AC catalysts were about 10~40 nm. The compositions and d-spacing of Cu-Ni/AC and V-Cu-Ni/AC were confirmed by XRD patterns and TEM micro-images successfully. The NH_3-TPD indicated that V addition resulted in a decrease of surface acidity of catalyst. A good correlation between catalytic activity and acidity (acid amount) was found in NH_3-TPD. V-Cu-Ni/AC catalyst could be readily prepared and applied in the direct synthesis of DMC from CH_3OH and CO_2. The experimental results showed that V could effectively improve the catalytic activity and the selectivity of catalysts.

Effect of Microemulsion-Synthesized Support in the Aqueous Phase Reforming Reaction of Glycerol

Lombardi E.*, Basile F., Fornasari G., Mafessanti R., Vaccari A.

University of Bologna, Dep. of Industrial Chemistry, Bologna, Italy

* erica.lombardi@unibo.it

Keywords: microemulsion, aqueous phase reforming, glycerol

1 Introduction

Glycerol has been studied intensely in the last years due to its high potential availability both to produce fuels and to transform it into high valuable platform molecules. Within different approaches the Aqueous Phase Reforming reaction (APR) represents a valuable pathway to obtain liquid products and hydrogen, with the main products depending on the reaction conditions and catalyst [1]. The most used catalysts for this type of reaction are VIII group metals supported on oxides. Several studies have analyzed the effect of alloying of different metals or modifying the acid/basic sites of the support, whereas little attention has been devoted to the control of the support morphology and the metal dispersion and accessibility.

The present study is focused on the analysis and enhancement of the APR reaction modifying the reaction parameters and studying a Pt based catalyst supported on TiO_2 synthetized by water in oil microemulsion technique [2]. Microemulsion synthesis of oxides, compared to other traditional pathways (i.e. precipitation and co-precipitation), allows a better control of the parameters of reaction, so the obtainment of nanocrystals with controlled porosity and morphology and, in case of particular mixed oxides, a peculiar crystalline phase.

2 Experimental

TiO_2 was synthesized optimizing a method reported in literature [3] by mixing an acid-containing water-in-oil microemulsion with a solution of organics containing the titanium precursor. The obtained microemulsion under stirring allowed the slow hydrolysis to form the oxide. The reaction was completed and the solid extracted from the micelles by heating at reflux temperature. The oxide was than calcined and impregnated with different metal loadings of Pt.

APR reactions were carried out in a 300ml stainless steel Parr autoclave loaded with 17,1% wt. glycerol in water solution and 0,45g of catalyst. Temperature and time were set in the range 200-250°C from 30minutes to 7h and under autogenous pressure. Liquid products were analyzed by HPLC with RID detector and gas products by GC equipped with TCD detector.

3 Results and discussion

Characterization data of TiO_2 obtained by microemulsion (TiO_2-m) were compared with a commercial sample. The former method shows a higher surface area ($200 m^2/g$) and progressive size and shape pores (type H2 hysteresis) with narrow distribution of the pore diameter. In contrast, the commercial sample presented slit shaped pores (type H3) and wider distribution of pore diameter confirming that microemulsion synthesis allows a more homogeneous support preparation and a better control of pore dimension. The TEM image (Fig.1) shows as a result a very small and narrow distribution of the Pt particles supported on TiO_2-m.

The synthesized catalysts were tested in the APR reaction of glycerol. TiO_2-m showed

higher yields (2,5% H_2 yield) than the commercial (1,5%) at 1% wt. Pt loading after 3h of reaction at 250°C, evidencing the importance of the support preparation in the APR reaction.

The Pt/TiO_2-m catalyst was applied for a wide study of APR reaction with extended liquid and gas product analysis and modifying the reaction parameters. Temperature effect on the reaction indicates after 3h a small glycerol conversion (9%) and hydrogen productivity (0,24mol/h*g^{Pt}) at 200°C with Pt/TiO2-m 1% wt. catalyst. Increasing the temperature at 225°C and 250°C leads to conversions up to 12% and 51%, but in both cases H_2 productivity was respectively 0,7 and 1,3mol/h*g^{Pt} with increasing selectivity towards liquids: propylene glycol lactic acid, hydroxyacetone, and 1-propanol accounting for the 90% of the products in solution.

A change on Pt/TiO_2 metal loading from 1% to 3% wt. produced at 225°C an increase in conversion from 12 to 31% with a rate proportional to the amount of metal. The same trend was not observed on the 3% wt. Pt on commercial TiO_2, which shows lower performances. These data indicate that the TiO_2 prepared by microemulsion allows high dispersion and accessibility of the Pt even at high metal loading. The observation is confirmed by TEM analyses showing the metal particles between 1-2nm for both the 1% and 3% wt. Pt catalysts. At 250°C the increase in metal loading leads to a conversion of 73% with a hydrogen productivity of 0,68mol/h*g^{Pt} with a significant enhancement of yields in the four main liquid products.

A study on the mechanism of reaction and liquid products was performed at 225°C using different times of reaction and solutions containing to 5,7% wt. of glycerol to enlighten the trend of the primary and secondary products in a wide range of glycerol conversion. Primarily, the conversion increases constantly up to 7h of reaction. In the gas phase H_2 selectivity decreases slightly during reaction while CO_2 and CH_4 remain constant; on the other hand, the production of light hydrocarbons as ethane and propane increases with the time of reaction. Liquid phase primary product from dehydration reaction is hydroxyacetone (in accordance with [4]) that leads to secondary products with high yields as propylene glycol and 1-propanol. Moreover, the dehydrogenation of the primary hydroxyl group of glycerol through an aldehydic intermediate gives ethylene glycol by C-C cleavage and lactic acid by rearrangement as primary products; the latter further decarboxylated to ethanol. No products were observed for the possible dehydration of the secondary hydroxyl group of glycerol, probably due to the adsorption mechanism favoured by small dimension of Pt particles.

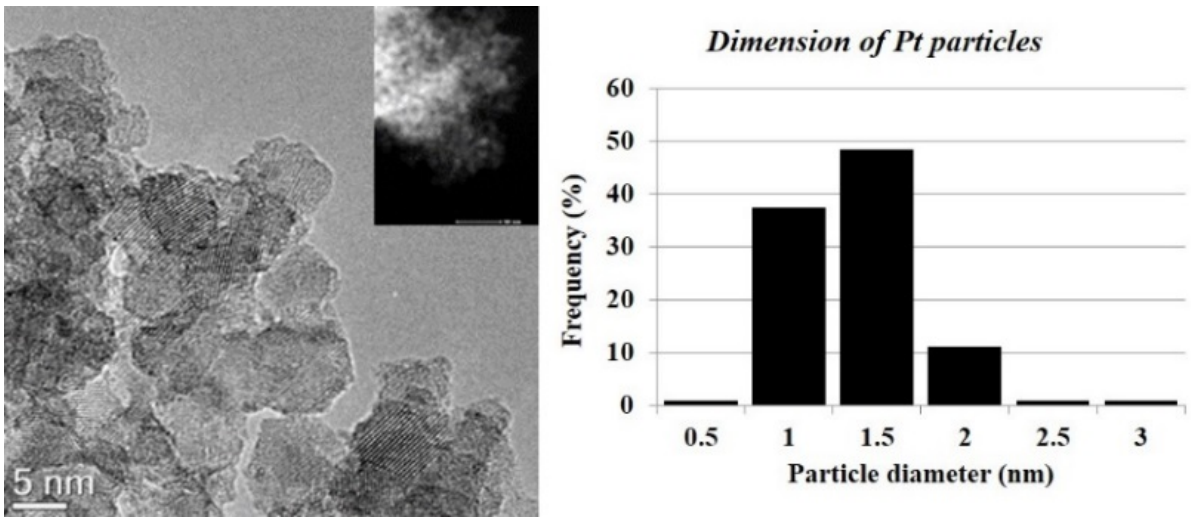

Fig. 1: TEM images of Pt dispersion on TiO_2-m and STEM-HAADF image of the porous structure of the support (left); Pt particles dispersion on the surface (right)

4 Conclusions

The application of microemulsion synthesis of TiO_2 in APR is beneficial to conversion of glycerol, H_2 productivity and selectivity in liquid products. The study on the reaction conditions

and the complete identification of liquid and gas products allow to indicate two main pathways (dehydrogenation and dehydration) leading to different products. This is the base to address the APR reaction towards platform molecules in the liquid phase.

Keywords: hydrogenation, (Z)-3-hexene, nickel, modified alumina, 3-hexyne

1 Introduction

The selective hydrogenation of internal alkynes for Z-alkene stereoisomers is applicable in the petrochemical and pharmaceutical industry. Nickel catalysts are still an interesting alternative low-cost compared with Lindlar or Pd catalysts [1]. This paper evaluates the activity and selectivity of a Ni 1% catalyst in the selective hydrogenation of 3-hexyne modifying the alumina support with a 5 and 10% magnesium precursor with excellent results in conversion values (ca.100%) for the reaction time considered.

2 Experimental

Due to the low values of solubility of Mg salt in water the preparation of the catalysts was performed by successive impregnations of the alumina support with a magnesium salt solution ($MgS0_4.7H_2O$) for obtaining 5 or 10 % of MgO. After each impregnation, the sample was dried in an oven approximately 18h , cooled in the desiccator 30 minutes, and calcined 3 h at 823K. These modified supports were impregnated with a 1% wt nickel nitrate precursor salt solution of $[Ni(NO_3)_2.\ 6H_20]$, dried in oven at 1273K, cooled down in a desiccator for 24 h and calcined 3h at 823K. Previously to each catalytic test, the samples were reduced 1h at 673 K.
The concentration of Ni and Mg were checked by ICP in OPTIMA 21200 Perkin Elmer equipment. The electronic state of the metals, and the atomic ratios was studied by X-ray photoelectron spectroscopy (XPS) on a VG-Microtech Multilab Equipment. C 1s signal was used as a reference.

The catalyst evaluations were carried out in a semicontinuous stainless steel stirred tank reactor equipped with a double helix stirrer, using 75 mL of a 2% (v / v) 3-hexyne in toluene solution. The tests were conducted using the following conditions: 1.5 bar of hydrogen pressure, reaction temperatures 303 and 323 K; 800rpm, catalyst mass 0.3 g, particle size 60-100 mesh during 200 min. The reactants and products were analyzed by gas chromatography using a flame ionization detector and a capillary column PRO GS-GAS.

3 Results and discussion

Table 1. shows the Ni $2p_{3/2}$ binding energies (BE) for the monometallic nickel catalysts reduced at 673 K, and the Ni/Al and Mg/Al atomic ratios. Accordingly to the bibliography these BE can be assigned to electro-deficient nickel species (Ni^{n+}, with n close to 2), probably interacting with alumina [2]. The BEs of Mg modified monometallic catalysts are slightly higher than the unmodified catalyst, attributed to an electronic effect due to the higher electronegativity of Ni.

In Figure 1 shows the total conversion of 3-hexyne vs. time for the monometallic Ni catalysts supported on γ -alumina unmodified and modified with Mg at 303 and 323 K. As expected in the Figure it can be seen the higher values of conversions are obtained at higher reaction temperature. At 303 K, Ni1 % catalyst modified with 5% MgO on alumina presented

the highest 3-hexyne total conversions. This result could be explained by a synergistic effect of Mg on Ni , which promotes increased generation of actives sites as mentioned by other authors [3] . On the other hand, at 323K there is very slight difference of total conversion between the unmodified and Mg modified catalysts.

Table 1. Binding energies (BE) for Ni $2p_{3/2}$ and atomic ratios obtained by XPS.

Catalysts	XPS			Selectivity to (Z)-3-hexene	
	BE (eV)	Atomic ratios			
	Ni $2p_{3/2}$	Ni/Al	Mg/Al	303K	323K
NiN1%	857,34	0,013	-	63	70
NiN1% +5%MgO	856,92	0,005	0,048	69	59
NiN1% +10%MgO	856,97	0,015	0,086	63	63

On Table 1 are presented the selectivities to (Z)-3-hexene at 303 and 323K. It can be seen that moderate selectivities are obtained for the nickel unmodified or modified catalysts. Lower selectivities are obtained at 323K for the modified Mg catalysts.

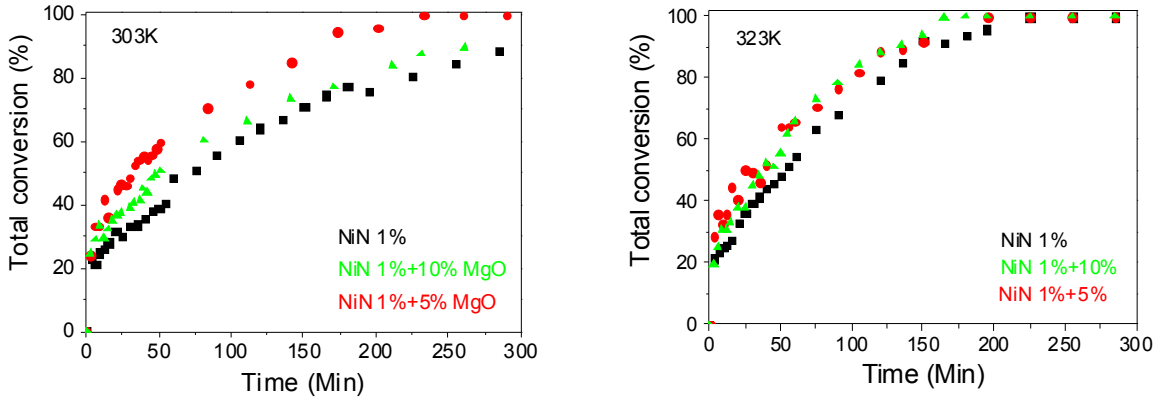

Fig. 1. Total conversion of 3 - hexyne vs reaction time for the Ni/Al_2O_3 modified and unmodified at 303 and 323K

4 Conclusions

Low-cost monometallic nickel (1wt % of Ni) catalysts unmodified or modified with Mg were prepared. The Ni1 % catalyst modified with 5% of MgO presented higher values of 3-hexyne total conversion (ca. 100%) and moderate selectivity (□70%) at 303K. Besides this prepared catalyst is inexpensive compared to the Lindlar catalyst (5 wt % of Pd) or others mentioned in the literature.

Keywords: natural gas, GTL, syngas, partial oxidation, catalytic carbonylation

1 Introduction

Gas-to-liquids (GTL) processes intended for production of synthetic liquid fuels as well as other chemical and petrochemical products (methanol, lubricants, waxes et.) from hydrocarbon gases have been of interest for the past three decades. At the same time manufacturing GTL products is extremely expensive. The technology of their production traditionally consists of three steps, and each of these steps is costly itself, especially the step of syngas production.

2 Main Principles of Alternative GTL Processes. New GTL Products

We have suggested an alternative "without syngas" route for GTL. It consists of two stages: direct partial oxidation of natural or associated petroleum gases into methanol and CO and/or olefins and CO with subsequent catalytic carbonylation of oxidation products [1] (Fig. 1).

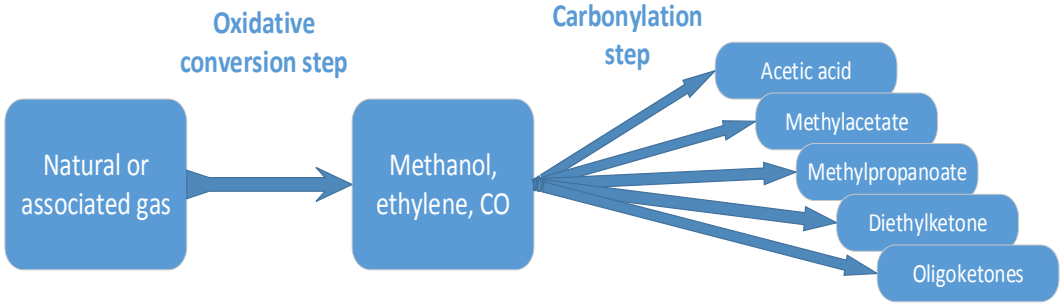

Fig. 1. Suggested scheme of alternative GTL processes

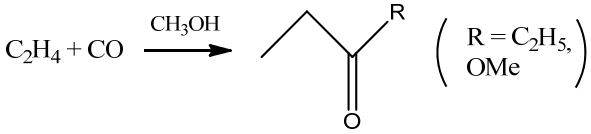
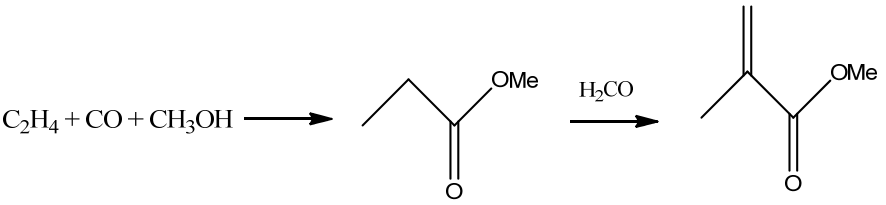
At present many carbonylation reactions operate industrially in large-scale production. Platinum group metals based catalysts (PGM catalysts) are the most effective catalysts for carbonylation processes [2]. PGM catalysts represent metal complexes with organic heteroatom ligands of different structure that is responsible for catalyst activity and selectivity to definite product. Of especial interst are processes which use all three main oxidation products – ethylene, methanol and carbon monooxide, e.g.:



This reaction is catalyzed by palladium complexes with phosphine ligands under relatively

low pressures.

The process with participation of all above mentioned oxidation products (ethylene, methanol, CO) forming the most value-added product – MMA, represent combination of methoxycarbonylation of ethylene into methyl propanoate and condensation of the latter with formaldehyde yielding methyl methacrylate. The route of these consecutive reactions was firstly commercialized in the *Lucite Alpha process:*



Such approach to gas conversion is particullarry attractive because CO unconditionally forms along with the methanol and ethene during the partial oxidation of natural gas in quantities suffucient for a further carbonylation step. Therefore, there is no need for energy consuming steam conversion or oxidation of methane into syngas. PGM catalysts are active under milder conditions and show much higher selectivity compared to other catalysts.

This approach allows developing an integrated two-stage conversion (an alternative GTL). Methanol and olefins produced according to this method can form such valuable marketable chemicals and petrochemicals as diethylketone, methylacetate, dimethylcarbonate, methylpropanoate, ethylidenediacetate, oligoketones, polyketones etc., avoiding energy consuming steps for separation of intermediate products. High efficiency of new GTL processes is determined by not only production of chemicals with high added value, but also by simultaneous production of purified dry fuel methane gas with high methane index.

3 Conclusions

Combination of gas phase partial oxidation and subsequent catalytic carbonylation makes possible to develop alternative GTL processes without complicated and costly stage of syngas formation. Such new type GTL processes can be successfully used for the monetization of stranded natural and associated petroleum gases by converting them into high value-added marketable products in demand.

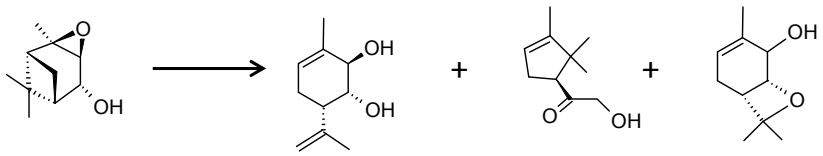
Keywords: zeolite, isomerization, pharmaceutical, terpenoid

1 Introduction

Development of new pharmaceuticals, especially from natural compounds is currently of high interest. Some of the commonly used drugs have also severe side effects, for example Levodopa, which is the main drug for the Parkinson desease. It is a chiral amino acid, (*S*)-2-amino-3-(3,4-dihydroxyphenyl)propanoic acid, which is known to cause several side effects, such as nausea, hallucinations, paranoia [1]. In verbenol oxide isomerization the desired product is diol (2) (Fig. 1), which has been previously synthesized in the presense of a large amount of K10 clay [1].



1 2 3 4

Fig. 1. The reaction scheme for production of diol (2) starting from verbenol oxide (1). The other main products were cyclopentyl hydroxyl ketone (3) and oxetane (4).

The aim of this work is to systematically study for the first time catalytic isomerization of verbenol oxide (VO) (1) to diol (2) over different zeolites by varying the SiO_2/Al_2O_3 ratio and structure of zeolites. This diol is a potential alternative to L-Dopa.

2 Experimental

Several commercial NH_4-USY and NH_4-ZSM-5 zeolites with different Si/Al ratio were used as catalysts. They were transformed to corresponding proton forms via step calcination at 500°C. The isomerization of verbenol oxide was performed typically in dimethylacetamide as a solvent at 140°C using the initial concentration of VO 0.016 mol/l and 75 mg catalyst. In addition, high stirring speed (390 rpm) and small catalyst particles (<90 Φm) were used in order to avoid the mass transfer limitations. The samples were withdrawn from the reactor and analyzed by GC. The reaction products were identified with GC-MS and NMR. The catalysts were characterized by XRD, nitrogen adsorption, SEM, TEM, solid state MAS NMR and pyridine adsorption desorption with FTIR.

3 Results and Discussion

The structures of H-Y and ZSM-5 zeolites were confirmed by XRD. The specific surface areas of H-Y zeolites were about 800 m^2/g, whereas those for ZSM-5-23 and ZSM-5-80 were 443 and 570 m^2/g, respectively. The number in zeolite name denotes different SiO_2 to Al_2O_3 ratio. The amount of Brønsted acid sites determined by ^{27}Al MAS NMR at 55.2 ppm for H-Y-12 was 8.9 fold that of H-Y-80 (Fig. 2a). Furthermore the pyridine adsorption showed that the amount of Brønsted acid sites was inversely proportional to SiO_2 to Al_2O_3 ratio. The amount of Lewis acid sites was also higher with the zeolites possessing low SiO_2/Al_2O_3 ratio.

a) **b)**

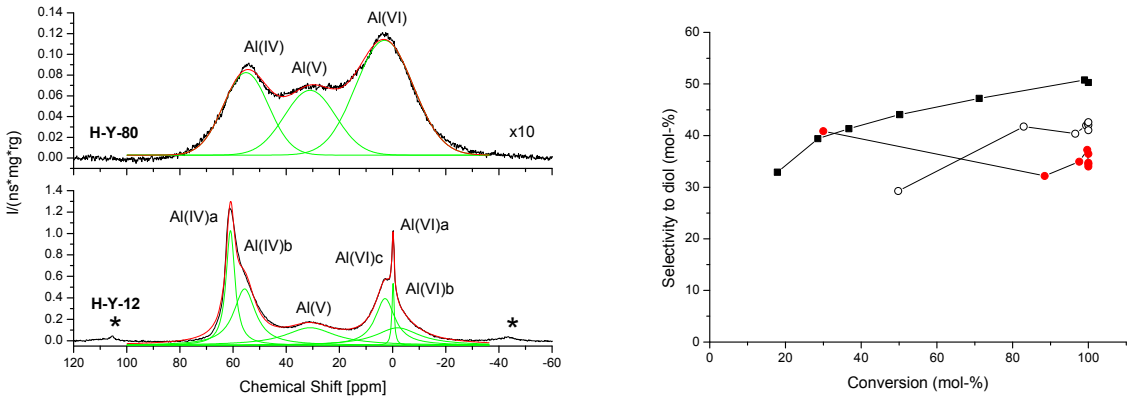


Fig. 2. a) ^{27}Al MAS NMR spectra of H-Y-80 (above) and H-Y-12 (below), b) selectivity to the desired diol (2) as a function of verbenol oxide conversion at 140°C in dimethyl-acetamide. Symbols: H-USY-80 (■), H-USY-15 (o) and H-USY-12 (●).

The most active catalysts were the large pore H-Y zeolites with a low Si/Al ratio, whereas medium pore ZSM-5 zeolites exhibited lower initial rates. The large pore zeolites facilitated the total conversion of verbenol oxide within 120 min, whereas over medium pore zeolites ZSM-5-23 and ZSM-5-80 only 51 % and 58 % conversion, respectively, was achieved.

Selectivity towards the desired diol (2) decreased as a function of verbenol oxide conversion over the most acidic H-Y-12 zeolite, whereas it increased over the mildly acidic H-Y-80 zeolite being 48 % at complete conversion of verbenol oxide (Fig. 2b). The second most abundant product was a cyclo pentyl ketone (3), which was formed parallelly with a diol. These results showed that a large pore zeolite H-Y-80 with relatively mild acidity was the most efficient in diol formation.

4 Conclusions

Catalytic isomerization of verbenol oxide to the diol exhibiting anti-Parkinson activity was for the first time systematically investigated for the first time. The results showed that a large pore zeolite H-Y with a mild acidity was active and selective for the studied reaction. In the final work the catalyst physic-chemical properties will be related to the catalytic performance and the reaction mechanism will be proposed.

Keywords: 3-cyanopyridine, 2-methylglutaronitrile, cyclodehydrogenation, niacin

1 Introduction

Niacin (nicotinic acid) is a compound with a yearly market growth of around 5-6%, total consumption of 40.000-50.000 tons, 75% of which is used as additive for feed, the rest in food industries and pharmaceuticals. Commercial production of niacin is conducted either by means of the direct liquid phase oxidation of alkylpyridines with nitric and chromic acid or by the catalytic gas-phase ammoxidation of 3-methylpyridine (β-picoline) and hydrolysis of 3-cyanopyridine [1]. With the aim of finding new routes for the synthesis of β-picoline and cyanopyridines, we investigated the feasibility of two alternative routes, i.e., the direct cyclodehydrogenation of 2-methylglutaronitrile (2MGN), an inexpensive raw material obtained as a by-product from the DuPont Adiponitrile process, and the condensation of acetaldehyde and acetonitrile.

2 Experimental/methodology

Magnesium oxide-based catalysts (Mg/Fe/O, Mg/Cr/O, Mg/Al/O) were prepared by coprecipitation in the form of mixed hydroxycarbonate; the resulting precipitate was dried at 120°C and calcined at 450°C. In bifunctional systems, the metals (Pd, Pt) were deposited over the basic support by means of incipient wet impregnation, starting from the organic salt of the metal. Catalytic tests were carried out in a continuous-flow lab reactor. In the first set of experiments 2MGN was vaporised and mixed with nitrogen as carrier gas. The mixture was passed through the catalytic bed (prereduced with hydrogen at 350°C for bifunctional catalysts) and products were accumulated in an acetone trap. Contact times were 0.35-0.40s, feed composition was 5% 2MGN in nitrogen with a total flow of 40ml/min. The solution containing the products and the unconverted reagent was analyzed by means of GC. In the second set of experiments a mixture of acetonitrile and acetaldehyde (in form of paraldehyde) was vaporized and mixed with nitrogen as carrier gas. The reagents were passed through the catalytic bed and products were accumulated in an acetone trap.

3 Results and discussion

As reported in the literature [2], 2MGN can be hydrogenated to produce the di-amino derivative, which is then cyclised in the presence of a bifunctional catalyst to produce 5-methyl-2,3,4,5-tetrahydropyridine after release of ammonia; the latter is then dehydrogenated to β-picoline and finally ammoxidised to 3-cyanopyridine. We investigated if it was possible to cyclise 2MGN directly, while avoiding the loss of the ammonia molecule (which finally has to be reintroduced to produce the cyanopyridine). We used bifunctional catalysts containing a metal active species (Pt, Pd or Ru, 1% wt) supported over basic (MgO) or acidic/basic ($MgFe_2O_4$, $MgCr_2O_4$ $MgAl_2O_4$, ZrO_2) supports.

Catalysts showed different reactivity as a function of composition (nature of the active element, nature of the support), but in general the predominant products were short-chain nitriles with negligible formation of cyanopyridines or methylpyridines. This is shown, for example, in Figure 1, reporting the distribution of products obtained with the catalyst based on

Pd1%/$MgAl_2O_4$. Besides the formation of propionitrile, crotylonitrile, acrylonitrile and methacrylonitrile, also relevant amounts of C deposits accumulated on the catalyst surface. Some experiments were also carried out in the presence of air, with the aim of both achieving a more favourable equilibrium conversion at moderate temperature and limit the accumulation of carbonaceous deposits, however, only limited improvements were achieved. Results demonstrate that under the conditions examined radical-like fragmentation of 2MGN is highly favoured compared to cyclisation.

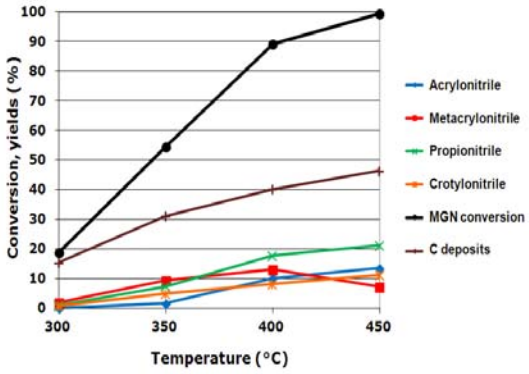

Fig. 1. 2MGN conversion and selectivity to products as a function of temperature with Pd1%/$MgAl_2O_4$ catalyst.

Another set of experiments was carried out by co-feeding acetaldehyde and acetonitrile (with a large excess of the latter compound), using either acidic (HY zeolite), basic (MgO), or bifunctional systems (Mg/Fe/O, Mg/Al/O). In this case, it was expected that the condensation of two acetaldehyde and one acetonitrile molecules would generate picoline. The reaction, carried out in the gas-phase between 350 and 450°C, led to the formation of several products with low yield to picolines, mainly due to the lower reactivity of acetonitrile compared to acetaldehyde.

4 Conclusions

We explored alternative synthetic pathways for the production of picolines and cyanopyridines by means of gas-phase transformations using basic or bifunctional catalysts, starting from either 2-methylglutaronitrile or acetonitrile/acetaldehyde mixtures. The reactions showed low selectivities due to strong fragmentation of the reactant 2MGN into smaller nitriles or to scarce reactivity of acetonitrile leading to a preferred transformation of acetaldehyde into several by-products.

Keywords: stereoselective, hydrogenation, alkyne, heterobimetallic, complex, Pd-Cu catalyst

1 Introduction

The semihydrogenation of carbon-carbon triple bond is of fundamental importance for both fine chemicals production and laboratory practice. Pd-supported catalysts are proved to be the best for hydrogenation of alkynes to alkenes in terms of selectivity. However Pd can catalyze undesirable C=C double bond hydrogenation, which results in the loss of selectivity. Improved selectivity of Pd catalyst in semihydrogenation can be achieved using bimetallic compositions (Pd-Ni, Pd-Zn, Pd-Ag, Pd-Cu) and the main problem is to avoid or minimize formation of monometallic Pd^0 species. A possible solution of this problem is the use of Pd-M heterobimetallic acetate complexes for the catalyst preparation as a precursor of active component. Pd and second metal atom in this complex are linked together by strong acetate bridges thus remaining in contact during all stages of catalyst preparation. The precursor structure enables formation of highly homogeneous bimetallic nanoparticles in a final catalyst [1].

2 Experimental/methodology

Selective semihydrogenation of diphenylacetylene (DPA) was studied as a model reaction. The catalysts were prepared by impregnation of Al_2O_3, (Sasol, S_{sp}=150 m^2/g) with acetic acid solutions of $PdCu(CH_3COO)_4$, $Pd_2Cu(CH_3COO)_6$ $PdCu_2(CH_3COO)_6$ complexes (pH = 2.6-2.8). The catalysts were dried overnight at room temperature, calcined (550°C, 4 h) and reduced in 5%H_2/Ar (550°C, 1 h) before catalytic measurements. A commercial Lindlar catalyst («Aldrich») was taken for comparison. Reaction was carried out in autoclave at 10 atm H_2 and room temperature in methanol. The reaction kinetics was monitored by the rate of H_2 uptake, and the reaction products were analyzed using H-NMR.

3 Results and discussion

The Pd-Cu/Al_2O_3 catalysts demonstrate extremely high selectivity in the hydrogenation of DPA to olefin. It was found that increase of the Cu content from Pd:Cu = 2:1 to Pd:Cu = 1:2 leads to a nearly complete suppression of the hydrogenation of stylbene to diphenylethane (Fig. 1).

A detailed kinetic study revealed substantial change of the reaction kinetics due to Cu addition. Introduction of Cu increases the reaction order in DPA from 0 to ~ 0.5-0.8, indicating a significant decrease in the strength of the alkyne adsorption on the surface of the bimetallic nanoparticles. The reaction rate of the second hydrogenation stage is reduced by 10-15 times (Fig. 1) thus increasing turnover frequency ratio TOF_{DPA}/TOF_{ST} from 4.9 to 30, which enables effective kinetic control of alkyne hydrogenation over Pd-Cu bimetallic catalyst.

The change in the reaction kinetics significantly improves selectivity of Pd-Cu catalyst in stylbene formation and *Z-/E*-olefin ratio (Table 1).

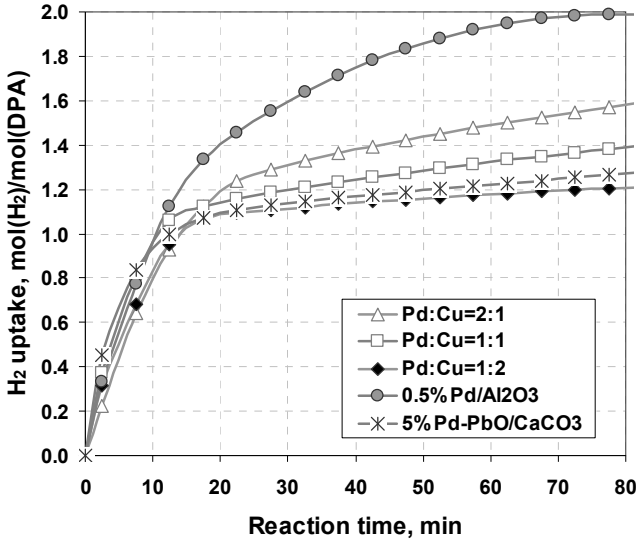

Fig. 1. Effect of Pd:Cu ratio on the performance of Pd-Cu/Al_2O_3 in DPA hydrogenation in methanol. Conditions: P=10 atm, t = 25°C, $m_{Pd:Cu}$ = 2.5 mg, $m_{Lindlar}$ = 7.5 mg

Thorough study of Pd-Cu catalysts by IR spectroscopy of adsorbed CO revealed formation of highly homogeneous bimetallic particles as evidenced by the almost complete disappearance of bridged bonded CO. On the other hand, Pd electronic state does not significantly changed, as indicated by the coincidence of the absorption band of the linear bonded CO for mono- and bimetallic catalysts.

Remarkably, comparison of characteristics for Pd-Cu and Lindlar catalysts demonstrate that the bimetallic Pd-Cu system is superior to Lindlar catalyst in terms of selectivity, being more active.

Table 1. Kinetic characteristics of DPA hydrogenation over Pd-Cu/Al_2O_3 catalyst with various Pd:Cu ratio.

Catalyst	TOF_{DPA}, s^{-1}	TOF_{ST}, s^{-1}	TOF_{DPA}/TOF_{ST}	S_{ST}, %	Z/(E + Z), %
Pd:Cu = 2:1	2.65	0.22	12.0	-	-
Pd:Cu = 1:1	3.05	0.15	20.0	90.6	96.1
Pd:Cu = 1:2	2.45	0.08	30.1	95.7	99.3
5%Pd-PbO/$CaCO_3$	0.16	0.01	29.0	94.1	97.5
0.5%Pd/Al_2O_3	5.77	1.17	4.9	73.2	90.3

4 Conclusions

Pd-Cu catalysts synthesized via acetate heterobimetallic complexes demonstrate excellent selectivity to stilbene and high stereoselectivity in terms of *Z-/E*-olefin formation. From the practical viewpoint this result is of great interest, since it was found that the Pd-Cu catalyst demonstrates superior activity and selectivity in comparison with commercial Lindlar catalyst (Pd/PbO/$CaCO_3$). It should be noted that this performance is achieved at a substantially lower content of noble metal (1% instead of 5% Pd). Furthermore, the absence of toxic Pb components makes Pd-Cu catalyst promising for usage in pharmaceutical and food industries.

Catalytic Conversion of Cellulose to C_2-C_3 Glycols by a Dual Combination of a Homogeneous Metallic Salt and a Perovskite-Based Heterogeneous Catalyst

Girard E.*, Delcroix D., Cabiac A.

IFP Energies Nouvelles, Rond-Point de l'Echangeur de Solaize, Solaize, France

* etienne.girard@ifpen.fr

Keywords: biomass, cellulose, glycols, dual catalysis, cerium salts, perovskites

1 Introduction

The conversion of cellulose to C_2-C_3 glycols is usually achieved under hydrothermal - above 100°C and 1 bar- and reducing conditions via a cascade pathway including depolymerization of cellulose to glucose, subsequent retro-aldol reactions and hydrogenation of the resulting glycolaldehyde and glyceraldehyde molecules.[1] Multifunctional catalytic systems are thus necessary to achieve a selective formation of C_2-C_3 glycols. Depolymerization being achieved through water autoprotolysis at high temperatures, the ideal catalytic system should combine a retro-aldol active species and a hydrogenation component. A fine balance between acidic, basic and hydrogenation catalytic sites associated with an excellent hydrothermal stability of the heterogeneous support is thus necessary to achieve a high selectivity in glycols. Original dual catalytic systems combining a homogeneous metallic salt and a platinum-supporting heterogeneous catalyst for the conversion of cellulose into C_2-C_3 glycols are presented. The results obtained for the conversion of glucose with the different catalytic systems were discriminated as a function of the selectivity of key transformation products of cellulose, namely ethylene glycol (EG), ethanol (EtOH), 1,2-butanediol (1,2-BDO), propylene glycol (PG), 1-propanol (1-PrOH), lactic acid (LA), sorbitol and 1,2-hexanediol (1,2-HDO). These products were regrouped in C_2-C_4, C_3 and C_6 molecule pools depending on the main reactions implied in their formation. Thus, this methodological approach allowed us to identify original and efficient dual catalytic systems for the conversion of cellulose to C_2-C_3 glycols.[2] This communication aims to illustrate the great potential of such catalytic systems to achieve enhanced selectivities in ethylene and propylene glycols (EG and PG) from cellulose.

2 Experimental/methodology

The heterogeneous catalysts were prepared by dry impregnation and tested as powders sieved under 150 microns. Catalysts were reduced under a H_2 flow. Catalytic tests were performed in a high throughput apparatus possessing six 100mL autoclaves working in parallel. In a typical experiment, cellulose (1.3g), cerium chloride (500 ppm) and the heterogeneous catalyst (550 mg) were dispersed in degassed water (50mL). The autoclave was sealed and thoroughly degassed. A hydrogen pressure was set at room temperature before heating and stirring at 500 rpm.

3 Results and discussion

To explore this dual concept, an initial screening of heterogeneous catalysts with varying acid base properties was first performed with a $CeCl_3.7H_2O$ homogeneous catalyst (see Entries 1 to 4). The Lewis acid nature of Pt/ZrO_2 yielded a high selectivity in LA. Being reported as basic oxides, mixed oxides of earth alkaline elements and zirconium and perovskites in particular were then considered as promising candidates.[3] Among the different solids tested – $Pt/CaZrO_3$,

$Pt/SrZrO_3$ and $Pt/BaZrO_3$– the $Pt/BaZrO_3$ catalyst achieved the highest selectivities in glycols with 21.7% and 19.2% for EG and PG, respectively. C_2-C_4 molecules were preferentially formed using $Pt/BaZrO_3$ while $Pt/CaZrO_3$ produced enhanced yields of C_3 molecules. No particular selectivity was noted using $Pt/SrZrO_3$. Remarkably, the $Pt/BaZrO_3$ could be additionally shown to exhibit enhanced hydrothermal stability.

The influence of the homogeneous catalyst was then investigated using Pt/BaZrO as the reference heterogeneous catalyst. A blank experiment confirmed the strong impact of the homogeneous catalysts on selectivity (see Entry 5). Three other rare earth chlorides with various sizes and electronegativities –$NdCl_3.7H_2O$, $GdCl_3.7H_2O$, $ErCl_3.7H_2O$– were then tested to study cation effects (see Entry 6 to 8). The overall glycol selectivity was lower than those obtained for $CeCl_3$. Unlike $CeCl_3$, the preferential formation of C_3 molecules was observed. This illustrated the specific results obtained with a light rare earth chloride salt.

The impact of the counter-anion on the selectivity of the reaction appeared significant too (see Entries 9 and 10). Using a cerium triflate salt allowed to achieve high selectivities to glycols (>30%). Selectivities with cerium sulfate were comparatively slightly lower. In both cases, the preferential formation of C_3 molecules was determined. Thus, it was evidenced a strong versatility of this system with a balance between C_2-C_4 and C_3 molecules strongly dependent on the type of counter-anion.

Table 1. Experimental results for the conversion of cellulose at 230°C with an initial H_2 pressure of 25 bar for 12 hours.

4 Conclusions

Original and efficient combinations between a metallic salt homogeneous catalyst and hydrogenation heterogeneous catalyst were explored for the selective conversion of cellulose to C_2-C_3 glycols under hydrothermal conditions. The appropriate choice of the support through its acid-base balance was particularly critical to access high yields of glycols. Perovskites and particularly barium zirconate exhibited a promising potential to do so. Its association with $CeCl_3.7H_2O$ achieved the highest selectivity in ethylene glycol and propylene glycol, leading to a global value of 40.1%. The selection of a light rare earth homogeneous catalyst, *i.e.* cerium chloride, was a key result in this study. A strong versatility between C_2-C_4 and C_3 molecules was also demonstrated using chloride, sulfate or triflate counter-anions in cerium salts.

MoCrGa Catalysts Supported on Natural Clays for the Process of Oxidative Conversion of Propane-Butane Mixture

Massalimova B.

Arkalyk State Pedagocical Institute after named I.Altynsarin, Arkalyk, Kazakhstan

* massalimova15@mail.ru

Keywords: propane-butane, oxidation, clays

1 Introduction

Due to the depletion of natural hydrocarbon resources, the need of implementation of the intensive technologies and solutions of environmental problems increases urgency with a more efficient chemical processing of components such as oil and gas. According to forecasts for the near future, saturated C_1-C_4 hydrocarbons not only will retain but also will strengthen their position as a raw material for the production of unsaturated hydrocarbons. Therefore, the problem of searching for the ways of their effective conversion into different oxygen-containing compounds is also urgent. Only the optimal choice of catalysts can ensure targeted synthesis with the predominant formation of a desired compound selected from these products [1].

2 Experimental/methodology

The experiments were carried out at atmospheric pressure in a continuous-flow unit with a fixed-bed quartz-tube reactor. Oxidative conversion of propane-butane mixture by air to oxygen-containing compounds at T=573-873K and space velocity 330-15000ч$^{-1}$ on polyoxide catalysts containing 1-10% Mo, Ga, Cr of different composition and ratio supported on natural Torgai clays (TC), Sary-Ozek, Chankanai, IK-30 and IR-301 zeolites. Analysis for the reactants and products was carried out chromatographically with an "Agilent Technologies" instrument. The catalysts were characterized by XRD analysis, and their surface area, porosity, and elemental composition were determined [1].

3 Results and discussion

It was found that the partial oxidation of propane and the propane-butane mixture at 350-750^{o}C with varying the catalytic mixture composition and the contact time (τ) yielded acetone, methyl ethyl ketone, methanol, acetaldehyde, crotonic aldehyde, butanol, and acetic acid, as well as C_2-C_3 unsaturated hydrocarbons. The main products are oxygen-containing compounds (mainly acetone and acetaldehyde), propylene, ethylene, and CO.

The tests on natural clays (white clay, the base phase is kaolin $Al_2[OH]_4Si_2O_5$ (ASTM-29-1488) and α-quartz SiO_2, as well as red clay, which differs from the white clay by the presence of haematite Fe_2O_3 and the absence of α-quartz (less than 1%) showed that investigation in this direction is also of certain interest. The treatment of clay specimens with hydrochloric acid slightly changed their phase composition. The specific surface area and porosity of the sorbent specimens examined were determined by the Brunauer-Emmett-Teller low-temperature nitrogen adsorption technique. It was found that the clay surface area is 10-16 m^2/g and the optimum pore radius of ranges from 20 to 50 Å. The treatment of sorbents with 10% HCl facilitated the development of pores and an increase in the pore radius. The elemental analysis of the initial sorbent specimens and those treated with 10% HCl showed that the clay specimens predominantly contained oxide compounds of Si and Al, as well as Ca, Mg, Fe, and Na. The SiO_2/Al_2O_3 ratio (silica modulus) was 5-0.4. The silica modulus increases after acid treatment.

Supported polyoxide catalysts on the basis of Mo, Cr, Ga, Bi, and Ce as well as natural clays of Kazakhstan, were tested in the process of oxidative conversion of propane-butane mixture. The influence of reaction temperature, contact time, composition and content of active component of catalyst were determined. The gas mixture used for oxidation contained from 6,6 to 80,0% C_3H_8-C_4H_{10} mixture and from 7,0 to 20,0% oxygen in different ratios at 523-873K and W=300-15000h^{-1}.

It was found that the partial oxidation of propane-butane mixture with varying the catalytic mixture composition and the contact time yielded acetone, methyl ethyl ketone, methanol, acetaldehyde, crotonic aldehyde, butanol, and acetic acid, as well as C_2-C_3 unsaturated hydrocarbons. It was shown that conversion proceeds with the formation of gaseous and liquid products. Important petrochemicals, such as acetone (773-823K) and acetaldehyde (623-673K) are main liquid products. Ethylene is the main product of gas phase. Yield of ethylene increases beginning from 723K.

The investigation on influence of the nature of carrier on yield of acetone from reaction temperature was carried out. It was shown that more high yields of acetone were produced over Torgai white clay (TWC).

Ternary catalyst is more active than two-component samples. Optimal space velocities for catalysts with different content of active phase over carriers were determined. Up to 50,9% of acetone and 38,0% of methyl ethyl ketone on 5%MoCrGa/TC were produced at W=450h^{-1}. Increase of content of methyl ethyl ketone in catalysate was observed at reduction of propane-butane in reaction mixture. The determination of the product composition showed that the process follows a complex mechanism including oxidation, oxidative dehydrogenation, and cracking [1-2].

The optimal conditions for synthesis of products were detected:

- 50,9% of acetone was produced on 5%MoCrGa/TWC catalyst at 823K and W=450h^{-1} in reaction mixture C_3-C_4:O_2:N_2:Ar=5:1:4:5;
- 41,0% of acetaldehyde was produced on 10%MoCrGa/TWC catalyst at 723K and W=450h^{-1} in reaction mixture C_3-C_4:O_2:N_2:Ar=5:1:4:5;
- 80,0% of methyl ethyl ketone was produced on 5%MoCrGa/TWC+ZSM-5+$Al_n(OH)_{3n-1}NO_3$ catalyst at 723K and W=3150h^{-1} in reaction mixture C_3-C_4:O_2:N_2:Ar=1:1:4:1;
- 71,4% of ethylene was produced on 1%MoCrGa/TWC catalyst at 723K and W=450h^{-1} in reaction mixture C_3-C_4:O_2:N_2:Ar=5:1:4:5;
- 83,0% of benzene was produced on 1%MoCrGa/TWC catalyst at 823K and W=750h^{-1} in reaction mixture C_3-C_4:O_2:N_2=7:1:4.

4 Conclusions

Suggested in this research work catalytic reactions can be base for creation of industrial C_3-C_4 mixture utilization process and for production of valuable oxygen-containing compounds.

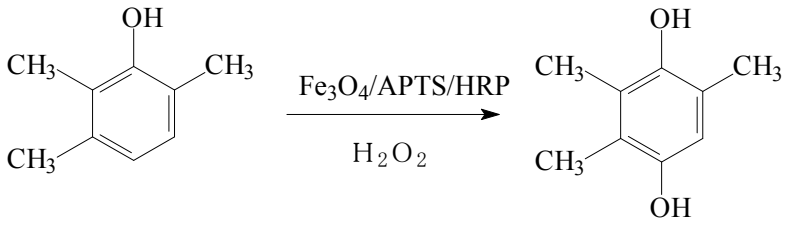
Keywords: oxidation, horseradish, peroxidase, magnetic nanoparticles, immobilization

1 Introduction

Currently the new applications of enzymes are developed, among them are fine organic synthesis, pharmaceuticals, biosensors, biofuels and many others. The improvement of the stability of enzymes allows the reducing of its required amount in the reaction, the extension of the life of enzyme reactors, the increasing of the potential for enzyme reuse or maintaining of good biosensors signal [1]. Therefore, the immobilization of enzymes on various organic and inorganic supports is one of the most promising fields of biotechnology. It is obviously that the immobilization of enzymes can directly affect the cost of the process and the quality of the target products.

The recent years, the magnetic nanoparticles are an alternative support for immobilized enzymes, which have a number of advantages in comparison with conventional matrixes. Among them are the large surface area, which leads to the increase in contact between the reactants and the catalyst, good catalyst activity and availability, simplicity and efficiency of the magnetic separation of the catalyst from the reaction mixture. These advantages can optimize operating costs and improve the purity of the product [2,3].

In this paper the activity of the enzyme peroxidase (EC 1.11.07, HRP) immobilized on magnetic nanoparticles Fe_3O_4 was studied. The syntesized biocatalyst was studied in the oxidation reaction of 2,3,6-trimethylphenol (TMP) with hydrogen peroxide to 2,3,5-trimethylhydroquinone (TMHQ), the precursor of vitamin E (Figure 1).



2,3,6-trimethylphenol 2,3,5-trimethylhydroquinol

Fig. 1. Trimethylphenol oxidation reaction.

2 Experimental

$FeCl_3 \cdot 6H_2O$ (3 mmol), succinic acid (1 mmol) and urea (30 mmol) were completely dissolved in ethyleneglycol (30 ml). The solution obtained was inputted in a teflon beaker (50 ml) in the stainless steel autoclave (Parr Instr.) and was soaked at 200°C for 4 hours. After cooling to the room temperature, the black precipitate was separated with magnet and washed with ethanol several times until a clear solution. Then the obtained nanoparticles were treated with the solution of 150 ml of ethanol, 1 ml of water and 35 µl of 3-aminopropyltriethoxysilane (APTS). The solution was stirred for 5 hours on a magnetic stirrer and then washed with distilled water and ethanol. Then APTS-coated nanoparticles were treated HRP. As the result the biocatalyst Fe_3O_4/APTS/HRP was obtained.

3 Results and discussion

In this work the effect of pH and temperature on the rate of formation of TMHQ was studied. The biocatalyst has the higher activity at pH = 7.2. The 50°C was the optimum of the temperature. The biocatalyst had the activity decrease only by 29% during 8 cycles.

To compare the activity of native and immobilized peroxidase the dependence of activity on the concentration of trimethylhydroquinone in time at the temperature 40°C was plotted (Figure 2).

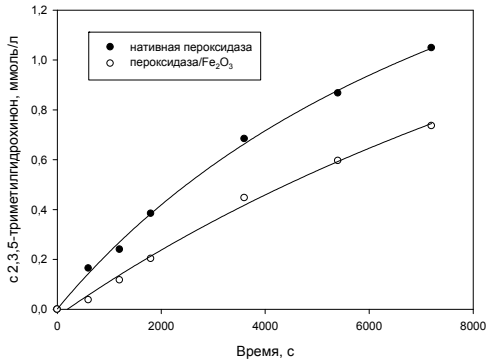


Fig.2 – Kinetic curves of the TMHQ yield dependence on time (c_{TMP} = 0.0015 mol/l, T = 40 ^{0}C, pH = 6.5)

From Figure 2 it can be concluded that the activity of peroxidase immobilized on the magnetic nanoparticles was slightly reduced compared to the activity of the native enzyme. It can be explained by the fact that peroxidase immobilized on magnetic nanoparticles is stabilized by the formation of stable complexes with iron.

4 Conclusions

The results indicate the prospects for further researches to improve the method of catalytic oxidation of TMP to TMHQ and improving the effectiveness of the biocatalyst based on HRP, immobilized on magnetic nanoparticles.

Keywords: heterogeneous catalysis, oxidation veratryl, alcohol, lignin, veratraldehyde, ruthenium

1 Introduction

Lignin is the second most abundant natural polymer and represents 40% of the energy content in lignocellulosic biomass. It is viewed as the obvious candidate to serve as a renewable feedstock of basic aromatic chemicals. In lignocellulosic material the composition as well as the molecular weight and structure of the lignin differ from plant to plant (hardwood, softwood, grass etc.), impeding the developments on lignin valorization processes. However, three monolignol monomers p-coumaryl, coniferyl and sinapyl alcohol are common building blocks. They are connected with various linkages with the most common one being the β-O-4 linkage. Due to lignin complexity and variability, several simpler, low molecular weight lignin model compounds have been prompted in the study of lignin valorization [1-3]. The oxidation of veratryl alcohol to veratraldehyde is a benzylic oxidation representing the valorization of one of the β-O-4 model compounds of lignin. Since the product veratraldehyde is a useful flavorant and odorant the transformation has been comprehensively studied by both enzymatic and homogeneous catalyst systems [4-5].

2 Experimental/methodology

In the present work we have prepared, characterized and examined the performance of heterogeneous catalysts with ruthenium or other transitions metals supported on γ-alumina for the conversion of veratryl alcohol to veratraldehyde by aerobic oxidation in water (Fig. 1). Ru/Al_2O_3 showed superior catalytic activity yielding up to 89% veratraldehyde at 160 ^oC with 5 bar air pressure. Under prolonged reaction time the decarbonylated product veratrol formed but no increase in formation of veratric acid was observed. The Ru/Al_2O_3 catalyst could be reused in three consecutive reaction but with gradually lower yield [6].

Keywords: metal organic frameworks, nanocatalyst, biomass conversion, selective oxidation

1 Introduction

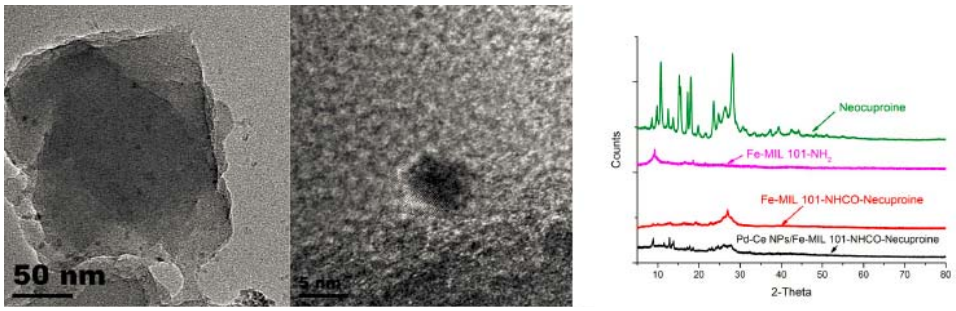
Glycerol is a by-product of biodiesel. Due to the increased demand of biodisel, glycerol production is continually increased [1]. Therefore, selective oxidations of glycerol into more value added chemicals are of great interest in current biomass research. Dihydroxyacetone (DHA), a simple oxidation product of glycerol, is currently the most popularly used sunless tanners, which is the only active ingredient approved by the US Food and Drug Administration (FDA) for sunless tanning [2]. Currently, DHA is mainly produced from an atom-inefficient fermentation process [2]. Transition-metal nanoclusters with particle size around 5nm own big surface area, and demonstrate physical and chemical properties which are significantly different from their bulk counterparts. In addition, the type catalysts own the advantage of both homogeneous and heterogeneous catalysts, well dispersion in reaction mixture and easily separation from product mixtures [3,4]. We have studied the potential applications of the metal organic frameworks supported metal nanoparticles-based catalysts for the oxidation of biomass-based glycerol to DHA. In the presentation, we report the synthetic methods and catalytic performances the Pd-Ce NPs/functional Fe-MIL-101 for the selective oxidations of biomass-based alcohols of glycerol, ethanol, etc. to corresponding aldehyde and ketone products.

2 Experimental/methodology

All reagents were purchased from Sigma. Neocuproine functionalized MOF was synthesized by reacting MOF Fe-MIL 101-NH_2 with great excess of 1,10-phenanthroline-2,9-dicarbonyl dichloride, which was in situ generated from 2,9-dicarboxylic acid-1,10-phenanthroline and thionyl chloride, in dichloromethane. Catalyst Pd-Ce NPs/functional Fe-MIL 101 was prepared by co-precipitation methods from precursors of $PdAc_2$ and $Ce(acac)_3$ reducing by $NaBH_4$ in DMF. The catalyst was characterized by TEM, XPS, FT-IR and ICP. Oxidation was conducted in a mixed solvent of acetonitrile/Deion water. Oxygen (3bar) was used as oxidant in the presence of co-oxidant benzoquinone at 60°C. The products were analyzed by GC and HPLC.

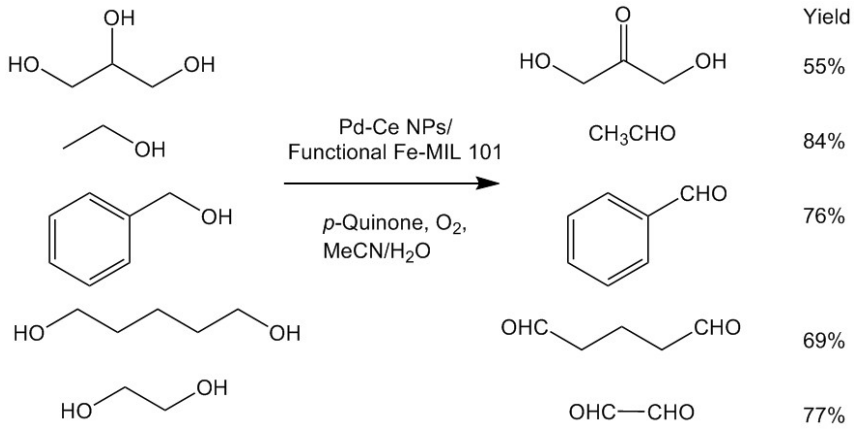
3 Results and discussion

Figure 1 (a,b) shows the TEM images of the supported catalyst. It can be seen that the Pd-Ce NPs are small, ~5nm, and well dispersed on the functionalized Fe-MIL 101. The catalytic oxidation results are detailed in Scheme 1. No significant difference was observed for Pd-Ce NPs supported and pristine functional Fe-MIL 101 as demonstrated in Figure 1 (c). The catalyst shows reasonable activity for glycerol oxidation to DHA, which is comparable with other supported metal nanoparticles such as Pt-Bi/C (DHA yield 44.8%)[5]. Ethanol and other alcohols also have been converted to corresponding aldehydes with medium yields. Further, the catalyst can be easily recovered by conventional filter or centrifugation with sustained activity.



(a) (b) (c)

Fig. 1. TEM images (a,b) of and XRD spectra (c) of the catalyst composites.



Scheme 1. Pd-Ce NPs/functional Fe-MIL 101 catalyzed alcohol oxidation.

4 Conclusions

Neocuproine-functionalized Fe-MIL 101 supported Pd-Ce NPs-based catalyst, Pd-Ce/Fe-MIL 101-N=$CH_{Neocuproine}$, has been synthesized. The catalyst shows medium to good activity for selective oxidation of glycerol to DHA and other alcohols to produce corresponding aldehydes.

Keywords: selective oxidation, ethane, ethylene, Mo-V-Te-Nb mixed metal oxide catalyst

1 Introduction

The oxidative dehydrogenation (ODH) of light paraffins is one feasible alternative to the current industrial productions of olefins. This method has several important advantages. Firstly, ODH – is an exothermic process which should serve as an incentive to implement it in a production of olefins. Secondly, the oxygen, entered with the feedstock, reacts with the carbon and prevents the formation of coke on the catalyst surface.

MoVTeNbO catalysts, prepared by hydrothermal synthesis, were found to be extremely active and highly selective in the ODH of ethane [1].

2 Experimental

Mo/V/Te/Nb mixed metal oxide catalyst was prepared by hydrothermal synthesis as reported [2]. Ammonium heptamolybdate, telluric acid, vanadyl sulfate and niobium oxalate were used to prepare the catalyst. Mo/V/Nb mixed metal oxide catalyst was prepared similarly as the Mo/V/Te/Nb catalyst. The prepared catalyst was characterized by XRD, SEM and XPS analysis.

The catalytic tests were carried out under steady-state conditions at atmospheric pressure, using a fixed-bed titanium reactor (an inner diameter of 1 cm and a length of 54 cm), in two modes: cyclic (separate feeding of reagents) and flow-type (continuous feed gas mixture). In the flow-type mode the feed (60 ml min^{-1}) consisted of a mixture of ethane/oxygen with molar ration of 75/25. Experiments were carried out in the 340 to 400 temperature range. The catalyst volume was 1.8 cm^3 (2 g), and the remaining volume of the reactor was filled with quartz particles. In the cyclic mode the feed consisted of ethane. Reactants and reaction products were analyzed by gas chromatography, using two columns: Porapak Q and Zeolite A.

3 Results and discussion

The catalytic results for the oxidative dehydrogenation of ethane on MoVTeNbO and MoVNbO catalysts are presented in Table 1. Ethylene, carbon oxides and water were the main reaction products. Acetic acid was found in trace quantities.

Table 1. ODH of ethane on MoVTeNbO and MoVNbO catalysts (the flow-type mode)

Sample	Temperature, °C	Conversion, %	Selectivity, %		
			C_2H_4	CO_2	CO
MoVTeNbO	340	6	98	2	0
	360	18	92	3	5
	380	34	88	3	9
	400	37	85	3	12
MoVNbO	360	9	68	16	16
	400	21	70	9	21

According to the presented data on MoVTeNbO catalysts high selectivity to ethylene is reached at 340 °C. Conversion achieves 37% at temperature 400 °C; however selectivity to

ethylene decreases to 85%. Some growth inhibition of conversion upon transition from 380 to 400 °C is connected with that about 95% of the oxygen are consumed at 380 °C. At 400 °C the full consumption of gaseous oxygen takes place.

The lack of an oxidizer of reactionary mix leads to irreversible changes of the catalyst, decrease of the activity and selectivity (fig. 1). Rise in temperature to 400 °C facilitates tellurium reduction by ethane from Te^{+6} oxidation level to Te^{0}-state with the subsequent its sublimation and destruction of an active and selective phase.

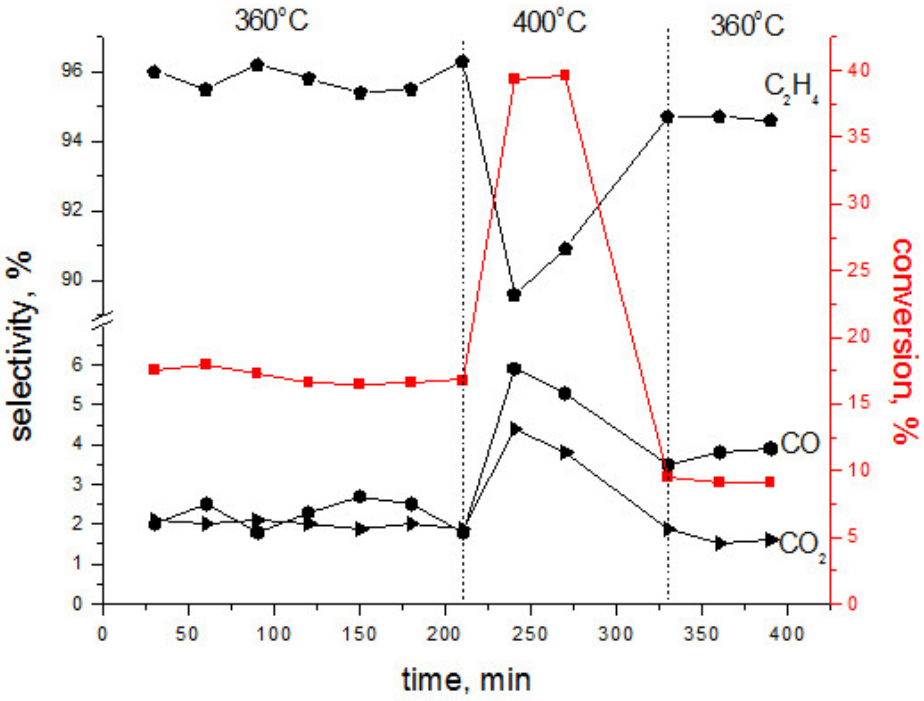

Fig. 1. Change of ethane conversion and selectivity to products over MoVTeNbO catalysts as the function of reaction time. (Reaction conditions for ethane oxidation: C_2H_6/O_2 molar ratio of 3/1, m_{cat} = 2.0 g, the flow rate 60 ml/min)

At research of the oxidative dehydrogenation of ethane in the cyclic mode it was established that the molar fraction of the active oxygen, participating in reaction, compounds 3%.

4 Conclusions

Low values of exchange oxygen of solid and gas phases may be cause high selectivity to ethylene. In the most optimum process parameters conversion of ethane reaches 18%, oxygen - 50%, selectivity to ethylene - 92% at 360 °C. Rise in temperature to 400 °C increases conversion of ethane; however selectivity to ethylene decreases to 85%. Under such conditions the catalyst is irreversible deactivated in connection with tellurium reduction. Thus, the catalyst deactivated in reaction of the ODH of ethane shows lower conversion and selectivity to ethylene which are similar to the data received for Mo-V-Nb catalysts which aren't containing tellurium.

Keywords: catalysis oxidation, biomass, glycolaldehyde

1 Introduction

Lignocellulosic biomass is a potential renewable carbon-source for industrial production of important chemical compounds, e.g. polymers, fuel components etc. The most studied catalytic strategy for conversion of polymeric carbohydrates into chemicals and fuels includes acid catalyzed depolymerization of cellulose or hemicellulose to glucose or xylose, followed by dehydration to produce C6 and C5 chemicals such as 5-hydroxymethylfurfural (HMF) and furfural. Both of these chemicals can be transformed into a range of de- or re-functionalized "furanic" compounds, with varied carbon content, by reduction, oxidation, esterification, retro Diels-Alder, etc. thus serving as valuable platform chemicals.

2 Experimental/methodology

Lignocellulose can also be transformed into smaller liquid chemical building blocks by partial thermal degradation (i.e. by pyrolysis). A major byproduct obtained from pyrolysis is the C2 chemical, glycolaldehyde (GAD). Noticeably, glycolaldehyde contains, like HMF, both an aldehyde and an alcohol moiety which potentially makes glycolaldehyde prone for re-functionalization into value-added and useful "glycolic" chemicals in an analogous manner as demonstrated for HMF. However, since glycolaldehyde has received significant less attention, only limited chemo-catalytic technology have been developed for efficient and selective transformation of glycolaldehyde. An overview of the breakdown of cellulose to glycolics is presented in Fig. 1.

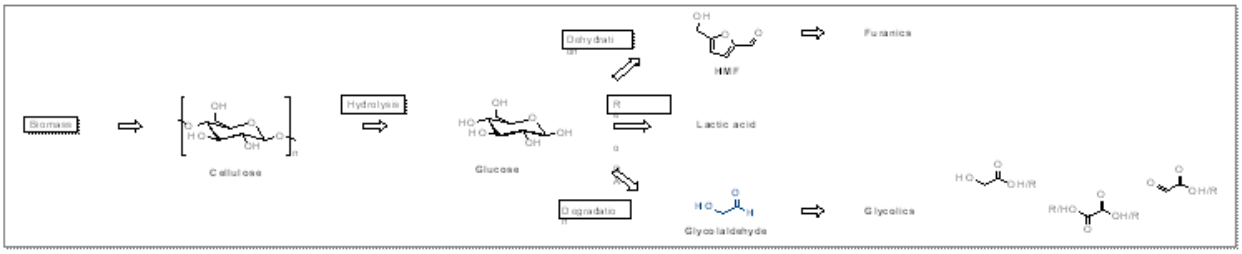

Fig. 1. Breakdown of cellulose into glycolics

In this work, oxidative functionalization of GAD are explored using heterogeneous metal-catalyst with air as oxidant under relative mild reaction conditions. Generally, catalyst activity and selectivity were found to depend significantly on the nature of catalyst as well as the applied reaction conditions thus making an *a priori* selection difficult. However, a few very promising catalyst candidates have been identified.

Mathematical Analysis Options to Upgrade Plants of Dehydrogenation Isoamylenes to Isoprene and Conduct Pilot Tests

Keywords: dehydrogenation of isoamylenes to isoprene, pilot tests

- Introduction

As a result, the flow of the endothermic dehydrogenation reaction in the adiabatic regime, there is a decrease in reactor temperature, the value of which depends on the amount of steam fed is an inert coolant. Reducing the temperature drop in the range of 20 °C can be achieved only by diluting feed steam in the ratio 1:40 mol/mol (or 1:10 kg/kg). An amount of steam consumption increases the cost of the product and reduces the efficiency of the process. Thus, the use of an adiabatic reactor capacitive contact type in this case is uneconomical.

The intensification of the dehydrogenation reaction can be obtained by increasing the gas temperature by heating it or by introducing additional superheated steam, in a catalyst layer. It is also possible to implement the systems consisting of two reactors in series, where the gas is passed through the first reactor is heated again, and then passes through the second reactor. In this paper, we consider three possible options for the implementation of the dehydrogenation process with an additional intensification of the process:

- a reactor with an additional introduction of superheated steam into the catalyst bed;
- two consecutive heated reactor with intermediate gas;
- two consecutive reactor by adding additional superheated steam into the gas before it is fed into the second reactor.

The aim of this work is the mathematical modeling of the various areas of technological process optimization in the dehydrogenation of isoamylenes to isoprene, analysis of the results and selects the best in terms of energy efficiency optimization method, and conducting pilot tests.

2 Experimental/methodology

The object of research is the process of dehydrogenation of isoamylenes to isoprene (Figure 1) in the presence of a potassium and cerium promoted iron oxide catalyst. The chemical composition of the catalyst is presented in Table 1.

Table 1. Chemical composition of a potassium and cerium promoted iron oxide catalyst

Composition	Fe_3O_4	K_2O	CeO_2	CaO	MgO	MoO_3
ω, % wt.	72,51	3,60	14,90	2,60	3,10	3,29

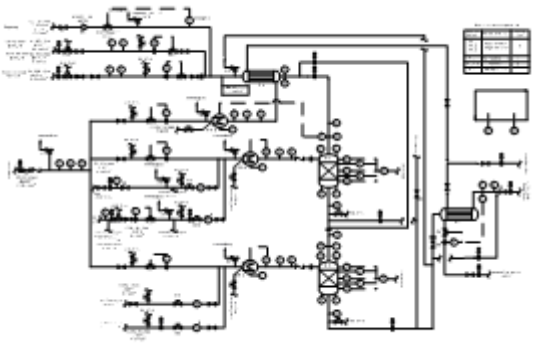

Fig. 1. Block diagram of a pilot plant test a potassium and cerium promoted iron oxide catalyst during the dehydrogenation of isoamylene to isoprene

3 Results and discussion

Carrying out the process for the dehydrogenation of isoamylenes to a two-reactor circuit further supplying steam into the second reactor in comparison with traditional allows to increase the absolute yield of isoprene 13-15 %, while maintaining selectivity at a level of 86-90 %. Thus, the total dilution steam to feedstock weight ratio of 1:10 at a volumetric feed rate of 0.8 h^{-1} to activity allowed to increase to 52 %.

Thus, the operation of the plant with an additional supply of steam to the second reactor indicated on the existing scheme in the second dehydrogenation step technical limitations to exploit the potential of iron oxide catalysts in full. The main limitation on the degree of conversion of the existing scheme is insufficient thermal energy necessary for the occurrence of endothermic dehydrogenation reaction. In this connection the modernization of reactors to ensure the supply of steam into the middle catalyst layer.

4 Conclusions

In order to improve the effectiveness of existing factory circuits dehydrogenation of isoamylenes explored to increase the yield of isoprene. To compensate for heat losses occurring in the reactor by the endothermic reactions, necessary heat input to the reaction zone.

Optimal in terms of energy efficiency was selected (two consecutive reactor by adding additional superheated steam into the gas before it is fed into the second reactor) optimization method. Implementation of this scheme is expected to increase the activity on 10-12 % while maintaining selectivity.

For practical realization of the goal to increase the yield of isoprene were conducted pilot tests in the dehydrogenation isoamylenes to isoprene process using a pilot plant with two reactors connected in series with additional steam to the second reactor. Thus, sampling and analysis was carried out of the contact gas, after the first and after the second reactor, enabling a comparative analysis of the results using the conventional scheme, and an intermediate circuit with a two-reactor steam supply.

Based on the results conducted by pilot test shows that carrying out the process for the dehydrogenation of isoamylenes to isoprene a two-reactor circuit further supplying steam into the second reactor in comparison with traditional allows to increase the absolute yield of isoprene activity 13-15 %, while maintaining selectivity at a level of 86-90 %. Thus, carrying out the dehydrogenation process with an intermediate supply steam to the reactor is promising, and may be used in the present dehydrogenation process cycle plant. On the basis of pilot tests, it was proposed to test the scheme in terms of operating the dehydrogenation reactors.

Hypercrosslinked Polystyrene-Supported Palladium Catalysts for Suzuki Cross-Coupling Reaction

Lyubimova N., Nikoshvili L.*, Matveeva V., Sulman M., Sulman E.

Tver Technical University, Tver, Russia

* nlinda@science.tver.ru

Keywords: Suzuki cross-coupling, palladium, hypercrosslinked, polystyrene

1 Introduction

Palladium-catalyzed reactions of C-C bond formation are a versatile tool in organic synthesis. Among the existing coupling reactions the Suzuki coupling is of particular importance. It involves the reaction between aryl halides and arylboronic acids to yield unsymmetrical biaryls with high selectivity. Suzuki coupling requires mild reaction conditions and is tolerant to the presence of different functional groups [1].

Catalysts used in the Suzuki reaction have been traditionally based on homogeneous palladium phosphine complexes, which are rarely recoverable without elaborate and wasteful procedures, and therefore commercially unfavorable. Moreover, phosphine ligands are expensive, toxic; and in large-scale applications the phosphines may be more costly than the metal itself. In recent years there has been an increasing interest in developing greener processes. In this context, heterogeneous catalysis is emerging as an alternative to homogeneous processes since the catalysts can be recovered and reused. Catalyst recovery also decreases contamination of products with residual metal species [2].

In the last decade the development of new ligand-free catalytic systems, which allows for the Suzuki reaction under mild conditions in aqueous media, attracted increased attention of scientific community. The most well known ligand-free catalyst is Pd/C [3]. In comparison with the expensive and unstable homogeneous palladium complexes, Pd/C is easy to manufacture and can be separated from the reaction mixture by conventional filtration or centrifugation. However, the main disadvantage of the use of ligand-free catalysts is irreversible leaching of palladium. Therefore, the problem of searching of new ligand-free catalysts is still of great importance. Despite the diversity of methods of synthesis of ligand-free catalysts (using inorganic carriers (oxides and metal salts, zeolites, magnetic nanoparticles), carbon supports (activated carbon, carbon nanotubes, graphene)), nanostructured polymers can be considered as the most promising supports [3, 4] in order to govern nanoparticle growth and prevent their aggregation. The variety of properties (presence of functional groups, degree of crosslinking, hydrophilicity or hydrophobicity, etc.) of polymers provide the opportunity to influence the process of formation of nanoparticles [5].

In this work we investigated the hypercrosslinked polystyrene (HPS)-supported palladium catalysts in Suzuki cross-coupling of 4-bromoanisole and phenylboronic acid (Fig. 1).

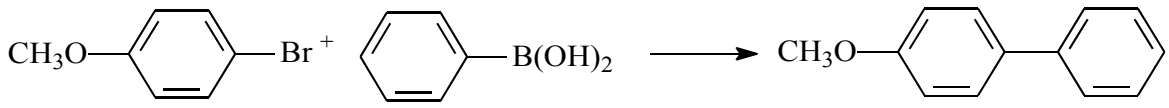

Fig. 1. Suzuki cross-coupling reaction of 4-bromoanisole and phenylboronic acid

2 Experimental

Pd/MN100 catalysts with different metal loadings were synthesized via conventional wet-impregnation method according to the procedure described elsewhere [6] using the following

metal precursors: $PdCl_2(CH_3CN)_2$, $Pd(OAc)_2$, $PdCl_2$. In a typical experiment, 3 g of pretreated, dried and crushed (<60 m) granules of MN100 were impregnated with 9 mL of precursor (e.g. $(CH_3CN)_2PdCl_2$) solution in THF of a certain concentration. The Pd-containing polymer was dried at 70°C, treated with Na_2CO_3, washed with distilled water till neutral pH, and dried again at 70°C.

The Suzuki cross-coupling reaction was carried out in a 60 mL isothermal glass batch reactor installed in a shaker and connected to a gasometrical burette. The total volume of liquid phase was 30 mL. Reaction was carried out at ambient pressure at variation of solvent nature and composition, temperature, nature and concentration of base, substrate-to-catalyst ratio and stirring rate.

Samples were periodically taken and analyzed via GC-MS (Shimadzu GCMS-QP2010S) equipped with a capillary column HP-1MS (30 m × 0.25 mm i.d., 0.25 μm film thickness). Helium was used as a carrier gas at flow rate 1 mL/min. Analysis conditions: oven temperature 60 C (isothermal), injector and interface temperature 280 C, ion source temperature 260 C, range from 10 up to 200 m/z.

3 Results and discussion

During the variation of solvent nature it was found that the use of mixture of low-molecular weight alcohols (e.g. EtOH, *i*-PrOH) with water allows relatively high activity at mild temperatures (60-70°C) along with the absence of the necessity to use phase transfer agents. Besides, the mixture of EtOH with water is favorable from the environmental point of view. Best results were obtained for the catalyst synthesized while using $PdCl_2(CH_3CN)_2$ as the precursor, e.g. in EtOH/water mixture of 5:1 at 70 ºC, conversion of 4-bromoanisole for 1 h was more than 93%.

The possibility of catalyst separation and multiple reuses was also investigated. After first run the catalyst was separated by filtration, successively washed with ethanol, hexane and acetonitrile and allowed to dry at 80 ºC. The separated catalyst was reused under the chosen reaction conditions. It was revealed that synthesized Pd/HPS catalysts can be reused four times without essential loss in activity.

4 Conclusions

HPS-supported palladium catalysts were found to be promising (active, selective and stable during four runs) for the Suzuki cross-coupling reaction of 4-bromoanisole and phenylboronic acid in order to produce the corresponding biaryl with high yield at mild reaction conditions in environmentally favourable solvents.

Enantioselective Hydrogenation of Prochiral Arylketones and Keto Acid ethers Catalyzed by $Pd(acac)_2$- Chiral Base

Nindakova L.O.*, Strakhov V.O., Chvanova K.A.

Irkutsk State Technical University, Irkutsk, Russia

* nindakova@istu.edu

Keywords: palladium, chiral, modifier, enantioselectivity, hydrogenation

1 Introduction

Enantioselective hydrogenation of organic carbonyl compounds with prochiral C=O bond now use for synthesis of optical active secondary alcohols, which have be employed for production drugs, perfume components and agrochemicals.

Metal nanoparticles application for catalytic hydrogenation of unsaturated bonds is very exciting and becoming popular research area [1, 2], since they could be effective and selective catalysts in such cases.

Enantioselective hydrogenation of prochiral ketones (acetophenone) and keto acid ethers by molecular hydrogen over colloidal palladium, which have been formed in system $Pd(acac)_2$ - chiral base - H_2 was studied.

2 Experimental

Hydrogenation experiments carried out in autoclave Büchiglasuster cyclone 075 at pressure 5 bar). Reaction monitoring was studied by Gas Chromatograph-Mass Spectrometers Shimadzu QP2010 Plus in electron impact mode at 70 eV; capillary column Equity 5 (30мх0.25 мм, 95% dimethylpolysyloxane, 5% diphenylpolysyloxane, carrier gas - hellium). Enantiomeer product excess was determined by Gas Chromatograph GC Agient 7890A, flame-ionization detector and chiral capillary column CYCLODEX-B (length 30 m, internal diameter 0.25 mm). Optical rotation of pure compounds and solutions was determined by automatic digital ADP 410 at wave length 589 nm (l = 50 mm, C = 1–5 g/100 ml).

Microstructure and morphology of Palladium nanoparticles was studied by high-resolution **TEM** method. Images were obtained in FEI Tecnai G^2 c with accelerating voltage 200 kV, equipped energy dispersion detector (EDAX) for carrying out elemental analysis.

In situ drop of catalyst solution (C_{Pd} = 1-5 mmol/l) was applied on supporting grid, which coved by carbon film, and dried in Argon atmosphere. Coverage conditions eliminate melting and decomposition of researching compounds under the influence of electron beam.

3 Results and discussion

In system $Pd(Acac)_2$-chiral base-H_2 the formation of colloid Palladium is taking place during 1 hour. As a chiral bases we used natural alkaloid (-)cinchonidine (Cin) and its N- and N,N'-protonated derivatives: Cin*HCl and Cin*2HCl, they were preliminary synthesized and characterized by physical and chemical methods.

We found that reaction rate of hydrogenation of acetophenone at p_{H_2} = 5 bar decreases with increasing ratio of Cin/Pd in ratio range 0.5 - 1.0 – 1.5 (2.31; 1.17; 0.73 mmol/l*h) and increases in modifiers series Cin < Cin*HCl < Cin*2HCl.

The highest hydrogenation rate is observing in hydrogenation of ethylbenzoylformate (up to 180 mol Sub/g-atom Pd*h).

In hydrogenation of methylpyruvate we found abrupt decreasing of reaction

enantioselectivity (from 86% to 55%) during the reaction time. It needs optimizing reaction conditions to prevent this phenomenon.

Palladium nanoparticles, formed in catalytic system $Pd(acac)_2$- chiral base –MeOH after 1 hour, were studied by high-resolution TEM method. Measured the average size of nanoparticles is 6,0±0,9 *nm* for chiral base = (-)-cin; 4,4±0,9 *nm* and 4,3±0,6 *nm* for Cin*HCl and Cin*2HCl, respectively. At the atomic resolution we can see crystal structure of nanoparticles. Figure shows microphotographies of colloidal dispersions, formed in systems.

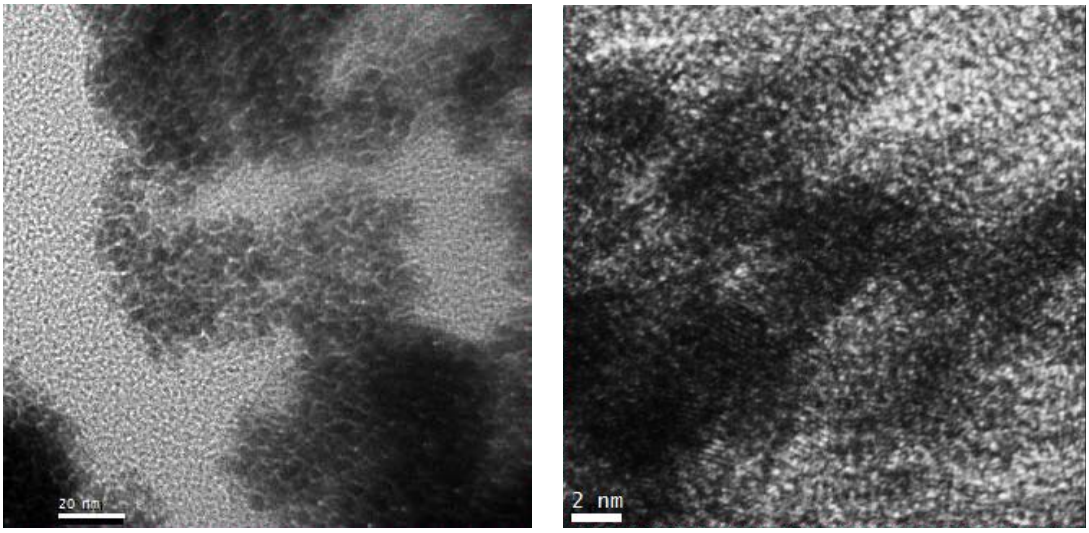

Figure. TEM microphotographies of dispersion from catalytic system $Pd[acac]_2$ - chiral base – H_2,: a) chiral base – (-)-Cin, (scale bar 20 nm); b) chiral base – Cin*HCl (scale bar 2 nm)

4 Conclusions

Ultradispersed (nanoscaled) catalysts based on $Pd(Acac)_2$ compounds were obtained and characterized by high-resolution TEM, X-ray analysis, scanning electron microscopy methods. As a modifiers was used nature alkaloid (-)-cinchonidine and its protonated derivatives. Catalysts were tested in hydrogenation of acetophenone and keto acid ethers. In hydrogenation of methylpyruvate enantiomeric excess reaches to 86% of predominant enantiomer methyl lactate.

Cumene Hydroperoxide Decomposition in the Presence of Organic Group II Metal Salts

Nurullina N.*, Batyrshin N., Kharlampidi Kh.

Kazan National Research Technological University, Department of General Chemical Technology, Kazan, Russia

* nyryllina@mail.ru

Keywords: 2-ethylhexanoates, cumene hydroperoxide decomposition, catalytic activity

1 Introduction

Advances in the oxidation of aromatic hydrocarbons are largely determined by the efficiency of the catalyst employed, specifically by its activity, selectivity, and ease of preparation. Among the known catalysts for "soft" initiation of activation processes, non-transition metal 2-ethylhexanoates are very active ones [1].

In order to understand why the decomposition of organic hydroperoxides depends on the nature of the metal, we studied the catalytic action of Subgroup IIA and IIB metal 2-ethylhexanoates ($M(EH)_2$) in the decomposition of cumene hydroperoxide (CHP).

2 Experimental/methodology

The catalytic activity of the ethylhexanoates was estimated in terms of CHP decomposition rate. CHP was decomposed using an ampule technique. CHP concentration was determined by iodometric.

3 Results and discussion

All of the ethylhexanoates catalyze CHP decomposition. The activity of $M(EH)_2$ decreases in the following order:

$$Mg(EH)_2>Ca(EH)_2>Cd(EH)_2>Zn(EH)_2>Hg(EH)_2.$$

The main products of CHP decomposition in the presence of any catalyst are dimethylphenylcarbinol (DMPC), acetophenone (AP), α-methylstyrene (α-MS), methanol, phenol, and acids.

The formal kinetic scheme of the process is

$$ROOH + M(EH)_2 \leftrightarrow [ROOH \cdot M(EH)_2], \quad (I)$$

$$[ROOH \cdot M(EH)_2] \rightarrow M(EH)_2 + \text{products}. \quad (II)$$

Using the Lineweaver–Burk method [2] we determined kinetic parameters of the overall decomposition process. The thermodynamic characteristics of complexation were calculated via the van't Hoff equation.

We discovered a correlation between the ionization potential of the metal and the rate of peroxide decomposition in the presence of $M(EH)_2$ (Table). Higher CHP decomposition rates are observed in the presence of the 2-ethylhexanoates of metals with lower ionization potentials (Mg, Ca and Cd). All parameters of the catalytic decomposition take their minimum values in the case of $Cd(EH)_2$, and it is cadmium that has the lowest ionization potential in the subgroup consisting of Zn, Cd, and Hg.

Magnesium and calcium, which differs noticeably in atomic and ionic sizes from the Subgroup IIB metals, has more pronounced metallic properties. Covalent bonds are less typical for magnesium and calcium than for zinc or mercury; like cadmium, magnesium and calcium more readily forms ionic bonds.

There is a large contribution from covalent bonding in the Zn and Hg complexes, and these

complexes are less active than the Cd, Ca and Mg complexes, in which the coordination bond is more ionic. This finding suggests that the higher the ionicity of the bond, the higher the activity of the catalyst. Accordingly, the purely ionic magnesium complexes should be much more active than the zinc-subgroup metal complexes. However, the zinc subgroup metal complexes also display high catalytic activity, which is obviously due to the additional polarization effect. This effect is favorable for the formation of covalent bonds in the mercury and zinc complexes and, to a lesser extent, in the cadmium complex.

4 Conclusions

Therefore, the catalytic properties of the Subgroup IIB carboxylates depend mainly on the nature of the interaction force in the formation of the ROOH–$M(EH)_2$ intermediate. For the compounds of cadmium, calcium and magnesium, which belong to the main subgroup, the bond in the intermediate is primarily determined by electrostatic factors. In the case of zinc and mercury a significant role in the intermediate is played by covalent bonding.

Keywords: biomass, hydrogenation, liquid phase, furfural, furfuryl, alcohol, silica

1 Introduction

Over the past decade there has been an increase in research utilising biomass as a start material due to the high demand and depleting stocks of fossil fuels. The production of fine chemicals is one of the many research areas to stem from this broad topic. Furfural is a functional by-product produced naturally from biomass in the biofuel industry. It has an extensive number of derivatives including furfuryl alcohol which is used extensively in the polymer and chemical manufacturing industry. Furfuryl alcohol is produced by the catalytic hydrogenation of furfural in liquid or vapour phase. Copper chromite catalysts are used for this process despite posing severe environmental threats as chromium is toxic to many aquatic organisms. The challenges associated with the disposal of this catalyst have created a significant research emphasis on attaining a suitable alternative. Literature has shown the use of chromium free catalysts can be used to produce furfuryl alcohol however they have proved unsuitable for industrial application due to high production costs and catalyst deactivation. The aim of this research is to produce an inexpensive catalyst suitable for industrial use.

2 Experimental/methodology

Eight precious metal catalysts were produced by wet impregnation techniques to make 1 and 2 wt% of copper, nickel, platinum or palladium supported on SiO_2. The catalysts were hydrogenated in the liquid phase under the following conditions: 100°C, 20 bar hydrogen, 1 g of catalyst, 25 ml of furfural and 175 ml solvent. A comparison was conducted between each catalyst for the conversion of furfural and the selectivity to furfuryl alcohol. Two solvents, ethanol and toluene were employed to establish the influence of solvent on the reaction. The superior catalyst was further exposed to five additional temperatures ranging from 50–170°C to investigate the influence of temperature on selectivity to furfuryl alcohol.

3 Results and discussion

From the selection of catalysts analysed 2%Pt/SiO_2 revealed the highest selectivity to furfuryl alcohol with ethanol employed as the solvent. Literature states that use of an alcohol as solvent has a positive influence on the reaction as the alcohol group acts as a hydrogen donor contributing to the conversion of furfural. The polarity of the alcohol influences the product selectivity and selection should oppose that of the reactant. Solvent testing showed the use of an alcohol as solvent had a significant influence of the production of undesirable products including difurfuryl ether and 2-furaldehyde diethyl acetal due to interactions between the alcohol and both the reactant and desired product furfuryl alcohol. Neither product was formed when toluene was employed however furfural conversion was lower. Temperature studies were conducted to establish an optimum reaction temperature in a low range with these results displayed in figure 1(a) and (b).

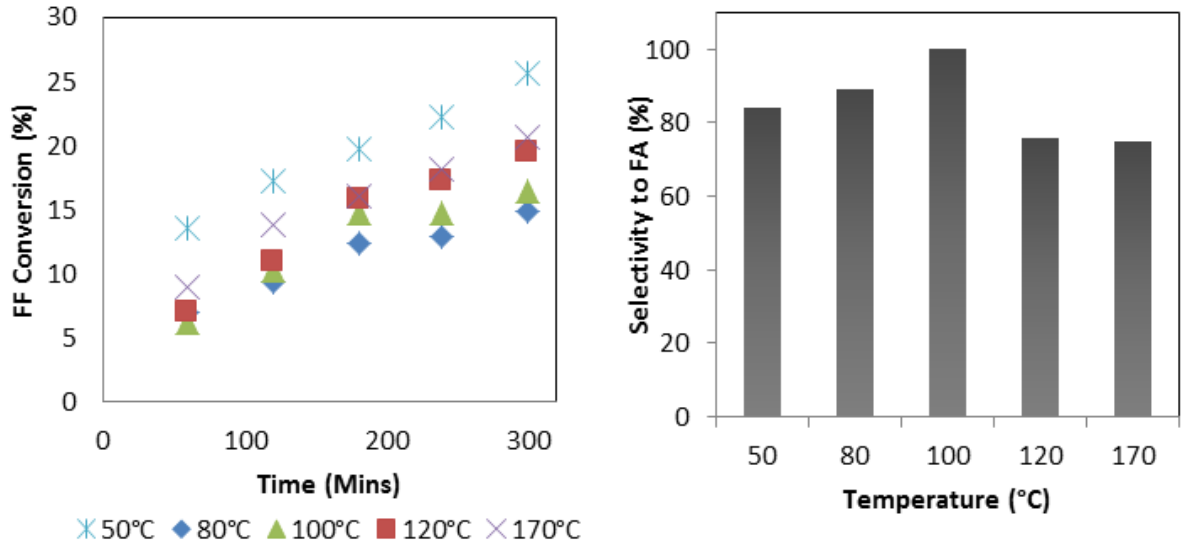

Fig. 1. shows the influence of temperature for (a) conversion of furfural using 2%Pt/SiO_2 with toluene as solvent and (b) selectivity to furfuryl alcohol at 15% conversion.

The percentage conversion of furfural increased over time for each temperature examined as seen in figure 1 (a). The selectivity to furfuryl alcohol was seen to follow a similar pattern indicating that the catalyst was still active at 300 minutes. This also indicates that there is no interaction between the solvent and the desired product which is confirmed as derived products are not formed. Figure 1 (b) shows the selectivity to furfuryl alcohol at 15% conversion where it was observed that the highest selectivity was at 100°C with higher temperatures giving lower selectivity. However, the difference observed between all temperatures is minor with a wide time range observed for the corresponding 15% conversion. This indicates that selectivity is independent of temperature and for this reaction it is dependent on conversion. The superior conversions are seen from 50°C and 170°C indicating that temperature is not a significant influence on conversion which is strongly dependent on solvent and catalyst selection.

4 Conclusions

The use of an alcohol as solvent results in interactions between the reactant and the desired product affecting the overall production of furfuryl alcohol. It was found that 2%Pt/SiO_2 hydrogenated at 100°C in toluene gave the best results for this segment of the research as there was no formation of undesired products. Further analyses of these results deemed selectivity and conversion to be independent of temperature and dependent only on solvent and catalyst selection with further work focused on the impact of bimetallic platinum based catalysts on the hydrogenation reaction.

Keywords: titania, polyvinylpyrrolidone, PdZn nanoparticles, selective hydrogenation, 3-methyl butynol

1 Introduction

Semi-hydrogenation of the triple bond in long-chain alcohols is of particular interest because hydrogenation products are intermediates in the synthesis of vitamins and fragrant substances. Wall coated capillary microreactors possessed distinct advantages such as improved temperature control, selectivity, and both environmental and safety issues resulting from the use of small quantities of reagents and solvents. Crystalline TiO_2 mesoporous thin films with embedded nanoparticles supported on the channel walls can be readily obtained via a template sol-gel process [1]. Bimetallic PdZn catalysts are widely used for selective hydrogenation of acetylene alcohols. In this paper we report the structure and catalytic studies of the incorporated into titania monometallic Pd and bimetallic PdZn colloid nanoparticles stabilized by PVPone (polyvinylpyrrolidone) and PVPine (polyvinylpyridine). The hydrogenation of 2-methyl-3-butyn-2-ol (MBY) was used as a probe reaction to evaluate the activity and selectivity of the samples in hydrogenation of acetylene alcohols. The results have been compared with the catalysts prepared by conventional impregnation.

2 Experimental

The PdZn bimetallic nanoparticles were synthesized by a polyol method. The amount of PdZn nanoparticles was chosen to obtain 1 wt.% Pd metal loading in TiO_2. The molar composition of the final solution was $1Ti(O\text{-}iPr)_4 : 0.009$ Pluronic F127 : $32C_2H_5OH:8C_4H_9OH : 1.3H_2O : 0.18HNO_3$. The solvent was evaporated at 293 K and relative humidity (RH) of 80%, followed by two activation procedures. The low-temperature activation included calcination at 573 K for 2 h under a residual pressure of 13 mbar with a heating rate of 1 K/min. The high-temperature activation comprised calcination in air at 673 K for 2 hours with stepwise equalizing every 100 K for 1 hour and a heating rate of 1K/min, and subsequent reduction in a 30 vol.% H_2/Ar flow at 673 K for 2 hours. The samples are noted according to their synthesis procedure: the letter denotes activation conditions. ‘‘L’’ and ‘‘H’’ stands for low-temperature and high temperature activation, respectively. For comparison we prepared samples by combined impregnation with inorganic $PdCl_2$ and $ZnCl_2$ precursors. The samples are marked in accordance with the synthesis procedure: “C” and “I” correspond to the samples obtained by embedding colloid nanoparticles and impregnation, respectively. The number at the end means the molar ratio PVP/Me. The symbol “-one” stands for polyvinylpyrrolidone and “–ine” means polyvinylpyridine. Catalysts were investigated by a few physical and chemical methods: HRTEM, XPS, AES-ICP, XRF, thermogravimetric analyses and differential thermal analyses.
Hydrogenation of 2-methyl-3-butyn-2-ol (MBY) was carried out in autoclave reactor with a total volume 130 ml at 333K and 5 bar H_2 pressure under intensive stirring at 2000 rpm. A substrate-to-palladium molar ratio was 2100. Prior to activity measurements, the samples were reduced at 523 K at a H_2 pressure of 10 bar for 2 h. Analysis of the reaction mixture was performed off-line with gas chromatograph Agilent 7890A equipped with a SKTFT-50X

capillary column (diameter: 0.22 mm, length: 30 m) and a FID detector

3 Results and discussion

Data in table 1 clearly show important differences between the impregnated and nanoparticle-based catalyst. An effect of stabilizer, PVP/Me ratio and activation conditions on catalytic properties was also given. The impregnated catalyst is less active and selective to MBE. Thus, the selectivity is about 68.3% for the impregnated $PdZn/TiO_2$ and reaches 88.9% for the nanoparticle-based catalyst. Increasing the concentration of PVPone when synthesizing the nanoparticles results in an improvement of the selectivity reaching 88.9% at a conversion of 95% at a molar ratio of PVP/PdZn 10, while activity varies slightly in the range 1.1 до 1.8 molPd/s. The activity and selectivity of the samples prepared from PdZn- PVPine is lower than those of the samples containing PdZn nanoparticles stabilized with polyvinylpyrrolidone. The samples subjected to low-temperature activation at 573 K and 13 mbar for 2 hours exhibit higher selectivity compared with the samples calcined in air at 673 K and reduced at 673 K in 30 vol.% H_2/Ar. These results can be explained by the electronic effect of the stabilizer and by the different average size and composition of the nanoparticles.

Table 1. Effect of stabilizer, PVP/Me ratio, activation conditions and preparation method on the activity at 50% conversion and selectivity at 95% conversion of the Pd/TiO_2 and $PdZn/TiO_2$ samples in hydrogenation of 2-methyl-3-butyn-2-ol.

Sample	PVP/Me, mol/mol	dn, nm	Activity, molMBY/molPd/s	Selectivity, %
Pd/TiO_2.C-5one	0	8.6	2.1	74.2
$PdZn/TiO_2$.C-L-10one	10	4.4	1.6	88.9
$PdZn/TiO_2$.C-L-5one	5	6.5	1.1	86.5
$PdZn/TiO_2$.C-L-2.5one	2.5	6.0	1.3	81.3
$PdZn/TiO_2$.C-H-2.5one	2.5	7-20	1.9	73.6
$PdZn/TiO_2$.C-L-0one	0	2.9-38	1.8	81.5
$PdZn/TiO_2$.C-L-10ine	10	2	1.0	70.2
$PdZn/TiO_2$.C-H-10ine	10	-	0.5	58.0
Pd/TiO_2.I-H	0	-	0.53	66.5
$PdZn/TiO_2$.I-H	0	2.5-56	0.41	68.3

4 Conclusions

Pd/TiO_2 and $PdZn/TiO_2$ on titania catalyst have been prepared following two methods: a traditional impregnation with inorganic salt followed by calcination and reduction and a colloidal approach in which mono- and bimetallic nanoparticles were first synthesized and subsequently embedded in support sol, dried and annealed in vacuum at 573 K. Nanoparticle-based bimetallic catalysts have shown higher activity and selectivity compared to impregnated PdZn catalysts when applied in selective hydrogenation of 2-methyl-3-butyn-2-ol. The main factor determining the high selectivity of samples is the use of polyvinylpyrrolidone as a stabilizer. In this respect, the kind and amount of the stabilizer, conditions of catalyst activation are key factors in the synthesis of the catalysts. Other important parameters are average size and composition of the particles. Bimetallic catalysts with average particle size of 4.4 nm and narrow particle size distribution was the most active and selective.

Keywords: capillary microreactor, Ce-doped titania, PdZn nanoparticles, selective hydrogenation

1 Introduction

Fused silica capillary to act as a microreactor for multiphase reactions has been recognized for the last decade. The application of this system in fine chemical synthesis is aimed to avoid mass- and heat-transport limitations and improve selectivity for a series of sequential reactions. The synthesis of fragrance and vitamins involves semi-hydrogentaion of alkyne alcohol as a crucial step. Thin films with embedded nanoparticles obtained via a sol-gel process using a template-based precursor solution have been developed as catalysts for selective hydrogenation. Recently the use of Ce-doped catalytic coatings has been highlighted to improve the stability of the mesoporous titania matrix [1]. Here we present the use of microcapillary reactor with Ce-doped titania films holding Pd or $Pd_{80}Zn_{20}$ nanoparticles for 2-methyl-3-butyne-2-ol(MBY) hydrogenation. The results are compared with the hydrogenation over Pd/(Ti, Ce)O_2 powder catalyst in a batch reactor at a hydrogen pressure 5 bar.

2 Experimental

The coatings and powders were prepared using a template sol–gel method. The molar ratio between the reagents in the resulting sol was 1 $Ti(O–iPr)_4$:0.05 $Ce(NO_3)_3{\cdot}6H_2O$: 0.009 Pluronic F 127 : 40 C_2H_5OH : 1.3 H_2O : 0.13HNO_3. The ethanol suspension of colloidal nanoparticles was added to the sol. The resulting sol was dip coated on the internal surface of fused silica capillary with an internal diameter of 250 μm and a length of 10 m. The gas (H_2/He) and liquid (0.05-0.3 M solution of 2-methyl-3-butene-2-ol in methanol) were mixed in a T-mixer. The capillary was annealed at 573 K for 2 h under a residual pressure of 13 mbar and in situ reduced at 573 K at hydrogen flow for 1 hour.

Pd/(Ti,Ce)O_2 powder was first annealed at 573 K for 2 h and placed in an autoclave reactor with a total volume 130 ml, then reduced in situ at 523 K at a H_2 pressure of 13 bar for 2 h. Hydrogenation of 2-methyl-3-butyn-2-ol (MBY) was carried out at 333 K and 5 bar H_2 pressure under intensive stirring at 2000 rpm. Analysis of the reaction mixture was performed off-line with gas chromatograph Agilent 7890A equipped with a SKTFT-50X capillary column (diameter: 0.22 mm, length: 30 m) and a FID detector.

3 Results and discussion

Figure 1 shows the selectivity to 2-methyl-3-butene-2-ol (MBE) at different conversion of 2-methyl-3-butyne-2-ol (MBY) on Pd/(Ti,Ce)O_2 powder in batch reactor and Pd/(Ti,Ce)O_2 coating on inner surface of capillary microreactor. The selectivity to alkene alcohol is higher than that observed in the batch reactor, where there is no need for a catalyst separation step.

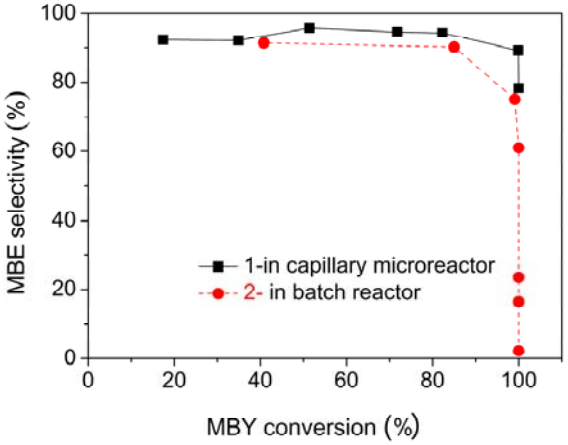

Fig. 1. Selectivity to MBE as a function of MBY conversion over Pd/(Ti, Ce)O_2 in capillary microreactor (1) and (2) batch reactor.

The effect of the liquid residence time, the presence of Zn and the hydrogen partial pressure was studied by comparing the Pd/(Ti, Ce)O_2 and $Pd_{80}Zn_{20}$/(Ti,Ce)O_2 coatings. An addition of Zn improves the selectivity to 2-methyl-3-butene-2-ol at high conversion of 2-methyl-3-butyne-2-ol (Figure 2). The selectivity was further improved towards 94 % at 99.8% over $Pd_{80}Zn_{20}$/(Ti,Ce)O_2 coating by decreasing hydrogen partial pressure to 0.5.

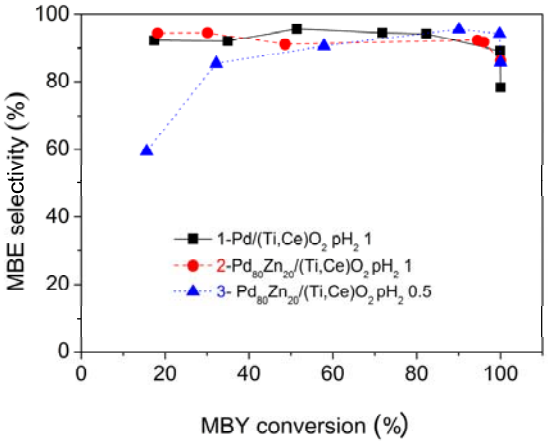

Fig. 2. Selectivity to MBE as a function of MBY conversion in capillary microreactor over (1) Pd/(Ti, Ce)O_2 H_2 partial pressure 1, (2) $Pd_{80}Zn_{20}$/(Ti,Ce)O_2 H_2 partial pressure 1 and (2) $Pd_{80}Zn_{20}$/(Ti,Ce)O_2 pH_2 0.5. Hydrogen flow rate 2 ml/min (STP). Temperature: 323 K

4 Conclusions

Capillary microreactors coated with Ce-doped titania containing embedded Pd or $Pd_{80}Zn_{20}$ nanoparticles were tested in the 2-methyl-3-butyne-2-ol hydrogenation. The Pd/(Ti,Ce)O_2 catalyst showed an order of magnitude higher activity compared to commercial catalyst and demonstrated an increased selectivity to 2-methyl-3-buten-2-ol of 89% at 99.9% conversion compared with batch reactor. The highest selectivity to semihydrogenated product of 94 % at 99.8% was obtained over $Pd_{80}Zn_{20}$/(Ti,Ce)O_2 coating at 323K and hydrogen partial pressure of 0.5.

New Catalysts for Lignin Depolymerisation

Opris C.M.*, Tudorache M., Parvulescu V.I.

University of Bucharest, Faculty of Chemistry, Department of Organic Chemistry, Biochemistry and Catalysis, Bucharest, Romania

* cristina_opris88@yahoo.com

Keywords: lignin depolymerisation, catalyst, niobia, cobalt, magnetite

1 Introduction

The depletion of the oil resources and the increase of the demand of oxygenated chemicals require new strategies for development. The use of renewable materials is one of alternatives. Despite their complex structure, lignin is usually seen as a waste product of the pulping process and a low value material [1]. By using an adapted conversion technology [2] it can be converted providing an important source for the production of phenolic compounds [3]. However, the variety of linkages between units and trends to forming condensed structures induces difficulties in catalytic processing of lignin [4]. The scope of this study is to present a catalytic alternative depolymerisation for the lignin by using bifunctional catalysts. It describes prepared stable catalysts stable under depolymerisation reaction conditions, able to improve the accessibility and activity of the metal sites as well as the minimisation of repolymerisation and related side reactions [5].

2 Experimental/methodology

Multicomponent separable magnetic heterogeneous catalysts were prepared by successive covery of magnetite by niobia and cobalt-nanoparticles. Magnetite core nanoparticles were prepared by co-precipitation method, using $Fe(NO_3)_3.xH_2O$ and $FeCl_2.4H_2O$ as as Fe^{3+} and Fe^{2+} sources. Niobia prepared by microemulsion method using an ammonium oxalate complex of niobium as precursor and hexadecyltrimethylammonium bromide as surfactant were deposed on these nanoparticles. Finally cobalt, in varied concentrations, was supported onto the Nb_2O_5/magnetite composite using the precipitation-deposition method by using cobalt acetate as cobalt source. Before catalytic tests the sample were calcinated and reduced in presence of hydrogen.

Synthesized catalysts (Nb_2O_5, Nb_2O_5-Fe_3O_4, x%Co-Nb_2O_5-Fe_3O_4 (x=1,2,3,4,5,10,20) were characterized by thermal analysis, powder X-ray diffraction, Raman spectroscopy, XPS, FTIR and DRIFT spectroscopy, BET analysis. Lignin depolymerization was carried out in autoclave, starting from lignin as a raw material in water or ethanol as solvents.

The identification and quantification of the fragments resulted from the lignin depolymerization were performed in both liquid and solid phase. The two phases obtained after reaction were separed by centrifugation and liquid phase was analised by HPLC. The fragment of lignin from solid phase was extracted with tetrahydrofurane and analysed by GPC. The solid reziduu remained after extraction was acetylated with pyridine and acetic anhydride and then analysed by GPC.

Table 600. **Results and discussion**

The immer erization techniques it offered a picture of the catalysts synthesized. Fig.1 depicts comparative XRD patterns of Co-Nb_2O_5-Fe_3O_4 catalysts and of their intermediates. These demonstrate that: i) the magnetic core remained unaffected by the next deposition steps, ii) niobia exists on amorphous layer, iii) cobalt, after reduction with hydrogen is present in cubic phase.

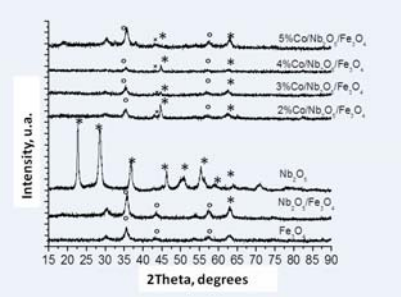

Fig.1. XRD pattern for synthesized catalysts (×=Cubic cobalt, card 00-042-1467, °=niobia, card 00-028-0317, *= magnetite, card 00-019-0629)

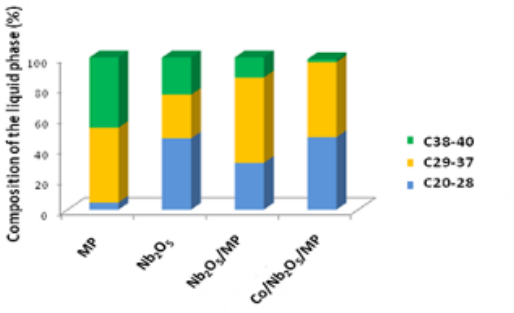

Fig.2. Composition of the liquid phase after lignin depolymerisation

The other immer erization techniques provided additional information about the oxidation state of the elements, size of the particles and dispersion. The performances of the catalytic tests were evaluated taking into account the lignin fragment distribution between liquid and solid phase of the reacted mixture. Fig.2. shows the composition of the liquid phase building block entities resulted after lignin depolymerisation. Lignin fragments found in the liquid phase (HPLC-DAD/MS analysis) were distributed in three different groups according to the fragments molecular weight, as it is shown in Table 1. These average molecular mass fragments correspond to immer, trimer and tetramer.

Table 1. Molecular fragments identified using the HPLC-MS/MS analysis of the lignin defragmentation products

Fragment group	MW range	Dominant MW
C_{20-28}	200-400	388; 361
C_{29-C37}	400-600	558
C_{38-40}	600-850	737; 744

The conversion of lignin on prepared catalysts varied from 15% for Fe_3O_4 to 53% for $Co/Nb_2O_5/Fe_3O_4$. The capability of niobia to catalyze the acidic hydrolysis of the β-O-4' bounds coupled to the affinity of the Co for assisting the breaking of the C-C bonds *via* hydrogenolysis lead to different dominant molecular fragment.

4 Conclusions

This study demonstrates that is possible to depolymerise lignin and to produce a cocktail of oxygenated compounds corresponding to dimer, trimer and tetramer building block entities of lignin.

Deactivation of Mixed Oxides as Catalysts for Ethanol Condensation: *in situ* DRIFT Spectroscopy Studies

Quesada J., Faba L., Diaz E., Ordonez S.*

University of Oviedo, Oviedo, Spain

* sordonez@uniovi.es

Keywords: catalyst deactivation, bioethanol, Guerbet reaction, basic mixed oxides, DRIFT spectroscopy

1 Introduction

Ethanol is nowadays considered as one of the most promising bio-platform molecules, being obtained by fermentation of different biomass feedstock [1]. Its high value is due not only to its good properties as biofuel but also to its potential as building block for the added-value chemical productions. The bioethanol upgrading implies the increase of its carbon chain length, usually by the Guerbet reaction of two short-chain alcohols coupling. This reaction is a key of interest in the last years, with several studies about catalytic activity and reaction mechanisms. The most accepted reaction pathway includes different steps catalyzed by different active sites, so catalytic properties have an important role in tuning the reaction to one of other products, in such a way that highest selectivities of 1-butanol are obtained with a good basicity/acidity equilibrium [2] whereas 1,3-butadiene is favored by strong basic materials [3].

Despite of the efforts devoted to identify the optimum catalyst, there are not deep studies about the stability of these materials, being these studies needed for scaling-up this process. A deep deactivation study implies the analysis not only of the evolution of reactant conversion and intermediates and products selectivities in gas phase, but also a study of possible changes in the morphological and structural catalytic properties by analyzing of the catalytic surface (with techniques as DRIFT spectroscopy). A complete study of Mg-Zr and Mg-Al stability in the ethanol condensation is presented in this work, justifying the conversion and selectivities evolutions by surface changes observed by DRIFT spectroscopy and different characterization techniques.

2 Experimental/methodology

Reactions were carried out in a 0.4 cm i.d. U-shaped fixed bed quartz reactor in which 0.02L/min (s.t.p.) of helium-ethanol mixture (1.5mL/min of ethanol) was fed. 150 mg of catalyst were used in each run. Reactor outgoing gases were on-line analysed by gas chromatography using a HP6890 GC with a FID detector. Spent catalysts were collected at 1, 2, 4, 6 and 8 h time on stream and characterized by different techniques, such as nitrogen physisorption and TPD.
Reactions at similar conditions were performed in a DRIFTS chamber (in a Nicolet Magma IRTF Spectrometer, using a ZnS window) in order to follow the evolution of the characteristic peaks of adsorbed reactants and products during the reaction. Kubelka-Munk method was used to analyse these results.

3 Results and discussion

Activity studies confirm the key role of catalytic properties in the ethanol gas-phase condensation. **Table 1** summarizes the main results obtained at different temperatures with Mg-Zr and Mg-Al catalysts. At medium temperatures, higher conversions are obtained with MgAl, whereas the conversion at 723 K is 40 % higher with MgZr (increase directly relate to a high ethylene production). MgAl is much more selective to the main route. The highest selectivity to 1-butanol is reached with MgAl at low temperatures, whereas the maximum of 1,3-butadiene is obtained with MgZr at 723 K. These results show the high influence of basicity to enhance the

condensation, since MgZr is more basic (1.71 μmol CO_2/m^2) than MgAl (1.01 μmol CO_2/m^2) and the selectivity to 1,3-butadiene is higher with this material, and the role of acidity in the other steps of the process (the acidity of MgAl is stronger than the acidity of MgZr, justifying the higher selectivity of 1-butanol).

Table 1: Summary of the results of catalytic activity at 523 / 623 / 723 K

	Conv. (%)	Ethylene (%)	Acetaldehyde (%)	1,3-butadiene (%)	1-butanol (%)
Mg-Zr	7.5 / 9.1 / 53.7	0 / 28.1 / 57.8	91.7 / 62.2 / 16.2	0 / 0 / 18.7	8.3 / 5.0 / 6.2
Mg-Al	15.1 / 17.4 / 38.3	1.3 / 7.1 / 16.5	81.3 / 80.8 / 65.8	0 / 0 / 0.5	15.5 / 7.0 / 11.1

Deactivation studies demonstrate a high influence of reaction temperature in the catalytic stability of both materials. Thus, there is not a relevant decrease neither in the ethanol conversion not in the product selectivities at temperatures lower than 700 K (decreases lower than 5% in 8 h), whereas an important decrease in the ethanol conversion is observed at 723 K, from 54 to 23% in 8 h time-on-stream in the case of MgZr and from 40 to 25% with MgAl. DRIFT spectroscopic studies demonstrate the existence of two different deactivation causes. In the case of MgZr, (**Fig. 1** shows the spectra evolution at 723 K, as example), bands related to ethoxide adsorption (deprotonated ethanol coordinated with a Mg surface atom) keep almost constant with time, so active sites that promote the first step do not suffer any modification, whereas signals of butoxide adsorption disappears after 6 hours. Bands of acetaldehyde and butanal adsorptions increase their intensity, as consequence of a stronger adsorption, but the loss of activity is proportional to the intensity of a new signal at 1536 cm^{-1}, related to the strong adsorption of molecules containing C=C. Considering the high selectivity of this side-product obtained with MgZr and the possible oligomerization of this compound, this fact is proposed as the main cause of deactivation. On the other hand, spectra of MgAl samples indicate a higher influence of other products adsorbed on stronger acid sites. These hypothesis were corroborated by results obtained in the characterization of spent catalysts.

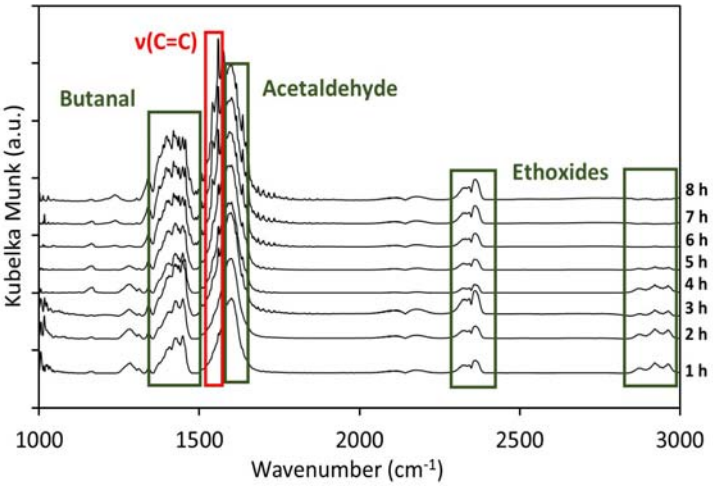

Fig. 1. Evolution of DRIFT results in the ethanol condensation at 723 K with MgZr

4 Conclusions

The higher acidity/basicity ratio was identified as the key catalytic property that justifies the activity of mixed oxides in ethanol condensation. According to DRIFT studies, olefin polymerization and adsorption of side-products were proposed as main deactivation causes.

Modification of Skeletal Nickel Surface on Effects of Hydrogenation for Adsorption Behavior of p–Nitrotoluene

Osadchaya T.*, Afineevskiy A., Prozorov D., Lukin M.

Ivanovo State University of Chemistry and Technology, Research Institute for Thermodynamics and Kinetics of Chemical Processes, Dep. of Physical and Colloid Chemistry, Ivanovo, Russia

* osadchayatyu@gmail.com

Keywords: liquid-phase hydrogenation, p-nitrotoluene, modifying skeletal nickel, catalyst, FTIR

1 Introduction

High-performance eco-friendly liquid phase hydrogenation technologies provide a high yield and quality of final products, raw materials and energy savings, can eliminate or substantially reduce the anthropogenic influence of existing production at the regional ecological environment due to a sharp decline in toxic gas emissions, waste water and solid waste. Hence, the problem of expanding the applications of catalytic technologies formulated industrial section of the European Association of Societies of catalytic EFCATS is a priority [1].

Skeletal nickel and supported palladium catalysts are the most widely used in laboratory practices and technologies, the liquid-phase hydrogenation of various classes of organic compounds [2].

Hydrogenation reaction of 4-nitrotoluene was selected as the most simple example of a large number of processes reduction of compounds containing nitro group and various substituents. 4-aminotoluene - complete hydrogenation product of 4-nitrotoluene - is a raw material for production of various fine chemicals, in particular, various grades of disperse dyes [3].

The purpose of this work is to investigation of the effect of surface modifiers of skeletal nickel on its activity in the liquid-phase hydrogenation of *p*-nitrotoluene.

The sodium sulfide was chosen as a modifier because due to the ability to block the active sites of skeletal Nickel catalyst [4, 5]. This property of modifying agents will affect the specific binding energy distribution.

2 Experimental/methodology

Skeletal Nickel catalyst was obtained by sodium hydroxide treatment of the Nickel-aluminum alloy according to the standard method [6]. Catalyst particle size was 4.8 μm. Active catalyst had a specific surface area: 90±2 m^2/g, porosity: 0.5±0.05.

The hydrogenation was carried out by static method in the closed system with intensive stirring liquid phase. All the experiments were carried out in a batch laboratory scale stirred tank reactor with stirring frequency of the reaction mixture about 3600 rpm, atmospheric pressure of hydrogen and temperature of the liquid phase being 303K. The aqueous solutions of 2-propanol with molar fractions of alcohol x_2= 0.073; 0.191; 0.68 were used.

Modification of the surface was carried out according to [4] by sodium sulfide.

Physicochemical analysis of quantitative and qualitative composition of reaction samples was performed by liquid chromatography (“Shimadzu LC-6A”). *p*-nitrotoluene adsorption behavior have been examined by means of in-situ FTIR spectroscopy (Avatar 360 FT-IR ESP, USA).

3 Results and discussion

Figure 1 shows the kinetic curves of *p*-nitrotoluene hydrogenation on sodium sulfide pretreatment catalyst. Sodium sulfide pretreatment generally leads to decreasing catalytic

activity [4]. However, the activity of the catalyst was increased almost in 1.5 times at low concentrations of sodium sulfide and reaches the maximum in 52 cm^3 (H_2)/ (s ·kg (Ni)) for 0.05 mmol Na_2S/g (Ni). This fact is possible to explain by the formation of new active centers of surface or by shifting the surface balance between individual adsorption forms of hydrogen toward the most active one in the investigated process [5]. In this case, the hydrogen and 4-nitrotoluene are adsorbed on the different active centers, "metallic" and "organometallic" respectively. α-form molecular hydrogen, H_2 or $H_2^{\delta+}$ associated with one or two surface atoms, γ-form - unionized form atomic hydrogen H or $H^{\delta+}$ with binding energy less than β-form but higher than the α-form are associated with the nickel surface [7].

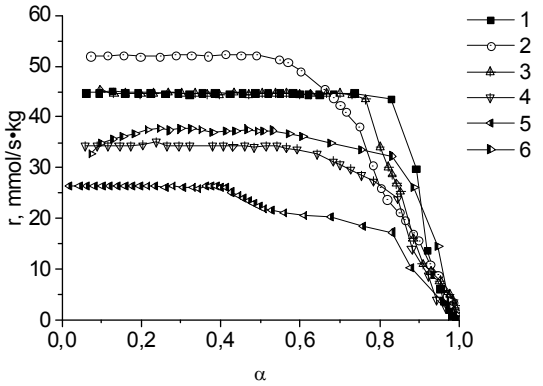

Fig. 1. Kinetic curves of *p*-nitrotoluene hydrogenation in the solvent 2-propanol-water (x_2=0.073): T=303K, $n_{p\text{-nt}}$=4.4·10-mol/gNi, m_{kat}=0.5 g, modified with sodium sulfide; 1 – 0.025 mmol Na_2S/g Ni; 2 – 0.05 mmol Na_2S/g Ni; 3 – 0.2 mmol Na_2S/g Ni; 4 – 0.6 mmol Na_2S/g Ni; 5 – 1 mmol Na_2S/g Ni; 6 - without sodium sulfide additive

4 Conclusions

We studied the kinetics of *p*-nitrotoluene hydrogenation on skeletal and modified skeletal Nickel catalyst in aqueous solutions of 2-propanol and find out that some condition can turn the effect of poison catalyst into promoter. This fact is possible to explain by the formation of new active centers of surface or by shifting the surface balance between individual adsorption forms of hydrogen toward the most active one in the investigated process. This enhance of the catalyst stability is explained by elimination of the most unstable-working surface active centers of the reaction space and by the stabilization of the remaining ones.

Fischer-Tropsch Synthesis over the Multicomponent Fe-Based Catalysts Modified with Additives of Rare Earth Metals

Ospanova A.Z.[1], Yemelyanova V.S.[2], Itkulova S.S.[1*], Abdullin A.M.[1], Nurmakanov Y.Y.[1], Imankulova S.A.[1]

Keywords: Fischer-Tropsch synthesis, Fe-based catalyst, syngas, rare earth metal

1 Introduction

The case for investing in alternative fuel-production technology to reduce dependence on crude oil has become increasingly compelling due to the uncertainty in oil prices combined with diminishing oil reserves. The Fischer–Tropsch synthesis (FTS) is an area that is receiving revived interest worldwide as an alternative technology to produce transportation fuels as well as chemicals from syngas [1].

Several group VIII metals such as iron, cobalt, nickel, and ruthenium are known to be active components of the FTS catalysts. Among the catalysts containing such active metals, iron-based catalysts have considerable merits, particularly when the FTS is performed with hydrogen-deficient syngas (H2/CO), due to their potential activity for a water–gas shift (WGS) reaction as well as their high activity and low cost [2–4]. Compared to other metal catalysts for FTS, an iron-based catalyst is distinguished by higher conversion, selectivity to the lower olefins, and flexibility to the process parameters. However, the use of iron catalyst does not solve the problem of insufficient selectivity, which represents a general limitation of FTS [5-7].

We have studied the Fe-containing catalysis promoted by the transition metals (M1 and M2), modified by additives of the rare earth metals VIII Group metals and supported on alumina in the Fischer-Tropsch synthesis. The FTS performance of catalysts was tested in a fixed-bed reactor and correlated with the characterization results.

2 Experimental/methodology

The Fe-containing catalysts were prepared by the impregnating alumina with appropriate compounds. Total metal content was 19 wt.%. The content of Ce or La was equal to 5 wt.%.

The Fe-based catalysts were tested in the Fischer-Tropsh synthesis. For hydrogenation of carbon monoxide the syngas with a ratio of H2/CO=2 was used. The process was carried out in a stainless steel reactor under pressure varied from 0.5 to 1.5 MPa, temperature region of 250-340ºC, and gas hourly space velocity (GHSV) of 1000-4000 h-1 with using 6 mL of the catalyst.

The physico-chemical properties of the catalyst were studied by BET, TEM, X-Ray and TPR-methods.

The initial and final reaction gaseous products were on-line analysed. The liquid hydrocarbons and aqueous fractions were analysed after their collection and separation.

3 Results and discussion

The effect of temperature on the process of hydrogenation of carbon monoxide over the 14% (Fe-M1-M2)-5% La/Al2O3 and 14% (Fe-M1-M2)-5%Ce/Al2O3 catalysts at H2/CO=2, P=1.0 MPa, and GHSV=1500 h-1 is presented in Fig.1a and Fig.1b respectively. With an increase in temperature from 270 to 340ºC, the CO conversion increases from 54.0 to 72.7% and

34.8 to 73.8 % respectively.

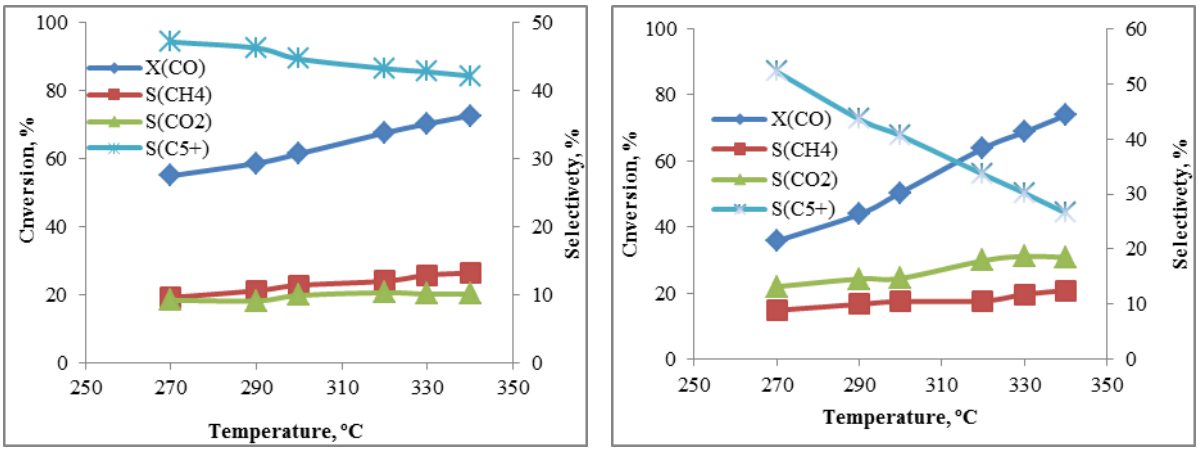

Fig. 1. Effect of temperature on the conversion of CO and selectivity by products over (a) 14% (Fe-M1-M2) -5% La/Al2O3, and (b) 14% (Fe-M1-M2)-5%Ce/ Al2O3 catalysts at H2 /CO = 2.0, P = 1.0 MPa, and GHSV = 1500 h-1

The liquefied hydrocarbons (C5+) are the main reaction products over both catalysts. The nature of rare earth metal has an effect on selectivity of Fe-based catalysts. Higher production of C5+ and methane is produced over the catalyst modified with La, while Ce additive causes the decrease in yield of C5+ fraction and length of hydrocarbon chain and promotes the carbon dioxide formation.

By TEM it has been shown that the catalysts are very dispersive. The particle size is less than 2 nm.

4 Conclusions

The results obtained show that the synthesized nano-sized iron-based catalysts have the high activity and selectivity on C5+ fraction in the FTS. They are active in the formation of narrow hydrocarbon fractions. Lanthanum -containing catalyst is an effective catalyst for the production of gasoline and kerosene fraction.

Keywords: Toluene, C-H bond activation, noble metals, benzoic acid

1 Introduction

The selective oxidation of hydrocarbons under mild conditions remains a challenging topic in the field of catalysis. Various studies have been reported concerning the oxidation of hydrocarbons, such as linear alkanes and aromatic compounds, using noble metals nanoparticles. The aim of this study is to investigate the selective oxidation of toluene using tertiary butyl hydroperoxide at 80 °C with supported noble metal nanoparticle catalysts prepared by sol-immobilisation techniques.

2 Experimental/methodology

Catalysts were prepared by Sol-immobilisation which involves the preparation of colloidal nanoparticles stabilised by PVA and reduced by NaBH4. Noble metal (Gold, Platinum and Palladium) colloids were used to form monometallic, bimetallic and trimetallic nanoparticles which were supported on activated carbon and TiO_2 with the catalysts having a total metal loading of 1wt%.

These catalysts have been tested for toluene oxidation with TBHP at 80 ºC, under atmospheric pressure in a first set of experiments followed by experiments using 10 bar pressure. Gas and liquid phase products were analysed and quantified by GC.

3 Results and discussion

Characterisation of the catalysts was carried out by STEM and XPS to confirm the core-shell and alloy structures of the particles. STEM analysis showed that the catalyst had a particle size distribution between 1 and 6 nm with a mean value of 2.3 nm (Figure 1), as well as the particle morphology. XPS confirmed the formation of the core shell. The order of addition of the metals into the preparation determined the morphology of the nanoparticles with sequential addition forming core shell structures and co-addition forming homogeneous alloy nanoparticles. [1]

All catalysts are selective to benzoic acid however for low conversion we observe benzaldehyde-dimethylacetal and methyl benzoate as reaction products. The highest activities were observed for catalyst containing Au. Time online reactions show that the addition of Pd and Pt has a promoting effect and the trimetallic alloy AuPdPt/ C catalyst shows the best activity.

Further experiments have been run using AuPdPt/ C catalyst; reuse tests and catalyst

characterisation after reaction reveal the contamination of the catalyst.

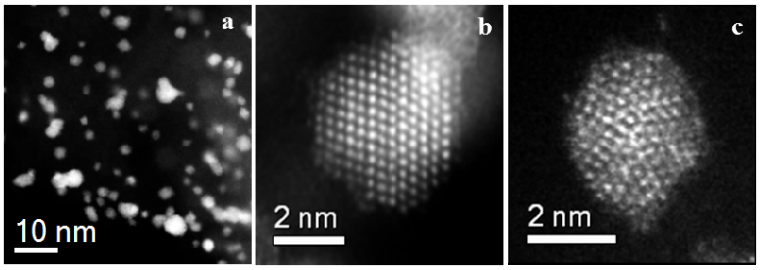

Fig. 1. Scanning transmission electron microscopy Electron microscopy analysis of the Au–Pt/C catalyst made by simultaneous sol-immobilisation. (a) A low magnification STEM-HAADF image; (b, c) higher magnification STEM-HAADF images.

4 Conclusions

Set of Au, Pd and Pt catalyst have shown their activity to oxidise toluene in presence of TBHP as initiator. Trimetallic catalyst supported on carbon shows promising results towards benzoic acid. Further experiments using O_2 as oxidant will be run in order to investigate to possibility of activated O_2.

Mechanistic Understanding on MoO_3 Catalyzed Transesterification between Phenol and Dimethyl Carbonate

Peng B.*, Ember E.E., Lercher J.A.

Lehrstuhl II für Technische Chemie and Catalysis Research Center, Department of Chemistry, Technische Universität München, Garching, Germany

* bo.peng@mytum.de

Keywords: transesterification, phenol, dimethyl, carbonate, MoO_3

1 Introduction

Polycarbonates (PC) are high-performance engineering materials with unique physicochemical properties that make them suitable for many applications. [1] However, the conventional synthesis routes toward PC often involve the use of highly toxic reagents, *e.g.*, phosgene. Therefore, in the last decades, considerable efforts have been made for the development of phosgene-free routes for sustainable PC synthesis. The two-step synthesis of diphenyl carbonate (DPC), a key monomer for phosgene-free PC synthesis, has been achieved by transesterification between phenol and dimethyl carbonate (DMC). In present investigation, supported MoO_3 catalysts have been explored as highly selective and active catalyst for the transesterification of DMC and phenol under mild reaction conditions. Combined spectroscopy and reactivity data showed that orthorhombic microcrystalline MoO_3 is the important phase for the selective transesterification between DMC and phenol.

2 Experimental /methodology

MoO_3-SiO_2 catalysts were synthesized by impregnation method. [2] The catalysts were characterized by XRD, Raman and IR. The catalytic transesterification was performed in a batch reactor between 433 and 473 K under inert conditions and the products were analyzed by GC. *In-situ* IR spectroscopic measurements were performed with Bruker ISF88 IR spectrometer.

3 Results and discussion

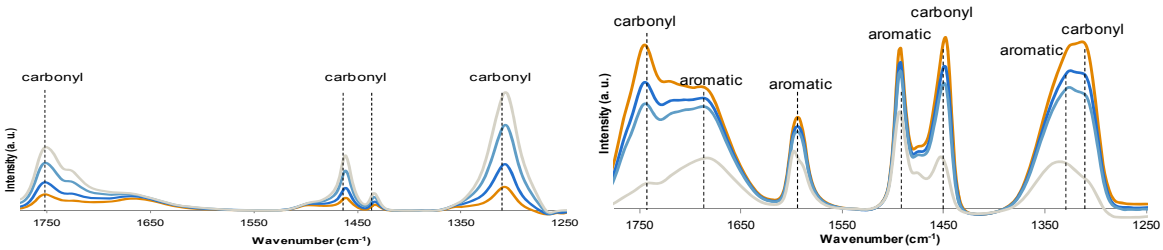

Figure 1. Comparison of the IR spectra of adsorbed DMC (left) and MPC (right) on MoO_3-SiO_2 followed by high temperature desorption.

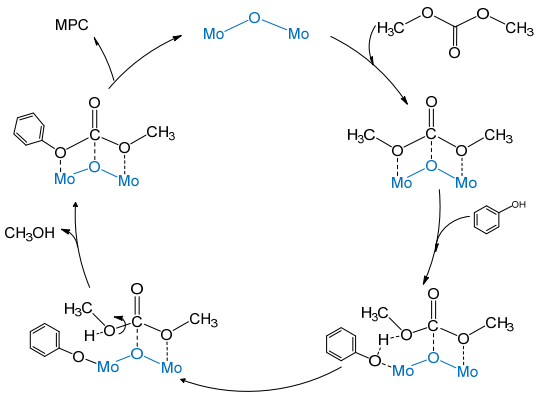
The catalytic activity and selectivity in DPC synthesis strongly depend on the surface morphology. Using an optimized synthesis procedure enabled the synthesis of a MoO_3 catalyst with high content of microcrystalline orthorhombic MoO_3. Detailed spectroscopic study on the complex composition of MoO_3 further showed the existence of a larger fraction of coordinatively unsaturated Mo-O. To understand the elementary activation processes better, temperature dependent IR measurements were performed using DMC and methyl phenyl

carbonate (MPC), a key intermediate formed during transesterification, as probe molecules. The comparative IR spectra of adsorbed DMC and MPC shown in Figure 1 indicated the formation of a symmetric surface adsorbed carbonate, when DMC is used as probe molecule while the formation of stable asymmetric carbonate species was only observed when phenol was present as well.



Scheme 1. Proposed catalytic cycle for the MoO_3 catalyzed MPC synthesis.

Summarizing all the experimental data on the interaction of the reactants enabled to propose a catalytic cycle for the most critical step in the transient DPC formation, shown in Scheme 1. The adsorption of DMC on the coordinatively unsaturated sites at microcrystalline MoO_3 results, thus, in the transient formation of symmetric carbonate species on the surface. In the presence of phenol, the concomitant formation of asymmetric carbonate takes place. This may occur by the more favored adsorption of phenol on the same catalytically active sites of the molybdena. Following the surface reconstruction and the release of a MeOH molecule, the formation of MPC takes place. The proposed reaction sequence is in line with the observed negative reaction order for phenol as well as the zero order for DMC at high DMC concentrations and first order at low DMC concentrations.

4 Conclusions

Active orthorhombic microcrystalline MoO_3 supported on SiO_2 was synthesized. Detailed spectroscopic analysis of the surface enabled reactions showed that the competitive adsorption of DMC and phenol on the coordinative unsaturated active sites of MoO_3 results in the formation of stable asymmetric surface carbonate species, from which target molecule is formed.

MP/C (M: Ni, Mo, W) Catalysts Hydrodenitrogenation of Aminocaprolactam: Effect of the H_2 Pressure

Abba M.O., Pereñiguez R.*, Caballero A.

Instituto de Ciencia de Materiales de Sevilla and Dpto Química Inorgánica (CSIC-Universidad de Sevilla), Seville, Spain

* rosa@icmse.csic.es

Keywords: hydrodenitrogenation, aminocaprolactam, caprolactam, high pressure

1 Introduction:

Catalytic hydrodenitrogenation (HDN) is an industrial process for the removal of organonitrogen compounds from hydrocarbons of crude oil to obtain stable and environmentally acceptable products. The HDN is performed for avoiding the burning of N containing fuels which generates NO_x emissions, known as pollutant gases that react to form smog and acid rain. The organonitrogen compounds removed are mainly quinolines and porphyrins and their derivatives, which can be grouped as heterocyclic nitrogen compounds, being also applied for aliphatic amines. HDN of petroleum has generally catalysed by cobalt and nickel as well as molybdenum disulphide or less often tungsten disulphide, supported on Al_2O_3 [1]. However, the HDN could be also applied in other routes, starting from heterocycle amines as alpha-aminocaprolactam (ACL) for producing high value compounds [2]. A previous work [3] studied the synthesis of alpha-amino-epsilon-caprolactam starting from L-lysine, which derived from biomass. This reaction involved the first step of the process (Fig. 1A) which final aim is the obtaining of epsilon-caprolactam (CL), by deamination of alpha-amino-epsilon-caprolactam (ACL). CL is a high value compound due to its implication as a precursor in the nylon 6 production. The aim of the present study is to perform a preliminary evaluation of the effect of pressure in HDN reaction of ACL to CL (Fig. 1B) using 10% monometallic phosphide (Ni, Mo and W) supported on carbon as catalysts.

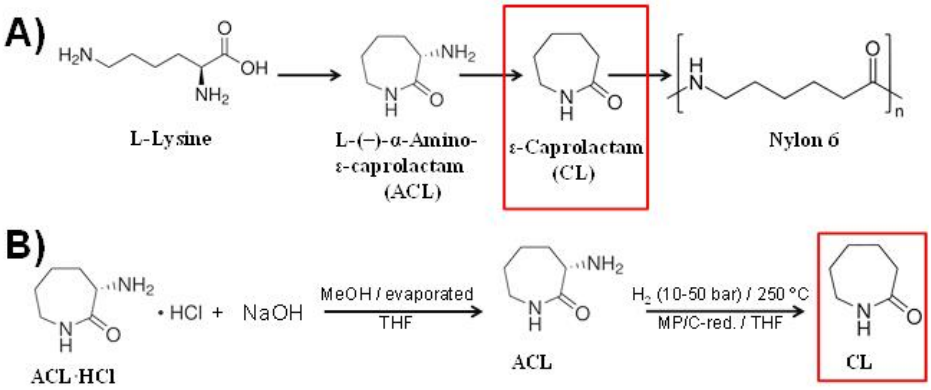

Fig. 1. Scheme of the reactions involved.

2 Experimental:

The catalysts were prepared by co-impregnation in a rotary of an aqueous solution containing the phosphorous and metal (Ni, Mo or W) precursors. This solution in contact with the carbonaceous support (Cabot Vulcan) was stirring at room temperature for 3 hours and then at 50 ºC under vacuum. The systems obtained were reduced in H_2 5% vol. in Ar at 900 ºC for 3h and then it was passivated in an atmosphere of O_2 0.5% vol. in He at room temperature for 4 h.

The catalysts are labelled as MP/C-red, being M: Ni, Mo or W at 10 wt. %. The physicochemical properties of the catalysts prepared were studied by the characterization techniques of XRD, BET, SEM, TPR and XPS. For the catalytic performance, the ACL·HCl precursor was firstly neutralized by adding NaOH in a methanol solution (0.1 M of ACL·HCl). After that, the solvent was removed and redissolved in tetrahydrofuran (THF), with the consequent precipitation of NaCl. For the HDN of ACL, the solution of 10 ml obtained (ACL/THF) was placed in a 70 ml stainless steel autoclave *Sentinel* with 20 mg of catalyst. The reactor was flushed with nitrogen, and hydrogen sequentially at room temperature. Then the system was pressurized in H_2 until the desired pressure, and heated at 250 ºC under stirring. After 15 hours, the conversion and selectivity were determined by GC analysis, using an HP 5890 gas chromatograph equipped with a capillary column (Elite 1).

3 Results and discussion:

The XRD data show two wide peaks ascribed to carbon phases that were also detected in the XRD of the support without metal impregnation. This fact makes difficult the ascription of phases resulting in a mixture of oxides, phosphates and phosphides of the metals. In the case of NiP/C-red., the Ni_2P phase was clearly identified. The micrographs obtained by SEM (Fig. 2), recording secondary electrons (SE) and backscattered electrons (BSE, to obtain better contrast for heavier elements like metals in contrast with C or P) show the formation of well dispersed nanoparticles (around 10 nm), mainly in MoP/C-red. system.

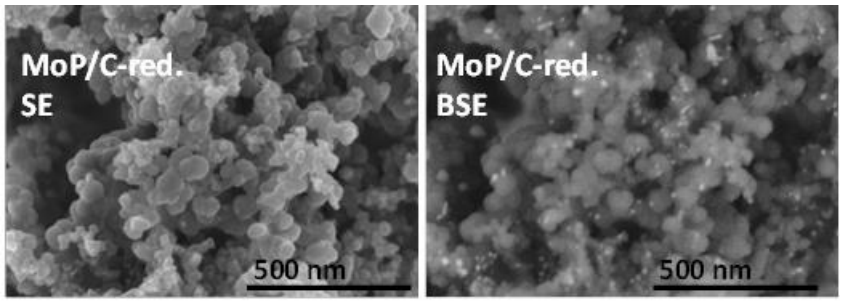

Fig. 2. SEM images of secondary electrons (SE) and backscattered electrons (BSE).

Table 1 presents the results of catalytic HDN of ACL for the systems MP/C-red. In general the conversion obtained was close to 100% in most of the cases, independently of the pressure applied even the catalyst tested. The main difference observed was the selectivity to the desired product CL, that was calculated as the percentage of the CL versus the total of products registered. In general, low and moderate pressures (10-30 bar) result in better selectivity, being the MoP/C-red. the most promising for HDN of ACL. These results would improve the costs for industrial application, compared with the previous one published [2], where the authors used noble metals as catalysts and a mixture of H_2/H_2S instead of pure H_2.

Table 1. Catalytic performance of the systems.

Catalyst	Pressure	S_{CL} (%)	Catalyst	Pressure	S_{CL} (%)	Catalyst	Pressure	S_{CL} (%)
	10	43		10	45		**10**	**75**

Keywords: catalyst, heavy oil, bituminous oil, conversion, viscosity reduction

1 Introduction

Development of human civilization and economically developed countries pursuit to resource independence inevitably leads to redistribution of world commodity markets. Hydrocarbon resources will remain the main energy generator for transport and power industry, and will be the basis of the most synthetic materials and chemical products over the next 50-100 years. All over the world there is a growing interest in the development of alternative types of reserves of hydrocarbon resources: gas hydrates, shale oil and gas, heavy oil and natural bitumen. Global reserves of natural bitumen are about 260 billion tons according to United Nations estimation. Russian reserves of the commercially available crude oil is about 1.8 billion tons and the volume of heavy crude oil is about 4.5 billion tons in the bituminous sands according to the major oil operator – British Petroleum (BP). That's why scientific researches, industrial experiment works and pilot projects on the new types of hydrocarbon resources development and on searching effective methods of their production and cost-effective technologies of processing are becoming relevant.

2 Experimental/methodology

Samples of bituminous oil from Ashalchinskoye field, that located on the territory of the Republic of Tatarstan, were selected as objects of the study. There are almost no n-alkanes in oil, and the light hydrocarbons yield is at least 20%. Metal compounds Fe2O3, ZnO, NiO, salt Co [acac] 2, NiSO4, NiCO3, CuSO4 were selected as additives for catalytic conversion of resine-asphaltene components in the light hydrocarbon oil, and the following components were selected as excipients: Al2O3, ethane, 2 -hydroxy-1,2,3-propanetricarboxylic acid and water. Fe2O3 magnetite was used in coarsely dispersed condition of 250 to 800 microns, in a finely dispersed state to 250 nm and nano-dimensional state to 25 nm. The advantage of nanoparticles is in their accessibility to organic molecules of oil stock practically of any shape and size, which is especially important in the processing of heavy types of hydrocarbons. Particles of silicon and aluminum oxides, Al2O3, and SiO2 were used in a coarsely dispersed state through to 25 microns and nano-dimensioned state 40 nm stabilized by 4-methyl-2-pentanone. Experiments on catalytic conversion of bituminous oil were held in a high pressure reactor at temperatures from 250 to 380 ° C, and pressures from 1 to 21MPa, with a different ratio of vapor to the crude oil from 1: 1 to 1: 4.

3 Results and discussion

Hydrocarbon yield is reduced by increasing the amount of tars during all experiments where the process temperature is below 300°C. The asphaltenes content is reduced by 28% in the conversion products in the presence of SiO2 and Al2O3, at a temperature of 290°C. Reduction of the content of alcohol-benzene resins up to 22% occurs after increasing temperature up to

375°C and using a catalyst of iron-oxide. The experiment in the presence of zinc oxide nanoparticles reduces the content of n-alkanes in the final product and the content therein of branched structures, also reduces the viscosity by more than 2 times, while the component composition is not changed practically. In conversion products is a noticeable reduction in the concentration of asphaltenes by 29%, with increasing content of alcohol-benzene resins after introducing into the reaction mixture Al2O3, Ni in the nano state and poly-α-olefins. Comparison of the results of component analysis of a bituminous oil and its thermocatalytic treatment indicates conversion of the resins into light hydrocarbons. Yield of the gasoline fraction increased from 9.8 to 15% with this slightly reduced yield of fractions 200-350°C in the conversion products after the experiment with Fe2O3 and NiCO3. Experiment held at 350 ° C and under pressure of 7.8 MPa in the presence of Al2O3 and nano sized Ni particles in a poly-α-olefins markedly increases the yield of light fractions up to 39% in conversion products. The amount of gasoline and diesel fraction increases to 42% in the transformed oil in a reducing atmosphere in the presence the reaction mixture of SiO2 and Al2O3.

4 Conclusions

Based on these studies, we evaluated the effect of various additives in combination with thermobaric effect on the conversion of heavy hydrocarbons into lighter fractions. The obtained results promote the evolutiont of this important area of refining, as a development of unconventional hydrocarbon resources.

Ethanol Conversion to Useful Products: Ethylene, Diethyl ether, Higher Hydrocarbons, Acetaldehyde and Acetone

Phung T.K., Garbarino G., Busca G.*

University of Genova, Department of Civil, Chemical and Environmental Engineering, Genova, Italy

* guido.busca@unige.it

Keywords: ethanol, ethylene, diethyl ether, hydrocarbons, acetaldehyde, acetone

1 Introduction

Ethanol produced by fermentation of lignocellulosics, denoted as "second generation bioethanol", could become a primary intermediate in the frame of a new industrial organic chemistry based on renewables.

Among the secondary intermediates potentially obtainable by converting (bio)ethanol, ethylene and diethyl ether can be obtained by catalytic dehydration

$C_2H_5OH \rightarrow C_2H_4 + H_2O$ (1)

$2\ C_2H_5OH \rightarrow C_2H_5OC_2H_5 + H_2O$ (2)

Also acetaldehyde can be obtained by ethanol, through dehydrogenation:

$C_2H_5OH \rightarrow C_2H_4O + H_2$ (3)

and it possibly condensates to acetone through aldol condensation reaction.

Moreover, a number of studies report on the possibility to produce other hydrocarbons, in particular aromatics and higher olefins, from ethanol.

The aim of this work is to investigate the feasibility of ethanol conversion to useful products over different acido-basic oxide catalysts and study the ethanol conversion mechanisms as well as the nature of the basicity/acidity of catalytically active solids.

2 Experimental/methodology

2.1 Characterization

Catalyst characterization was performed by TEM, XRD, UV-vis, TG-DTA, XRD, NH_3-TPD, Raman spectroscopy and IR spectroscopy.

2.2 Catalytic experiments

Catalytic experiments were performed at atmospheric pressure in a tubular flow reactor using oxide catalyst (60-70 mesh sieved) or the mixture of catalyst and quartz (60-70 mesh sieved) and feeding 7.9% v/v ethanol in nitrogen. The carrier gas was passed through a bubbler containing ethanol maintained at constant temperature (298 K) in order to obtain the desired partial pressures. The temperature in the experiment was varied stepwise from 373 K to 873 K.

The outlet gases were analyzed by a gas chromatograph (GC) Agilent 4890 equipped with a Varian capillary column "Molsieve 5A/Porabond A Tandem" and TCD and FID detectors in series. In order to identify the compounds of the outlet gases, a gas chromatography coupled with mass spectroscopy (GC-MS) Thermo Scientific with TG-SQC column (15 m x 0.25 mm x 0.25 μm) was used.

3 Results and discussion

Several catalysts allow essentially stable 99.9 % yield to ethylene. This can be obtained on H-FER on H-FAU zeolite at 523-573 K until > 400 min time on stream [1]. On very pure γ-Al_2O_3 at yield approaches 99 % at 573 K for 400 min [1-2]. Also with slightly sulphated zirconia yield to ethylene approaches 100 % at 573 K.

Maximum yields to DEE are obtained on H-MFI (50) zeolite at 453-473 K and on H-BEA zeolite and on a WO_3/TiO_2 catalyst [1] at 473 K (> 73 %) (Fig. 1, left). The reaction path in ethylene and diethyl ether synthesis has also been investigated by flow reactor measurements, TPSR as well as IR studies. The investigated catalysts were characterized by different techniques such as IR spectroscopy of adsorbed pyridine (Fig. 1, right).

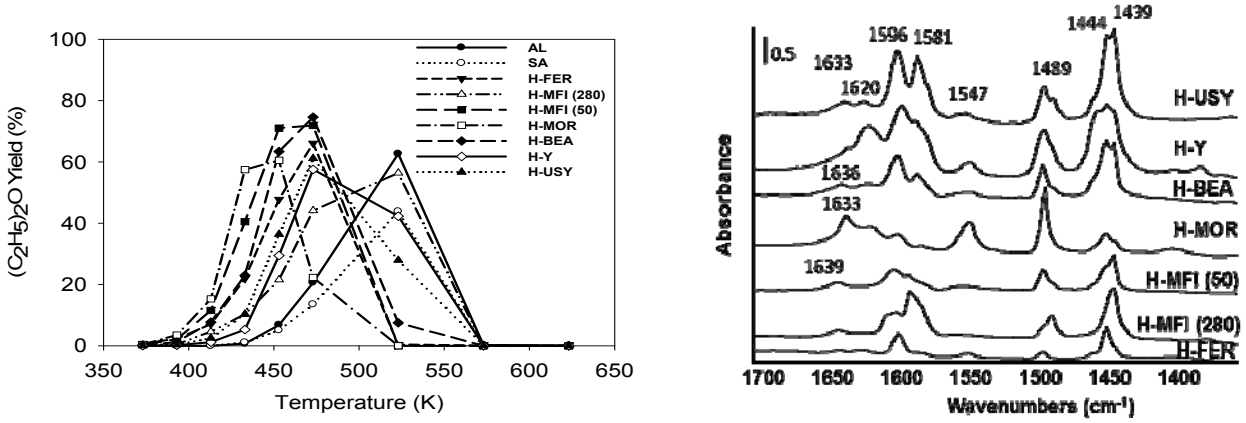

Fig. 1. (left) Diethyl ether yield as a function of temperature. Reaction condition: at atmospheric pressure in a fixed-bed tubular quartz reactor using 0.5 g of catalysts with 1.43 h^{-1} WHSV in nitrogen from 373 K to 623 K; (right) FT-IR subtraction spectra of surface species arising from pyridine adsorbed on pure zeolites at room temperature.

Using H-ZSM-5 zeolite depending on Si/Al ratio and modifiers (such as P, Fe and Ni), as well as reaction conditions, higher yields can be obtained in higher hydrocarbons such as propene, butenes and BTX aromatics.

Over catalysts displaying basicity (calcined hydrothalcite [4], La_2O_3-Al_2O_3) and semiconductor behaviour (ZnO, ZrO_2, TiO_2) a number of other products can be obtained, including carbonyl compounds and high hydrocarbons. On ZnO catalyst 50 % yield in acetone has been obtained at 773 K while selectivity of 64 % in acetaldehyde is found at 623 K (conversion 48%). Attempts to improve selectivity and yields into acetaldehyde, acetone, butenes, butadiene and aromatic have been undertaken.

4 Conclusions

Ethanol is a very versatile intermediate that can be converted with high selectivity/yield in a number of useful products over heterogeneous catalysts. The catalytic activity is correlated with acido-basic and electronic character of the catalyst.

Synthesis of Platform Molecules from Cellulose over Bifunctional Magnetic Nanocatalysts

Podolean I.*, Coman S.M., Parvulescu V.I.

University of Bucharest, Faculty of Chemistry, Department of Organic Chemistry, Biochemistry and Catalysis, Bucharest, Romania

* iunia.podolean@chimie.unibuc.ro

Keywords: biomass, valorization, ruthenium, niobium, magnetic, one-pot

1 Introduction

Research into the biomass valorization as a renewable raw material, received an unprecedented interest. A great variety of catalysts have already been tested for a such purpose. Among these, ruthenium based catalysts have proved to be very active and selective in transformations like hydrogenations (levulinic acid to γ -valerolactone, glucose to sorbitol, butyric acid to n-butanol), pyrolysis of lignocellulosic biomass, etc. [1]. Recently our group discovered that ruthenium supported magnetic nanoparticles are also very efficient in oxidation of levulinic to succinic acid [2]. On the other hand, niobium oxide gain increased interest as catalyst and catalytic support in hydrothermal biomass conversion in subcritical water, due to its high stability and acidity [3]. Based on these considerations, our purpose was to prepare bifunctional Ru/Nb_2O_5-based catalysts, using magnetic carbon nanotubes as support. Designed catalysts were testes in one-pot conversion of cellulose to platform molecules.

2 Experimental/methodology

Different techniques and precursors were used to prepare niobic acid ($Nb_2O_5 \cdot nH_2O$). Niobium ammonium oxalate was precipitated in the presence of NH_4OH or KOH while niobium ethoxide was mixed and heated with dodecylamine and precipitated with HCl. For comparison a commercial niobic acid purchased from Sigma-Aldrich was used as well. Commercial carbon nanotubes (CNTs) were functionalized with carboxylic groups before introduction of magnetic nanoparticles and deposition of niobic acid by treating with a 1:1 (v/v) mixture of concentrated H_2SO_4/HNO_3 at 70°C for 12hours. To introduce the magnetic nanoparticles into CNTs, Mohr salt was used as precursor and ammonium hydroxide as precipitating agent. Carbon nanotubes were functionalized subsequently by coprecipitation of niobic acid. To this material ruthenium was deposed by wet impregnation. The obtained catalysts were denoted as $MCNT@Nb_2O_5$_A_B_C@Ru, where A B and C are the niobium precursor, precipitation agent and calcination temperature. Rutenium was impregnated onto niobium modified MCNTs using a Ru(III)chloride solution in water. Overall, the catalyst synthesis is represented in Figure 1. The obtained catalytis were characterized by XRD, ICP-OES, TG-GTA, DRIFT etc. The catalytic tests were performed in high-pressure HEL reactor, using 50 mg of catalyst and 50 mg of cellulose in 10 mL of water at different temperatures (150°C, 180°C, 200°C).

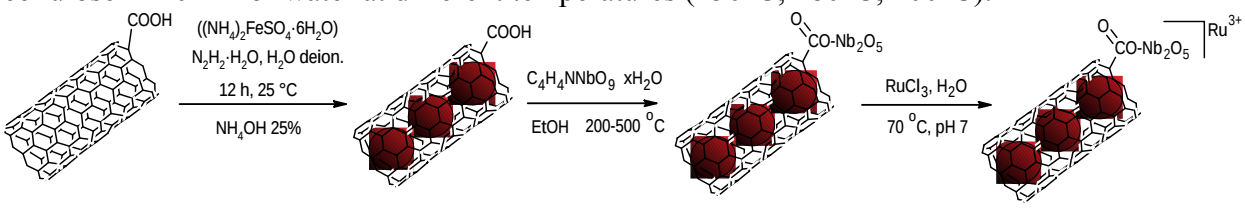

Fig. 1. Preparation of bifunctional $MCNT@Nb_2O_5@Ru$ catalysts

3 Results and discussion

The characterization techniques demonstrated the successful deposition of niobium and ruthenium onto magnetic carbon nanotubes. The hydrothermal conversion, and oxidation of cellulose led to very promising results. The cellulose conversion was between 60-90% at reaction times higher than 8 hours even at 150°C. Hydrothermal conversion of cellulose in the presence of niobium led to lactic acid (cca. 15%), glycolic acid (cca. 15%) and γ-hydroxybutyric acid (cca. 30%) as main products. There was no significant effect of the niobium precursor or precipitation agent, instead the calcination temperature of the catalysts influence the product distribution. Catalysts calcinated at lower temperature (200°C) led to the formation of levulinic acid (cca. 10%) at the reaction temperature of 200°C. All studies, regardless of the used technique (infrared spectroscopy in the presence of pyridine, butylamine titration, NH_3 volumetric and gravimetric analysis, NMR) showed the presence of Lewis and Brønsted acid sites on the surface of niobium pentoxide. Niobic acid treated at temperatures between 100°C and 300°C, contains more acid sites than those calcined at temperatures between 500°C and 600°C, which are practically inactive [4]. To obtain levulinic acid from cellulose the catalyst must possess both Lewis and Bronsted acidity, the optimum ratio being about 1:1 [5]. Commercial (crystalline) niobia was almost inactive. At lower reaction temperature of 150°C instead of levulinic acid the succinic acid was formed. Adding ruthenium to the catalytic system resulted in an important increase of the selectivity in levulinic acid (for hydrothermal conversion of cellulose) and succinic acid (for cellulose oxidation). Besides, the catalysts maintained their magnetic properties after recycles. Using glucose instead of cellulose as reaction substrate resulted in very different distribution of products. Lactic and glycolic acids were obtained in smaller quantities compared to cellulose. At the same time, hydroxymethylfurfural was the main product (around 70%) followed by xylose (around 15%) and ribose (around 10%).

4 Conclusions

A series of new magnetic bifunctional catalysts were obtained using carbon nanotubes as stable catalytic support, niobic acid for the acidic function and ruthenium as active species. Additionally, magnetic nanoparticles were inserted inside the carbon nanotubes offering more functionality for the catalyst recovery, especially in the case of microcrystalline cellulose conversion. A synergic effect of niobia and ruthenium led to a high cellulose conversion resulting in different platform molecules as lactic, glycolic and levulinic acids. Introducing oxygen in the system gave a good selectivity to succinic acid.

"Green" Propylene Glycol: Kinetic Determination for the Valorization of Biodiesel Side Stream

Rajkhowa T.*, Thybaut J.W., Marin G.B.

Laboratory for Chemical Technology, Ghent University, Gent, Belgium

* tapas.rajkhowa@ugent.be

Keywords: glycerol, propylene, glycol, intrinsic, kinetics, copper, biodiesel

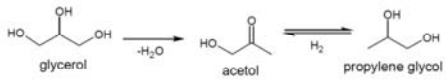
1 Introduction

In triglyceride transesterification to fatty acid methyl esters, 10 wt% of glycerol byproduct is formed. Upgrading the latter into a more valuable chemical will increase the sustainability and commercial viability of the biodiesel production process. Moreover, it will allow the synthesis of 'green' chemicals instead of petroleum-based ones. Among other alternatives, glycerol hydrogenolysis towards 1,2 propanediol or propylene glycol is a relevant and attractive valorisation route.

It has been widely accepted that glycerol hydrogenolysis on a Cu catalyst proceeds through a dehydration-hydrogenation with an acetol intermediate [1]. Although many researchers have investigated glycerol hydrogenolysis, very few have focused on investigating and modelling the kinetics [2]. In this work, the reaction kinetics were studied over an industrial copper catalyst supported on alumina. The objective of the work is to develop an intrinsic kinetic model for the hydrogenolysis reaction of glycerol to propylene glycol, aiming at a better understanding of the catalytic chemistry and opening up perspectives for rational catalyst design.

2 Intrinsic kinetic experimentation and modelling

The experimental glycerol hydrogenolysis investigation has been performed using a high throughput kinetics setup [3]. The experiments were performed using a trickle bed reactor in which pure glycerol was co-currently fed with hydrogen over a fixed catalyst bed. Intrinsic kinetic experiments were then performed by varying the space time, the hydrogen to glycerol molar ratio, hydrogen pressure and temperature.



$$r_1 = \frac{k_1 K_G C_G}{1 + \sqrt{K_H C_{H2}} + K_G C_G + K_A C_A + K_P C_P + K'_2 K_A C_A \sqrt{K_H C_{H2}}}$$

$$r_2 = \frac{k_2 K_A C_A K'_2 K_H C_{H2}}{\left(1 + \sqrt{K_H C_{H2}} + K_G C_G + K_A C_A + K_P C_P + K'_2 K_A C_A \sqrt{K_H C_{H2}}\right)^2}$$

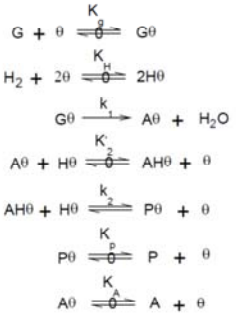


Figure 1: Reaction scheme for glycerol hydrogenolysis along with the proposed reaction mechanism and the corresponding rate equations.

The glycerol hydrogenolysis reaction mechanism has been proposed based on the one reported by Gandarias [4]. It was assumed that glycerol, acetol and propylene glycol competitively adsorb on identical active sites along with dissociative hydrogen adsorption. The surface reactions were considered to be rate determining with the adsorption steps being quasi-equilibrated.

3 Results and discussion

From a) it can be observed that at iso conversion and pressure, the selectivity towards the reaction intermediate, i.e., acetol, increases with temperature. b) illustrates how the glycerol conversion increases with the space time and how this increase is faster at elevated temperature.

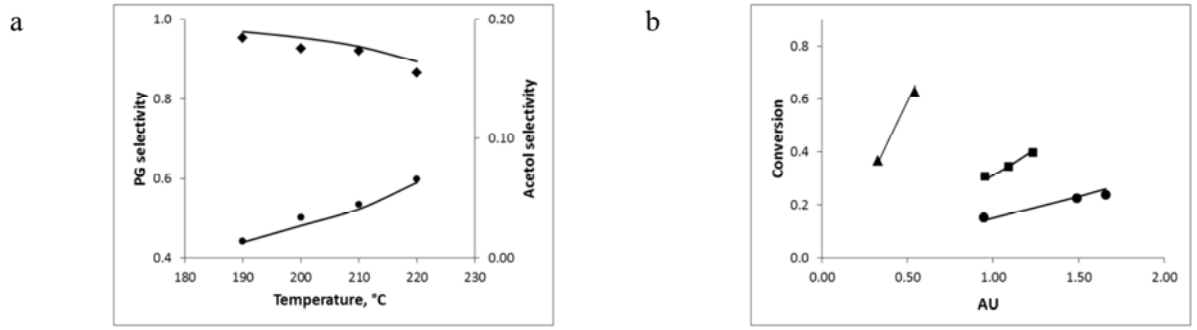

Figure 2: Temperature effect on selectivity and conversion. a) Propylene glycol(♦) and acetol(●) selectivity vs temperature b) Glycerol conversion at 200 °C(●), 210 °C(■) and 230 °C(▲) as a function of the space time. Symbols: experimental, solid lines: model simulations.

Model parameter values have been obtained by regression and are reported in Table 1, together with the corresponding confidence intervals, apart from the adsorption entropies which were fixed a priori based on statistical thermodynamics considerations. All parameter values were statistically and physically significant, e.g., the activation energy for acetol formation, $Ea_1 = 169 kJ\ mol^{-1}$, significantly exceeds the one for its further conversion into propylene glycol, $Ea_2 = 70 kJ\ mol^{-1}$, reflecting the above discussed temperature effect on the selectivity.

Parameter	Pre-exponential factor/ ΔS^0	$\Delta E_a / -\Delta H^0$
k_1^{comp} ($m^3\ kg^{-1}\ s^{-1}$)	$(76.9 \pm 2.2)*10^{-6}$	57.0 ± 4.2
k_2^{comp} ($m^6\ mol^{-1}\ kg^{-1}\ s^{-1}$)	$(25.6 \pm 0.74)*10^{-8}$	-38.2 ± 1.8
K_{H2} ($m^3\ mol^{-1}$)	$-30*10^3$	52.0 ± 0.8
K_G ($m^3\ mol^{-1}$)	-26.6	112.9 ± 4.3
K_A ($m^3\ mol^{-1}$)	-90	26.9 ± 1.05
K_P ($m^3\ mol^{-1}$)	-100	19.1 ± 1.4

Table 2 : Parameters estimates from the model simulation. $\mathbf{k_1^{comp} = k_1.K_G}$ and $\mathbf{k_2^{comp} = k_2.K_A.K_{H2}.K_2'}$

4 Conclusions and future work

Mechanistic insights into liquid phase glycerol hydrogenolysis has been gained. Temperature and space time effects on hydrogenolysis activity and product selectivity have been investigated and could be rationalized in terms of statistically significant model parameters. The methodology will be extended towards alternative catalysts, aiming at a rational catalyst design.

Research of Hydrogenation of the Nitrobenzene in Supercritical Carbon Dioxide with Use Ru/HPS Catalysts

Sulman E.*, Rakitin M., Petrova A., Doluda V., Matveeva V., Sulman M.

Tver Technical University, Tver, Russia

* sulman@online.tver.ru

Keywords: aniline, nitrobenzene, supercritical carbon dioxide

1 Introduction

Catalytic hydrogenation of a nitrobenzene is important chemical and technological process of receiving aniline which is in turn used as intermediate in synthesis of polyurethanes, rubbers, pharmaceuticals, pesticides and herbicides. Process of gas-phase hydrogenation of a nitrobenzene is usually carried out with use of Ni-or Cu-containing catalysts, fractional pressure of hydrogen of 1-5 atm. and temperature 250-300 ^{0}C, while liquid-phase hydrogenation - with use of Pt-, Pd-, Ni-containing catalysts at a temperature of 50-220 ^{0}C and pressure of 10-50 atm. both in the environment of various solvents, and in their absence, thus selectivity on a main product makes 75-95% [1].

Application of supercritical carbon dioxide ($CO_{2(sc)}$) in selective hydrogenation of a nitrobenzene has the considerable interest of researchers that is caused by advantages supercritical fluids application: high heat and mass transfer, formation of new molecular complexes and decrease of processes flammability.

2 Experimental/methodology

Catalytic hydrogenation of a nitrobenzene was carried out on the Parr Series 5000 Multiple Reactor System installation. It consists from six steel the thermostated reactors, the having unions for a purge, supply for gas and sample valve. Mixing was provided by the magnetic stirrer with electric motor (the maximal range of speeds in a minute – 1600). Control of pressure was made by means of pressure units. The thermostatting of the reactor is carried out by a programmable heating element. Accuracy of maintaining of temperature makes 0.1 °C.

Reference experiment in isopropanol was made as follows. A flask with shots of the catalyst, a nitrobenzene and isopropanol 3 times of 100 ml of nitrogen under pressure blew 2 MPa, then heated to necessary temperature in a nitrogen atmosphere and gave gaseous hydrogen.

Reference experiment in supercritical carbon dioxide was made as follows. A flask with catalyst and a nitrobenzene was purged 3 times of 300 ml of carbon dioxide under pressure blew 20 atm., then contents were heated to the necessary temperature then carbonic acid before achievement of the predetermined pressure (1-20 MPas) was pumped. On reaching equilibrium of $CO_{2(sc)}$ through a burette gave gaseous Hydrogenium to the reactor and began reaction timing. Hashing of a reaction mixture was made by the rotor four-blade mixer set in motion by the electric motor (the maximal range of speeds in a minute – 700). Monitoring of pressure was made by means of the manometer. The thermostatting of the reactor was carried out by the heating block with the programmable controller. Accuracy of maintaining of temperature makes 0.1 °C.

High-quality and quantitative identification of intermediates of synthesis was carried out by a gas-liquid chromatography method with mass and spectrometer detecting of substances. For this purpose used a gas chromatograph of GS-2010 (Shimadzu, Japan) with the capillary column HP-1MS which effectiveness made 4300 theoretical plates on pentadecane, and determined a gas one-quadrupole mass spectrometer of GSMS-QP2010S (Shimadzu, Japan) of Concentration of a nitrobenzene and aniline by reference substances and the corresponding gage dependences with use

of diphenylamine as the external standard.

3 Results and discussion

Data on activity of catalysts are presented in table 1. Temperature is specified for a maximum yield of aniline at maximum conversion of a nitrobenzene.

Table 1. Activity of the studied catalysts

Catalyst	Solvent	Temperature, ° C	Selectivity, %	Nitrobenzene conversion, %	Aniline yield, %
1% Ru/HPS	isopropanol	170	81.8	99.6	79.2
3% Ru/HPS	isopropanol	190	100.0	99.8	95.3
5% Ru/HPS	isopropanol	140	88.2	96.2	84.9
3% Ru/HPS	$CO_{2(sc)}$	100	100.0	99.8	96.2

From table 1 it is visible that use of supercritical carbon dioxide allows to reduce considerably temperature of carrying out process without decrease of aniline yields and conversion of nitrobenzene.

4 Conclusions

Carbon dioxide is perspective solvent for carrying out organic synthesis, including hydrogenation of organic nitrocompounds. On the example of process of catalytic hydrogenation of a nitrobenzene with use of the Ru-containing catalysts positive influence of $CO_{2(sc)}$ is shown. Decrease of influence of a matrix by activity of heterogeneous catalysts that testifies to increase in availability of the fissile Ru-centers to the reacting substratum in the environment of supercritical carbon dioxide is established.

Keywords: glycerol, gold catalysts, lactic acid

1 Introduction

In the recent years, renewable bio-based feedstock sources have become increasingly important in the chemical industry. Glycerol (Gly), as a large-scale by-product in biodiesel production, is a versatile feedstock for the synthesis of a wide range of different chemicals [1]. Among them lactic acid (LA) is an important platform molecule for the fine organic synthesis. In addition, poly-lactic acid is a well-known biodegradable polymer, which has a great number of applications in medicine and as a packing material [2]. The most prominent way to obtain LA from Gly is a catalytic oxidative route. Anyway, it is still a challenging task, and there are only a few works concerned with the aerobic catalytic Gly oxidation to LA with high to moderate yields [3-5]. The most beneficial results were obtained with supported bimetallic Au-Pt catalysts. In this work we aimed at evaluation of the activity of low-loaded Au-Pt catalysts supported on active oxides (TiO_2, CeO_2, $CeZrO_x$) in the Gly aerobic oxidation to LA. The catalysts were prepared by facile redox-method ensuring the formation of close contact between the two metal components (Au-Pt) responsible for the synergetic effect in the catalysts activity.

2 Experimental/methodology

The catalysts were prepared by the redox-method in a two-step mode described in our works [6-7]. The first step was the preparation of the parent monometallic Pt catalysts (Pt/MO_x, where MO_x = TiO_2, S_{BET} = 61 m^2/g; CeO_2, S_{BET} = 37 m^2/g, $CeZrO_x$, S_{BET} =73 m^2/g) by a deposition-precipitation method from an H_2PtCl_6 aqueous solution followed by the reduction of the catalyst with H_2. To deposit the Au species, the prepared parent monometallic Pt sample was saturated with H_2, and the required amount of an Au precursor solution ($HAuCl_4$) with a definite concentration was added to the monometallic sample. The obtained catalysts were characterized by TPR-H_2, STEM, XPS, DRIFTS-CO and CO adsorption techniques.

The liquid-phase oxidation of Gly was performed in the batch-mode in alkali media with a molar ratio NaOH:Gly =2-4 at 40-100^oC under the O_2/N_2 pressure of 5 bar or just in air under atmospheric pressure. The analysis of the products obtained in the liquid phase was performed by NMR spectroscopy (Bruker Avance II, 300 MHz) with an external standard (sodium benzoate). The experimental error was within 3%.

3 Results and discussion

The strong Au-Pt interaction in the bimetallic catalysts proved by XPS and TPR-H_2 methods drastically changed their activity compared to the monometallic Au and Pt samples in Gly to LA oxidative transformation. Moreover, it was observed that both the particle size of Au/Pt NPs and the support characteristics greatly influenced the catalyst activity and selectivity.

When performing the reaction with TiO_2 supported Au/Pt catalysts, the highest activity and selectivity to LA were obtained for the catalyst with the lowest Au content and the atomic ratio Au:Pt=0.025:1. Although the same was observed for the catalysts supported on either CeO_2 or $CeZrO_x$, among the low-loaded Au/Pt catalysts the highest conversion of Gly and selectivity to LA were characteristic of 0.025%Au/1%Pt/TiO_2 (Fig. 1 A). The use of this catalyst provided a 80% Gly conversion and a 50% LA selectivity in air at 60°C with a lowered ratio NaOH:Gly=2. The scheme of Gly oxidation to LA is presented in Fig. 1 B.

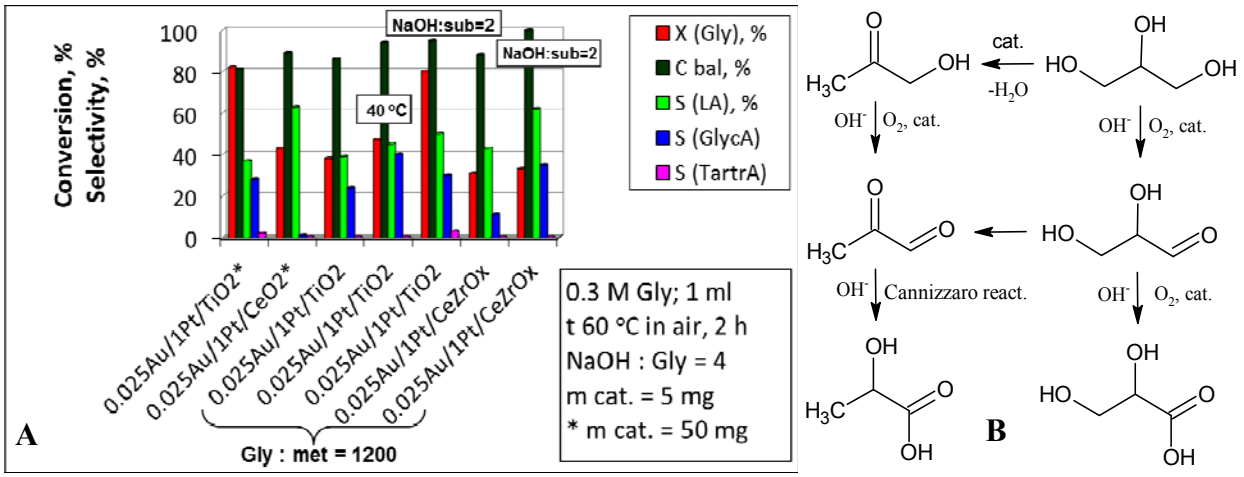

Fig. 1. The activity and selectivity of the low-loaded Au/Pt catalysts supported on TiO_2, CeO_2, $CeZrO_x$ in Gly to LA oxidative transformation. LA-lactic acid; GlycA-glyceric acid; TartrA-tartronic acid; C bal-carbon balance (**A**); the scheme of Gly oxidation to LA and GlycA (**B**).

It was noticed that the activity of the catalysts correlated with the degree of the "Au/Pt NPs-support" interaction, which changed according to the following order: Au/Pt/TiO_2 > Au/Pt/$CeZrO_x$ > Au/Pt/CeO_2. Furthermore, the lower was the size of Au/Pt NPs, the higher was the degree of the "Au/Pt NPs-support" interaction.

4 Conclusions

The low-loaded Au/Pt catalysts showed the high activity in Gly to LA oxidation even under very mild conditions not used before. The most efficient catalyst appeared to be 0.025%Au/1%Pt/TiO_2.

Keywords: alkylphenols, benzoquinones, catalytic oxidation, heteropoly acid, homogeneous, catalysis

1 Introduction

Alkyl-1,4-benzoquinones (ABQ) such as 2,6-dimethyl-1,4-benzoquinone (DMBQ) and 2,3,5-trimethyl-1,4-benzoquinone (TMBQ) are reactive synthesis precursors and have many applications known for this type of compounds. Nowadays the demands towards environment safety bring necessity to revise existing preparation methods of such compounds and to search for alternative synthesis ways. There are a lot of papers describing ABQ preparation by using various approaches to obtain green processes. However, most of the reported procedures require long reaction times, utilize strong oxidants in large excess, afford products with only modest yields, and use non-reusable catalysts. For this reason, the development of synthetic methods which enable a facile access to these quinones is desirable.

The benzoquinone preparation studies presented are entirely based on the use of heteropoly acids with formula $H_{3+x}PMo_{12-x}V_xO_{40}$ (Mo-V-P HPAs) that enter into the most widely used class of Keggin-type polyoxometalates (POMs). These POMs are characterized by strong Brønsted acidity, high proton mobility, fast electron transfer, high oxidation potential, and excellent resistance against hydrolysis and oxidative degradation in solution. These properties make them very attractive catalysts for oxidation of different organic substrates.

2 Experimental/methodology

2,6-Dimethylphenol (DMP) and 2,3,6-trimethylphenol (TMP) were purchased from Aldrich Chemical Company (99% purity) and used without additional purification. Organic solvents with purity of 98% were purchased from Sibreakhim (Novosibirsk) and applied without preliminary distillation.

A series of Keggin-type $H_{3+x}PMo_{12-x}V_xO_{40}$ aqueous solutions with different content of vanadium atoms (x = 2-6) as well as high-vanadium solutions of formula $H_aP_zMo_yV_xO_b$ ($2 \le z \le 3$, $9 \le y \le 16$, $7 \le x \le 12$, $50 \le b \le 89$) were synthesized from the stoichiometric amounts of V_2O_5, MoO_3, H_2O_2, and H_3PO_4 according to the methods described in [1-2].

The composition of catalysts before and after reaction was investigated by ^{51}V and ^{31}P NMR on a Bruker AVANCE 400 spectrometer at 105.24 MHz and 162.0 MHz, respectively, with $VOCl_3$ and 85 % H_3PO_4 as external standards. Redox potential *E* and pH of the HPA solutions were measured at room temperature by the pH-meter "inoLab pH 730" from Wissenschaftlich-Technische Werkstatten GmbH (WTW).

The oxidation reactions were carried out in a thermostatic glass reactor (volume 100 mL) under atmospheric pressure in a two-phase system: aqueous HPA solution/solution of substrate in a definite organic solvent. The reactor was equipped with a reflux condenser to avoid loss of water and organic solvent. After reaction completion the phases were separated by a funnel. The reduced catalyst was reoxidized in a separate step with O_2 at the temperature of 140-170 °C and partial oxygen pressure of 4 atm. The regeneration was performed in a thermostatic stainless

steel autoclave equipped with a backflow condenser.

Substrate conversion and product amount were determined by the GC-FID (gas chromatography with flame ionization detector) method using a HROMOS GH-1000 chromatograph with a capillary column St-WAX. Tetramethyl-1,4-benzoquinone (DQ) purchased from Merck-Schuchardt (99.9 % purity) was used as an internal standard.

3 Results and discussion

The different reaction parameters which determine relationship between reaction time and selectivity was investigated in order to get the best reaction conditions.

Firstly, the influence of a number of organic solvents (OS) on the selectivities of DMBQ and TMBQ was studied. The amount of quinones appears to be strongly dependent on the type of OS. It was found that the use of appropriate OS allows one to increase the product selectivity from ~7 to 41 % for DMBQ and from 20 to 58 % for TMBQ in the presence of trichloroethylene and octanol-1, respectively.

Encouraged by this result, we tried to improve catalyst activity and desired product yields based on the assumption that a higher reaction temperature and a presence of water-soluble organic component such as HOAc would be beneficial. The results obtained showed that increased reaction temperature as well as content of HOAc in the range of 30-45 vol. % (for oxidation of DMP) accelerate the reaction and improve the quinones selectivity.

The Mo-V-P HPAs are reduced easily and reversibly to form mixed-valence species, heteropoly blues, which retain the structure of the parent oxidized anions (as was confirmed by NMR). The total number of accepted electrons during the reduction of HP-anions in the course of substrate oxidation can be quite high and depends on the vanadium content in HPA solution. As a result, the high vanadium content is preferred to increase the catalyst productivity and makes it possible to carry out the catalytic oxidation processes at a lower catalyst concentration (catalyst to substrate molar ratio). Furthermore, the vanadium content has an influence on the oxidation potential of catalyst *E* that is one of the important factors affecting the oxidation rate and product selectivity. Since the anion structure retains upon reduction, the additional negative charge is compensated for by protonation of the anion from solvent. Therefore, the observed pH value after reaction is higher. The optimized reaction conditions are presented in Table 1.

Table 1. Optimized conditions of DMP and TMP oxidations to the corresponding quinones.

Substrate	Catalyst	OS	T [°C]	HOAc [vol.%]	[Cat]/[Su]	E_0 [V]	Time [min]	Selectivity [%]
DMP	0.25 M	trichloroethylene	60	30	5	≥ 0.91	20	85
TMP	$H_{17}P_3Mo_{16}V_{10}O_{89}$	octanol-1	60	-	3.3	≥ 0.98	45	99

4 Conclusions

The influence of various parameters such as concentration of substrate, solvent, temperature, catalyst composition et al. on the catalytic process was examined in details regarding the selectivity of 2,6-dimethyl- and 2,3,5-trimethyl-1,4-benzoquinones. At the temperature of 60 °C under optimized conditions, DMBQ was produced with selectivity of 85 % whereas the selectivity of TMBQ was 99 %. Actually no polymerization of substrate occurred under the optimized conditions. The catalyst can be separated and reused. Mo-V-P HPA solutions are remarkable catalysts because they possess not only a fairly high oxidation potential, but also their reduced forms are very easily reoxidized by oxygen (air).

Keywords: calcium, carbide, vinyl, sulphides, thiovinylation

1 Introduction

Catalytic organic reactions showed great potential in development of cost-efficient and environmentally benign synthetic procedures. A variety of techniques aimed for generation of new C–C, C–Hal, C–O, C–P, C–S bonds via catalytic processes, were successfully employed in the search for new pharmacological substances, materials, and synthetic building blocks. However, there are not many catalytic reactions, where inexpensive, ton-scale substance is used to produce useful building blocks in synthetic chemistry [1].

Calcium carbide is an industry-scale product, traditionally synthesizing from coal, hydrocarbons and biomass. The low production costs put calcium carbide in a better position to serve as a sustainable resource for organic chemistry.

2 Experimental

We developed an alternative straightforward protocol for the preparation of vinyl thioesters via reaction of calcium carbide with thiols. This elegant and cost-efficient procedure can be widely employed in laboratory practice towards preparation of useful building blocks. Mechanistic studies have demonstrated that the thiovinylation involves the initial *in situ* formation of acetylene, thus, clearly demonstrating the potential of calcium carbide as an acetylene replacement in organic synthesis.

Keywords: liquid-phase methanol synthesis, heterogeneous catalysis, polymer, carrier

1 Introduction

Modern chemical industry consume considerable amount of methanol for the obtaining of formaldehyde, for the synthesis of alcohol esters of organic and inorganic acids, methyl tertiary butyl ether [1]. Novel prospective ways of methanol application such as waste water purification, synthetic protein, fuel cells, conversion into hydrocarbons for the fuel obtaining have recently appeared. It was practically revealed that the gas for methanol synthesis must contain the components in a ratio close to stoichiometric. To obtain such a ratio it is necessary in most cases to change gas composition.

Now there exist gas-phase (two-phase) and liquid-phase (three-phase) catalytic methods of methanol synthesis. The simplicity of the reactor design, rather uniform distribution of liquid and gas over the reactor cross section, the possibility of the catalyst input and output without the system stoppage, rather low gas axial diffusion and effective use of the reaction heat as well as relatively low temperature of the process are the advantages of liquid-phase synthesis [2, 3].

In this paper the results of the study of the kinetics and modeling of methanol synthesis process on polymer-stabilized catalysts – Zn on hypercrosslinked polystyrene are presented.

2 Experimental

Synthesis of ZnO-containing catalyst based on MN-100. The catalyst was prepared by impregnation of MN-100 (Hypercrosslinked polystyrene, Purolite Int.) with $Zn(CH_3COO)_2$ in a solution containing THF, methanol and distilled water. In a typical procedure, 0.845 g of $Zn(CH_3COO)_2$ was dissolved under nitrogen in 7 mL of the solvent mixture consisting of 5 mL of THF, 1 mL of water and 1 mL of methanol, to which 3 g of MN 100 were added. The suspension was continuously stirred for 10 min to allow absorption of the solution by the polymer granules. Then the sample was treated with the Na_2CO_3 solution, and after 10 min stirring, it was dried. After that the catalyst was washed with water at pH=6.4-7.0 and dried. The ZnO content was calculated according to loading. The samples were designated as MN100-Zn-3%, MN100-Zn-5%, MN100-Zn-7.5%, and MN100-Zn-10%, respectively.

The above method was used for the synthesis of ZnO/Cu-containing catalysts.

Experimental technique

The experiments were conducted in a flow-type laboratory steel reactor (Parr Instruments), volume 25mL. The reaction mixture was analyzed by the method of gas chromatography on KRISTALLUX 4000M chromatograph.

3 Results and discussion

Some ZnO-containing catalysts based on MN100 were characterized by the low-temperature nitrogen physisorption:

ID cat.	BET specific surface area (SSA), m^2/g

MN-100	723
MN100-Zn-3%	834
MN100-Zn-5%	770
MN100-Zn-7.5%	665
MN100-Zn-10%	446

By liquid nitrogen physisorption it was shown that all the catalysts have micro-mesoporous structure with the SSA varied from 446 m^2/g to 834 m^2/g depending on Zn loading. It is noteworthy that the decrease of the SSA at higher zinc concentrations is mainly due to the decrease of microporosity. The existence of mesopores as well as high values of the SSA makes HPS based catalytic systems promising candidates for methanol synthesis from the viewpoint of catalytic NP stabilization inside the HPS mesopores.

The results of XPS study revealed the presence of zinc in the form of Zn^{+2} in the catalysts.

It was found out during the preliminary experiments that methanol is most actively synthesized on MN100-Zn-3% catalyst which has the best results according to the data of nitrogen low-temperature adsorption. Methanol synthesis on this catalyst was performed at varying the pressure (1.5 – 5 MPa), the rate of the initial gas mixture feed and the temperature. Isopropyl alcohol was used as the reaction medium. Industrial MEGAMAX700 was tested for the comparison of the results obtained.

Methanol maximal yield was achieved at a temperature of 170˚C and a gaseous flow rate 270 mL/min. The data obtained were used for the calculation of the apparent activation energy (E_{act}) of methanol synthesis which made 6 - 10 кJ/mol. E_{act} low value is probably explained by relatively high temperatures of the process which provide prevailing of the kinetic stages rates over the diffusion ones.

In the case of bimetallic Zn-Cu catalysts, it was revealed that the method of the catalyst synthesis (consecutive impregnation of metal-containing salts or co-precipitation) does not play any significant role in the methanol accumulation rate. Moreover, the addition of Cu to ZnO seems to have no positive impact on methanol formation rate.

Keywords: hydrolysis, catalytic activity, nanoreactors, surfactants, solutions of low concentrations

1 Introduction

We have recently found that nanoassociates are formed in the highly dilute aqueous solutions of bioactive compounds (10^{-6}-10^{-20} M) with the participation of external physical (geomagnetic and low-frequency electromagnetic) fields [1]. These nanoassociates are responsible for their unusual physicochemical properties. In the present work we have study a catalytic activity of the highly diluted aqueous solutions (10^{-2}-10^{-16} M) of cationic surfactants **1**, **2** in the hydrolysis of phosphorus acid esters **3**, **4** by a complex of physicochemical methods (DLS, NTA, UV, ^{31}P NMR).

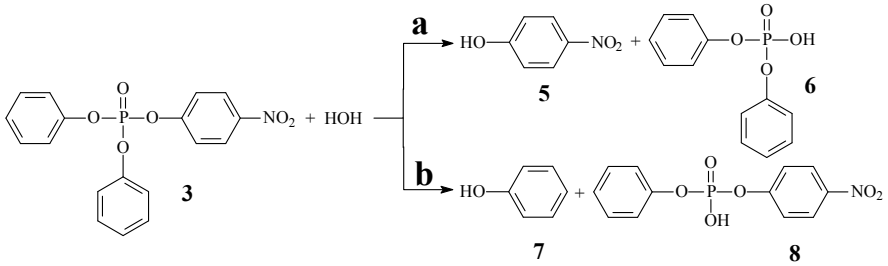
2 Experimental/methodology

Solutions prepared by successive serial dilutions were kept under ambient conditions and under conditions of reduced external physical fields (in a permalloy container) for 24 hours at 25°C. Using this approach allows to determine the threshold concentration (c_{th}) below and above which nanoassociates [1] and domains [2] are formed in diluted solutions.

3 Results and discussion

The solutions of surfactant **1** are dispersed systems in which micelles, domains and nanoassociates are formed in various concentration ranges (10^{-2}-10^{-3}, 10^{-2}-10^{-5}, 10^{-6}-10^{-12} M respectively) (fig. 1, curve 1) [3]. By NTA method it has shown that in the solutions **1** at $1\cdot10^{-5}$ M and $1\cdot10^{-7}$ M concentration of domains and nanoassociates equals approximately 10^{8} particles/mL. The formation of domains (D~300 nm) was also observed in water-ethanol (10 %vol. ethanol) solution **3** at $1\cdot10^{-4}$ M. Adding the water-ethanol solution **3** to diluted aqueous solution **1** leads to the formation of mixed domains **1+3**. Concentration dependences of size (D, effective hydrodynamic diameter) of nanoassociates **1** and domains **1+3** are comparable, but D of domains **1+3** (fig. 1, curve 2) is more then D of nanoassociates in solution **1** (fig. 1, curve 1) and D of domains in solution **3**. ^{31}P NMR signal of substrate **3** (δ = -17,4 ppm) and products of the hydrolysis **6, 8** (δ = -8,4; -9,4 ppm) (Scheme 1) disappears in case of the forming mixed domains **1+3**.

Scheme 1. Catalysis of hydrolysis of substrate **3** in nanoheterogeneous systems based on aqueous solutions of cationic surfactants of low concentrations



The kinetics of hydrolysis **3** and **4** in aqueous solutions of surfactants **1**, **2** was studied by spectrophotometry from the increase in optical density due to the formation of *p*-nitrophenolate (λ 400 nm) at pH 8.0. The correlation between self-organization of **1** and **1+3** solutions (fig. 1) and the observed rate constant (k_{obs}) of the reaction (fig. 2, curve 1) was established. In solutions **1+3** ($c_1=1\cdot10^{-9}$ M, $c_3=1\cdot10^{-4}$ M) where mixed domains with extreme size are formed (fig. 1, curve 2), k_{obs} is higher than k_{obs} in the micellar solution (10^{-2} M) and k_{obs} of alkaline hydrolysis **3** at pH 8.0 on approximately two and five orders respectively (fig 2, curve 1).

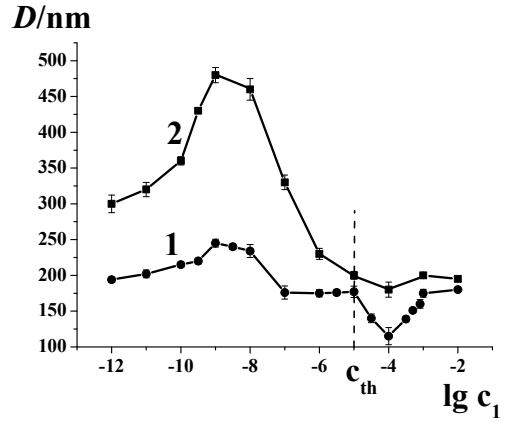


Fig. 1. Concentration dependences of the particle size (D) in solutions of **1** (*1*) and **1+3** (*2*); $c_3 = 1\cdot10^{-4}$ M, 25°C.

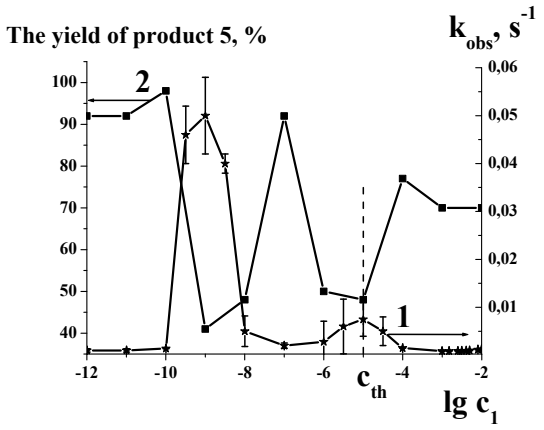

Fig. 2. Concentration dependences of k_{obs} (*1*) and the yield of the hydrolysis product **5** (UV method) (*2*) in solutions of surfactant **1**, pH 8.0, 25°C.

From ^{31}P NMR and UV experiments the yields of the hydrolysis products **5-8** (fig. 2, curve 2) are found. The results show that hydrolysis **3** occurs in two ways (scheme 1, **a** and **b**) in ranges of low concentrations of solutions **1** with maximum at $1\cdot10^{-9}$ and $1\cdot10^{-5}$ M, where nanoassociates and domains with extremely sizes are formed (fig. 1, curve 1). Analogical scheme was shown for hydrolysis of phosphorus acid esters in micellar systems [4, 5]. An important point is that the catalytic activity of nanoheterogeneous system formed at $1\cdot10^{-9}$ M is considerably higher than the catalytic activity of systems at $1\cdot10^{-5}$ M and $1\cdot10^{-2}$ M. Hydrolysis **3** occurs by one way (scheme 1, **a**) with maximum yield of product **5** by analogy with alkaline hydrolysis at $1\cdot10^{-4}$, $1\cdot10^{-7}$ M and 10^{-10}-10^{-12} M, where domains and nanoassociates are rearranged (fig. 1). The rate of hydrolysis at these concentrations is considerably lower (fig. 2, curve 2) then at $1\cdot10^{-9}$ and $1\cdot10^{-5}$ M. Nanoassociates are not formed at 10^{-6}-10^{-12} M in hypoelectromagnetic conditions, and catalytic activity disappears.

4 Conclusions

The obtained results demonstrate that a highly reactivity nanoreactors (mixed domains) are formed in systems based on aqueous solutions of cationic surfactants of low concentrations and solutions of phosphorus acid esters. The nanoreactors are capable to cleave phosphorus acid esters with high rate at low concentrations of surfactants in mild conditions mimicking hydrolytic enzyme reactions.

Differential Selectivity Measurements as Effective Means for Mechanistic Studies of Catalytic Reactions

Schmidt A.F.*, Kurokhtina A.A., Larina E.V.

Irkutsk State University, Chemistry Department, Irkutsk, Russia

* aschmidt@chem.isu.ru

Keywords: differential selectivity, mechanistic studies

1 Introduction

The differential selectivity of a catalyst is rarely considered in kinetic investigation. However, differential selectivity measurements have a number of advantages in comparison with catalytic activity measurements. When complex catalytic processes accompanied by intensive catalyst transformations occur outside the catalytic cycle (formation, deactivation and/or poisoning of the active species) the differential selectivity can be the sole tool to clarify the nature of the active species and kinetics of the elementary steps in the catalytic cycle. We attempted to briefly review the basic principles and practices of mechanistic studies based on differential selectivity measurements, including the use of artificially created competitive reactions.

2 Conclusions

The comparison with traditional kinetic investigations based on the activity measurements highlights that the approach has many advantages [1]:

1. Differential selectivity does not depend on the amount of true active species when the reaction products form on the same active catalysts. It makes the interpretation of experimental data much simpler.

2. Artificial multi-route reactions arising upon addition of several substrates with similar properties (competing reaction method) are completely sufficient to assume that the reaction products form on the same active catalyst.

3. The independence of differential selectivity on the total amount of active catalyst allows for the derivation of mechanistic information about catalytic cycle intermediates in reactions with numerous catalyst transformations occurring outside the catalytic cycle (formation and deactivation of active species), i.e. when the concentration of the active species is non-stationary.

4. The visualization of kinetic data by plotting the phase trajectories of the reaction products allows one to estimate the changes in the differential selectivity without using a mathematical description based on definitive mechanistic hypotheses.

5. The practice of studying differential selectivity in complex catalytic processes demonstrates that differential selectivity measurements provide information about the nature of the active species, the catalyst resting state, rate-limiting step within the catalytic cycle, and degree of reversibility of its stages.

6. The differential selectivity equations are much simpler in comparison with activity (rate) equations. This is only possible with differential selectivity measurements of a catalyst but not with activity measurement.

The greatest advantage of the study of differential selectivity is the possibility of studying the reactions carried out with high ratios of substrate/catalyst, i.e. real catalytic conditions, because model reaction studies may lead to incorrect conclusions.

Keywords: alkylation, zirconium-zeolit catalysts, high-octane component, resource-saving technology

1 Introduction

Nowdays, there is a constant tendency to improve not only operating characteristic but also environmental properties of motor gasoline. In order to reduce the total content of aromatic hydrocarbons manufacturers produce a high-octane reformate by dilution with non-aromatic components. One way of producing such components is the alkylation of isobutane with butylenes to produce isooctane and its isomers (trimethylpentanes). The desired product of this process named as alkylate. The alkylate complies with the technical, operational and environmental requirements of modern European and American standards. The alkylate has a low vapor pressure, it does not contain sulfur, oxygen, nitrogen and aromatics. The present work is focused on the development of efficient catalysts for producing of alkylate and new energy-saving technology of production gasoline based on the use of alkylate. The purpose of this research is to analyze the mechanism of heterophase alkylation reactions on ZrO_2-Al_2O_3/HY catalyst based on experimental results.

2 Experimental/methodology

The alkylation of iso-butane with 2-butene was performed in a plug-flow reactor operated in continuous mode. Operating parameters of the process: temperature range (50-125) °C; pressure 7 atm; paraffins / olefins ratio 19/1, space velocity 3 h^{-1}).

The calculation of the rate constants of reactions was carried out by Box complex method. The determination of the kinetic parameters (activation energy E_a and pre-exponential factors k_0) was carried out by least squares.

3 Results and discussion

The aim of this work was to examine the rates of different alkylation reaction. The main reactions occurring during the alkylation of isobutane and the rates equations for each reaction step are given in Table 1.

Table 1. Reactions and rates equations of the alkylation on ZrO_2-Al_2O_3/HY

Step	Reactions	Rate equations
1	$iC_4H_{10} + C_4H_8 \rightarrow C_8H_{18}$ (TMP)	$r_1 = k_1 \cdot P_{c4} \cdot P_{ic4}$
2	$iC_4H_{10} + C_4H_8 \rightarrow C_8H_{18}$ (DMH)	$r_2 = k_2 \cdot P_{c4} \cdot P_{ic4}$
3	$2C_8H_{18} \rightarrow C_{10}H_{22} + C_6H_{14}$	$r_3 = k_3 \cdot P^2_{c8}$
4	$C_{10}H_{22} \rightarrow C_4H_{10} + C_6H_{12}$	$r_4 = k_4 \cdot P_{c10}$

The rate constants of these reactions were determined by minimizing of function $\min_{k_{1}...k_{n}} \sum_{i=1}^{N}(C_i^{calc}(k_1...k_2) - C_i^{exp})^2$, where i – component index, N – component number, $k_{1}...k_{2}$ – rate constants, n – reaction number, C_i^{calc}– calculated concentrations of component i, C_i^{exp}– experimental results concentrations. Arrhenius equation was used for the temperature dependence of reactions rates.
Table 1 describes the determined activation energy and pre-exponential factors for reactions steps listed above.

Table 2. Kinetic parameters of the iso-butane/butene alkylation on ZrO_2-Al_2O_3/HY

Step No	E_a, kJ/mol	k_0, mol/(s·g)
1	7.3	54
2	21.0	356
3	26.1	3013
4	34.6	21998

The validation of the model was checked by comparison of the experimental and calculated values of the concentrations obtained using the kinetic parameters. The values of the concentrations of the reaction products at different temperatures are listed in Table 3.

Table 3. Experimental data and calculated results at different temperatures

Temperature, ^{0}C	Concentration, % mol.							
	50		75		100		125	
	experiment	model	experiment	model	experiment	model	experiment	model
$C_{8(TMP)}$	**78.0**	78.3	71.2	68.2	57.7	57.2	47.0	46.7
$C_{8(DMH)}$	**3.2**	3.1	3.8	3.9	4.4	4.5	5.0	4.8
$\sum C_6$	**10.0**	9.7	15.0	15.2	23.5	21.9	30.0	29.0
C_{10}	**8.0**	7.9	8.2	10.2	9.2	11.0	9.5	10.0
nC_4	**1.0**	0.9	2.0	2.5	5.0	5.4	8.0	9.5

4 Conclusions

Kinetics of heterogeneous iso-butane/butene alkylation over solid ZrO_2-Al_2O_3/HY catalyst was modelled using experimental data of a plug-flow reactor. The validation of the model was checked using all experimental data and the predicted results.

The results obtained is used for development of technology with fast and close contact of the catalyst and hydrocarbon at a high yield while minimizing trimethylpentane undesirable secondary reactions.

Alkylation of Phenol Using Ionic Liquid Catalyst: A Mechanistic Study

Shaurya M., Elavarasaran P., Parveen F., Upadhyayula S.*

IIT Delhi, New Delhi, India

* sreedevi@chemical.iitd.ac.in

Keywords: alkylation, tert-butylation, phenol, p-cresol, ionic liquid (IL), semi-empirical

1 Introduction

The Alkylation of Phenols using Ionic Liquid (IL) catalyst (N- butyl (1, 4-sulfonic acid) triethylammonium hydrogen sulphate) has been investigated by performing Quantum chemistry calculations to understand the *tert*-butylation reaction mechanism qualitatively at molecular level and obtain relative rates, reaction barriers, and product selectivity. All gas phase of reactants, products, intermediates and transition states were fully optimized using a semi-empirical PM3 method, in MOPAC'09. In order to identify transition state (TS), SADDLE calculations in MOPAC package were successfully applied, to generate trial geometries for unknown transition state complexes[1]. All ground states were positively identified for local minima (zero imaginary frequency, i.e. without –ve force constant) and for TS (one single imaginary frequency)[2] . Vibrational frequencies were also checked to confirm ground states and TS which are necessary for calculating thermodynamic parameters. In all experiments equimolar ratios of reactants were used along with ionic liquid.

2 Methodology

Saddle Calculation and Activation Energy calculations

SADDLE method automatically locates a transition state between the reactant and product geometries. It is particularly useful for finding complex transition states, when more than two bonds are involved (breaking or making). The input data consists of the geometries of the reactants and products, specified with same numbering and connectivity. The keywords SADDLE AND XYZ were used for finding the approximate geometry for TS. In these calculations, reactant and product geometries were optimized and compared in a progressive and systematic manner with reference to one another to converge or attain maximum heat of formation, by invoking the SADDLE keyword. Finally, we approach the approximate transition state region and this can be refined by gradient minimization procedure by invoking TS. The apparent activation was obtained for each set of reactant and products through force calculations on both ground state and transition state geometries by subtracting free energy of reactants from free energy of the TS

3 Results & Discussion:

Alkylation of p-cresol with tert-butyl alcohol is an acid catalysed reaction and product selectivity largely depend on acidity, solvent and temperature of the system. Major products of the reaction are C-alkylated and O-alkylated products. O-alkylated product is a result of t-butyl attack on oxygen in p-cresol (O-alkylation) that leads to the formation of ether besides the C-alkylated products.

According to this mechanism, the ionic liquid ester formed, also proceeds by two pathways, one via the formation of transition state GTS1, GINT and GTS2 to yield TBC and another via the formation of GTS3 followed by O-alkylated product, cresyl tert-butyl ether (CTBE) .The formation of ether is consistent with the observation of Liu et al[3] in the same reaction, using

pyridine based ionic liquid catalysts conducted, in a non-polar solvent. They explained that the ether product is thermodynamically unstable and continuously consumed to yield TBC via an intermediate. The formation of O-alkylated product is also explained by figure 1 which shows the corrected electronic energies (*E*) for *tert*-butylation of *p*-cresol excluding the effect of solvent

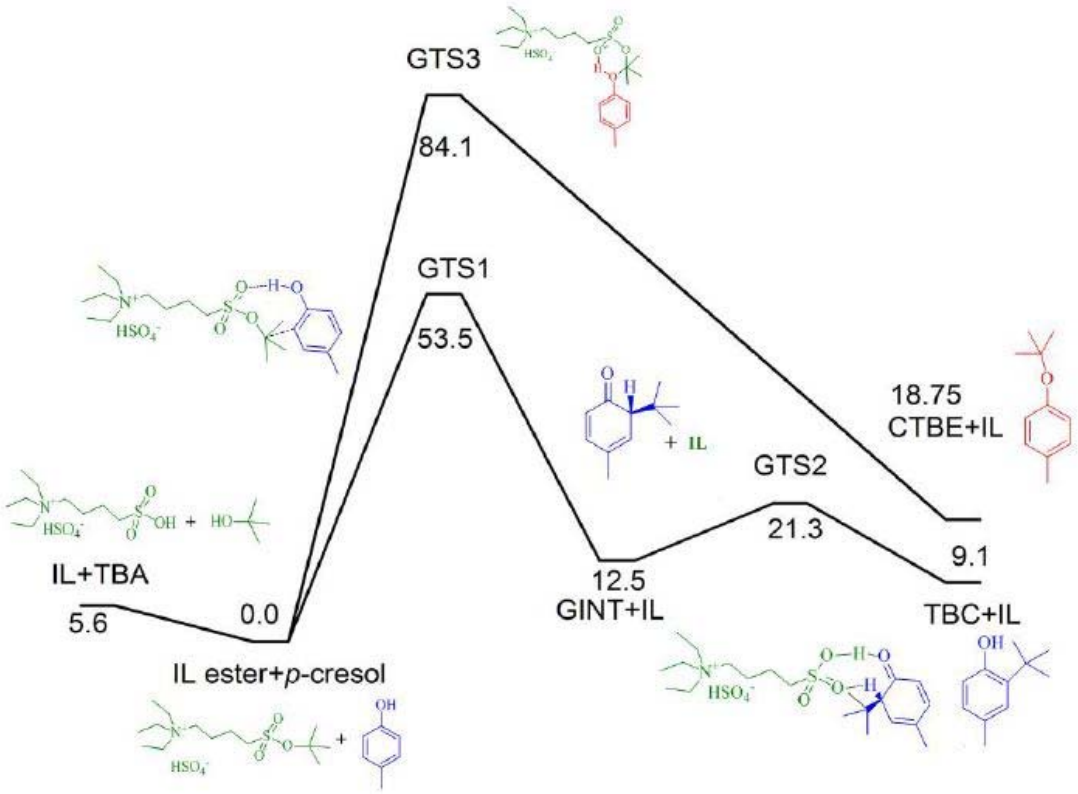

Fig. 1. Schematic view of corrected electronic energies (*E*) for *tert*-butylation of *p*-cresol excluding solvent effect as given in figure in cal/mol.

4 Conclusion

The *tert*-butylation of phenols in ionic liquids is modelled using semi empirical computational techniques considering the p-cresol alkylation. The mechanism involved and reactivity have been studied at the molecular level both in the presence and absence of solvent. In the presence of polar solvent C-alkylation pathway is favoured. In the absence of solvent or in the presence of non-polar solvent both C and O-alkylation pathways lead to the desired product formation.

Keywords: hydrogenation, carbon monoxide, olefins, ferrites, perovskite

1 Introduction

Hydrocarbon synthesis from CO and H_2 on heterogeneous catalysts (Fischer-Tropsch synthesis) is now regarded as a real alternative to their production of oil. Known and proven in industry processes provide a relatively wide range of products with different content of olefins in the individual hydrocarbons fractions. Therefore, an essential object of research is to increase the selectivity of the hydrocarbons synthesized by limiting the number of atoms C, as well as development of catalytic systems allowing to convert carbon oxides into olefins at atmospheric pressure, and having high performance in the processes described. In connection with the development of highly efficient catalysts based on nanostructured perovskite systems, study of the role of various factors affecting their adsorption, catalytic activity, selectivity and stability is promising.

2 Experimental/methodology

Studied in this paper layered oxides $GdFeO_3$, $SrFeO_{3+x}$, $GdSrFeO_4$, $Gd_2SrFe_2O_7$ and solid solutions $Gd_{2-x}Sr_{1+x}Fe_2O_7$ (x = 0,1 - 0,6) were synthesized by the high temperature solid state reactions and by sol-gel technology.

Characterization by powder X-ray diffraction (XRD) and scanning electron microscopy (SEM), has been performed for the determination of the structure and morphology of synthesized samples. XRD was performed on a Thermo ARL X'TRA diffractometer using CuKα radiation. The SEM images of synthesized samples were obtained on Carl Zeiss EVO 40EP and Zeiss Supra 40VP scanning electron microscopes. Mössbauer spectra have been recorded at room temperature by using spectrometer Wissel (57Co in a rhodium matrix with activity 10 mKu), the isomeric shifts were calculated with respect to α-Fe. In order to evaluate the part of paramagnetic species the intensity of the signals was determined precisely up to the factor of resonance absorption.

The hydrogenation of carbon oxide was studied in a flow catalytic unit at atmospheric pressure in a unit temperature range of 573 to 823 K, ratios of the components [$CO:H_2$] = 1:1, 1:2 and 1:4 and space velocities 1.5 - 3.0 l / h. Analysis of the products was performed by chromatography (Crystal 5000) using a column of stainless steel filled with Poropac Q at 393 K.

3 Results and discussion

Among synthesized ferrites there are three-dimensional perovskites $GdFeO_3$, $SrFeO_{3+x}$, and two-dimensional perovskite-type layered structures $GdSrFeO_4$, $Gd_2SrFe_2O_7$, $Gd_{2-x}Sr_{1+x}Fe_2O_7$, belonging to Ruddlesden-Popper phases $A_{n+1}B_nO_{3n+1}$ (n=1,2) and built up on the block principle from perovskite layers with different thickness. X-ray powder diffraction confirmed the presence of single phase for samples obtained both by high temperature solid state reactions and by sol-gel technology as well.

Scanning electron microscopy demonstrated decreasing of size of particles of complex ferrite from 10 μm, obtained by ceramic technology, up to 200 nm, obtained by the sol-gel technology. Mössbauer spectroscopy showed the difference of electronic state of complex ferrite, prepared by ceramic technology (Fe^{+3}) and oxides obtained by sol-gel technology (Fe^{+3} in the three different surrounding and Fe^{+4}).

Reaction products of hydrogenation of carbon monoxide are hydrocarbons C_1 - C_5, the main ones are methane, ethylene, propylene. The greatest amount of olefins formed in the reaction was observed in the stoichiometric ratio of CO and H_2. The catalytic activity (rate of product formation) increases in the series: $SrFeO_{3-x}$ < $GdSrFeO_4$ < $Gd_{1,6}Sr1_{,4}Fe_2O_7$ < $Gd_{1,8}Sr_{1,2}Fe_2O_7$ < $Gd_2SrFe_2O_7$ < $GdFeO_3$, that is a correlation with the number of alternating perovskite layers in the ferrites structure – 1, 2, ∞ . However, samples with n = 2 showed the highest selectivity for ethylene and propylene (Figure 1).

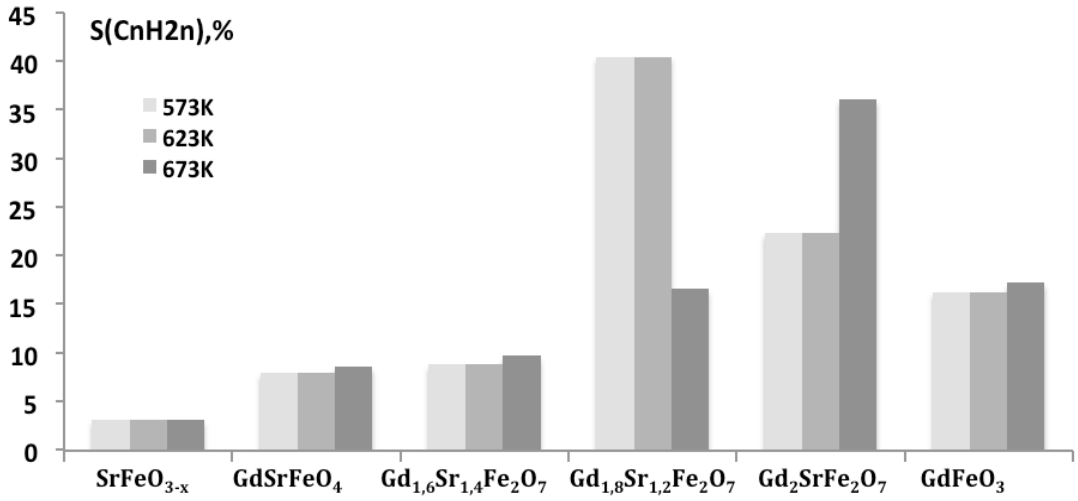

Fig. 1. Total olefin selectivity during the reaction in a ratio of $CO:H_2$=1:2.

The increase in strontium content in layered oxides $Gd_{2-x}Sr_{1+x}Fe_2O_7$ to x = 0.6 lowers the symmetry of atoms Fe^{+3} and increases the number of oxygen vacancies, which affect the selectivity (the maximum value of its observed at x = 0.3). Suggested that heterovalent state of iron (Fe^{3+}, Fe^{4+}) is favorable for the CO activation, which leads to the formation of C * and CH_x radicals. It is shown that under the influence of the reaction medium and the temperature there is changing the state of the active centers: probably a partial iron reduction.

Higher catalytic performance of perovskite-like ferrites synthesized by sol-gel method, may be related to their nanocrystalline state with a porous structure, as well as iron heterovalent state.

4 Conclusions

Catalytic properties of advanced materials - perovskite-type ferrites $A_{n+1}Fe_nO_{3n+1}$ (A=Gd, Sr; n=1, 2, ∞) were investigated in the carbon monoxide hydrogenation at atmospheric pressure. It was found correlation between the catalytic activity, selectivity to olefins and methods synthesis of complex oxides, the number of perovskite layers, crystallite size, cationic composition and iron valence state.

Keywords: hydrodearomatization, unsupported, catalysts, nickel-tungsten, sulfides, LCO

1 Introduction

In recent years the interest in studying of nanoscale particles as catalysts in dispersion systems significantly increased. It is connected to the fact that new promising possibilities of using nanomaterials in many areas of science and technology in particular to obtain of efficient and selective catalysts has been discovered [1-2]. The such dispersed-phase catalytic approach was used for hydroconversion of heavy oil residue, in Fischer-Tropcsh process [3]. In this research *in situ* synthesis and catalytic activity in hydrogenation of aromatic hydrocarbons in the presence of nanosized tungsten/nickel sulfides are described. The three different approaches for catalysts synthesis (from emulsion of ionic liquids in hydrocarbons, from emulsion of water in hydrocarbons and by thermolysis of precursor in hydrocarbon solutions) have been studied.

2 Experimental

To obtain the catalysts *in situ* in the ionic liquid, thermostable ionic liquid [BMPip][CF_3SO_3] as the solvent for the precursor has been selected. The complex of nickel-thiotungstate $[BMPip]_2Ni(WS_4)_2$ was used as a precursor. It was obtained by the new method of precipitation from the solution of ammonium thiotungstate $(NH_4)_2WS_4$.

Two types of precursors for the sulfide catalysts obtained *in situ* in hydrocarbon solution of substrate have been studied:

1) Complex of nickel-tiotungstate $[BMPip]_2Ni(WS_4)_2$,
2) Synthesis of catalysts through reverse microemultion (aqueous solution of precursors)/(hydrocarbon solution of substrate). Ammonium thiotungstate $(NH_4)_2WS_4$ and nickel nitrate were used as the precursors.

As a substrate the naphthalene, methylnaphthalenes and dimethylnaphthalenes in various solvents, such as hexadecane and benzene, have been selected. Using obtained catalysts the possibility of light cycle oil (LCO) hydrotreating has been investigated.

The hydrogenation of aromatic compound has been conducted under hydrogen pressure of 5 MPa and the temperature 350°C, with the hydrogen/feed about 60.

The catalysts were characterized by high resolution transmission electron microscopy (HRTEM), fourier transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS).

Analysis of hydrogenation products of model systems was performed on gas chromatograph. The quantitative content of aromatic hydrocarbons in the LCO hydrogenation products determined by high-performance liquid chromatography (HPLC). Component composition was determined by two-dimensional gas chromatography mass spectrometry (Pegasus® 4D GCxGC-TOFMS).

3 Results and discussion

Nickel-tungsten catalysts obtained *in situ* in a ionic liquid showed high activity in the hydrogenation of aromatic compounds. For example, when the ratio of naphthalene/tungsten was 7/1 and reaction time 10 hours naphthalene conversion was 100%. The main product was tetralin. When 1-octene used as a solvent conversion of naphthalene was 80%, whereas the 1-octene practically no hydrogenated, conversion in this case was only 5%. This is related to the fact that the aromatic hydrocarbons are well solved in ionic liquids, and the solubility of olefins in ionic liquids is limited. From the results we can conclude the following: ionic liquid can be used for the selective hydrogenation of aromatics in the mixture with olefins.

Nickel-tungsten catalysts obtained by *in situ* decomposition of the precursor $[BMPip]_2Ni(WS_4)_2$ in hydrocarbon solution of substrate showed high activity in the hydrogenation of aromatic compounds. For example, when the ratio of naphthalene/tungsten was 105/1 and reaction time 5 hours, naphthalene conversion was 100%. The catalysts gave high selectivity to decalins, at ratio of naphthalene/tungsten 7/1 and reaction time 10 hours decalins selectivity was 100%.

The possibility of *in situ* preparation of nanosized catalysts in hydrocarbon solution of substrate through reverse microemultion has been demonstrated. In this case a nonionic surfactant SPAN-80 has been used. The catalytic activity of obtained emulsions in hydrogenation reactions of aromatic hydrocarbons was studied for model systems as 10% solutions of naphthalene, 1-methylnaphthalene and 2-methylnaphthalene in n-hexadecane and benzene. The effect of surfactant concentration on the catalytic activity has been studied under optimal atomic ratio W/Ni = 1/1. Naphthalene conversion was 98% in optimal conditions. The main product was tetralin, decalins selectivity was 20%.

Also, the possibility of LCO hydrotreating using obtained catalysts has been investigated. It was shown that the total sulfur content decrease up to 0.02wt.%, and a significant reduction in the content of polyaromatic hydrocarbons was demonstrated.

4 Conclusions

In this research sulfide nickel-tungsten catalysts obtained *in situ* in ionic liquids and *in situ* in the hydrocarbon solution of substrate has been studied. Unsupported nickel-tungsten sulfide systems are the promising catalysts for the aromatic hydrocarbons hydrogenation processes in dispersion system. Also, the possibility of LCO hydrodearomatisation using obtained catalysts has been shown.

Keywords: hydrodearomatization, unsupported, catalysts, transition, metal, sulfides

1 Introduction

Traditionally, transition metal sulfides are used as hydrotreating catalysts for petroleum fractions. Alumina-supported Mo or W promoted by Co or Ni are often used as industrial catalysts [1]. These compositions have optimal combination of such properties as activity, stability, cost, etc. However, recently extensive studies have been conducted in the field of transition metal sulfides such as Nb, Os, Ru, Rh, Re. Ruthenium sulfide showed the highest hydrogenation and hydrodesulphurization catalytic activity [2-4]. For example, Lacroix et al. [4] presented that the ruthenium sulfide hydrogenating activity exceed in 6 times the activity of MoS_2.

Usually metal sulfides are supported on porous materials such as silica-alumina, Al_2O_3, silica oxide, to increase the surface area of the catalyst and decrease amount of the active component. A new approach to the synthesis of catalysts is renunciation of the use of supports in its synthesis, i.e. to use of nanoparticles of catalysts dispersed in the hydrocarbon feedstock.

In this research the possibility of obtaining sulfide catalysts *in situ* in hydrocarbon solution of substrate for hydrogenation of aromatic hydrocarbons has been investigated.

2 Experimental

The preparation method of sulfide catalysts *in situ* in the hydrocarbon solution of substrate for the hydrogenation of polyaromatic hydrocarbons was developed. Used precursors were oil-soluble salts: tungsten carbonyl $W(CO)_6$, ruthenium carbonyl $Ru_3(CO)_{12}$ and molybdenum carbonyl $Mo(CO)_6$.

Synthesized catalysts were characterized by HRTEM, FTIR-spectroscopy and XPS.

Catalytic activity in hydrodearomatization reaction was studied. As a substrate the solution of naphthalene in benzene have been selected. It was shown that the addition of 2.5 wt.% elemental sulfur to hydrocarbon solution is necessary for the formation active phase of sulfide catalysts. The hydrogenation of naphthalene has been conducted under a hydrogen pressure of 5-7 MPa and the temperature 350°C, with the hydrogen/feed about 60.

3 Results and discussion

The influence of metal carbonyl concentration on naphthalene conversion was studied and kinetic parameters of naphthalene hydrogenation were obtained. It was shown that ruthenium sulfide prepared from ruthenium carbonyl $Ru_3(CO)_{12}$ has the highest catalytic activity. When the ratio of naphthalene/ruthenium was 56/1 and reaction time 5 hours naphthalene conversion was 96% and decalin selectivity was 25%.

Also the influence of nickel addition on catalytic activity was studied. Added nickel was in oil-soluble salts form (nickel(II) 2-ethylhexanoate $Ni(C_7H_{15}COO)_2$). Catalytic activity obtained catalysts increases in the case of nickel addition and optimal M/Ni ratio was found (M = Ru, W, Mo), for tungsten W/Ni ratio was 1/2, for molybdenum Mo/Ni ratio was 1/2 and for ruthenium Ru/Ni ratio was 1/3.

Also effect of hydrogen pressure in process were investigated. It was shown that the catalytic system W/Ni (ratio was 1/2) has the the highest catalytic activity. When the ratio of naphthalene/tungsten was 210/1 and reaction time 5 hours naphthalene conversion was 100% and decalin selectivity was 64%.

4 Conclusions

In this research sulfide catalysts have been obtained *in situ* in the hydrocarbon solution of substrate using oil-soluble precursors such as metal carbonyl for the first time. Obtained unsupported transition metal sulfide catalysts are the promising catalysts for the aromatic hydrocarbons hydrogenation processes.

Keywords: selective oxidation, pseudocumene, polyoxometalate, hydrogen, peroxide

1 Introduction

The selective oxidation of aromatic rings of alkylsubstituted arenes with atom efficient and green oxidants, e.g., aqueous H_2O_2, is a challenging goal of organic synthesis. A demanding task is the aromatic oxidation of 1,2,4-trimethylbenzene (pseudocumene, PC) and 2-methylnaphthalene (2-MN) leading to 2,3,5-trimethyl-1,4-benzoquinone (TMBQ, vitamin E key intermediate) and 2-methyl-1,4-naphthoquinone (2-MNQ, Vitamin K_3), respectively. Recently, Mizuno and co-workers reported H_2O_2-based aromatic hydroxylation of some alkylbenzenes catalyzed by a divanadium-substituted polyoxometalate (POM), $[\gamma\text{-}PW_{10}V_2O_{40}]^{5-}$, in the presence of a mineral acid [1]. In this work, we explored the catalytic properties of this POM in the selective oxidation of PC and 2-MN and studied the reaction mechanism by experimental and theoretical methods.

2 Experimental/methodology

$(Bu_4N)_4H[\gamma\text{-}PW_{10}V_2O_{40}]$ (shortly, $\gamma\text{-}PW_{10}V_2$) was prepared according to the literature [2] with some modifications [3] and characterized by ^{31}P and ^{51}V NMR and IR spectroscopy. Other reactants were obtained commercially and used as received. Catalytic oxidations were carried out in temperature-controlled glass vessels at 30–80ºC under vigorous stirring. Reactions were initiated by the addition of H_2O_2 (30% in water) either in one portion or stepwise to a mixture containing aromatic substrate (PC or 2-MN), $\gamma\text{-}PW_{10}V_2$ catalyst and $HClO_4$ in 1 mL of MeCN/*t*-BuOH (1:1 v/v). Samples of the reaction mixture were taken periodically and analyzed. The oxidation products were identified by GC–MS and ^1H NMR and quantified by GC and HPLC.

DFT calculations were carried out with Gaussian 09 C01 release with B3LYP functional using IEF-PCM (MeCN as a solvent) implicit solvation model. For V and W atoms LANL2DZ pseudopotential was used. The 6-31G(d,p) basis set was used to C and H atoms as well as for O atoms of water and hydrogen peroxide molecules and directly bonded to V. For remaining atoms 6-31G basis set was used.

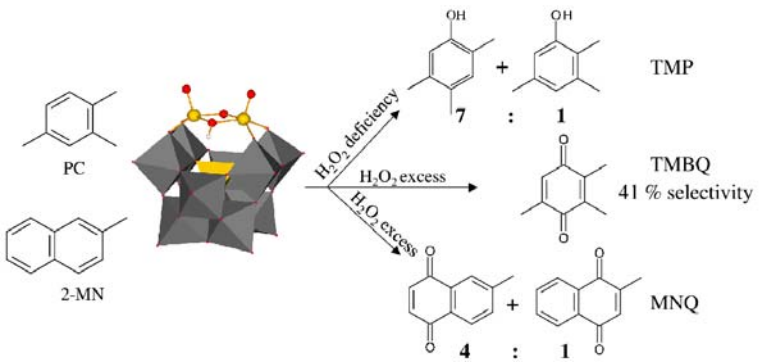
3 Results and discussion

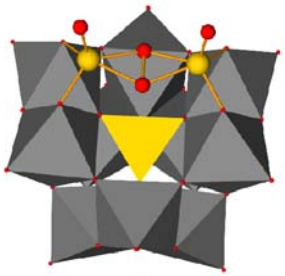
Under conditions of H_2O_2 deficiency, PC oxidation with H_2O_2 in the presence of $\gamma\text{-}PW_{10}V_2$ proceeded with high selectivity of aromatic ring hydroxylation (>95%) and unusual regioselectivity toward 2,4,5-trimethylphenol (2,4,5-TMP). The ratio of 2,4,5-, 2,3,5- and 2,3,6-TMP isomers was 7 : 1 : <0.15. Optimization of the reaction conditions has led to TMP yield of 73% based on the oxidant. The presence of a mineral acid ($HClO_4$) and *t*-BuOH was crucial for the catalytic activity. With an 8-fold excess of H_2O_2, TMBQ formed along with other overoxidation products; TMBQ selectivity reached 41% at PC conversion of 41%. Atypical

regioselectivity was also found in the oxidation of 2-MN where 6-MNQ predominated over 2-MNQ. The ratio of the 6-MNQ/2-MNQ isomers depended on the concentration of acid, catalyst and oxidant.

The lack of products derived from the oxidation of methyl groups indicates electrophilic hydroxylation mechanism and argues against electron transfer or hydrogen atom transfer mechanisms. Studies on PC oxidation by DFT revealed that the formation of 2,4,5- and 2,3,5-TMP is, most likely, due to peroxo complex $[\gamma\text{-}PW_{10}O_{38}V_2(O_2)]^{3-}$ (**I**), which may arise from dehydration of hydroperoxo complex $[\gamma\text{-}PW_{10}O_{38}V_2(OH)(OOH)]^{3-}$ (**II**) formed upon interaction of the diprotonated POM, $H_2[\gamma\text{-}PW_{10}V_2O_{40}]^{3-}$ (**III**), with H_2O_2. If **II** were the main oxidizing species, 2,3,6-TMP isomer would predominate. The oxygen transfer from peroxo complex **I** to the aromatic ring of PC presumably occurs through the formation of an arene oxide intermediate. The role of acid is, therefore, to favor the formation of **III** which then leads to **II.** In turn, *t*-BuOH may facilitate the formation of **I** through stabilization of the released water by hydrogen bonding. In contrast to PC oxidation, the presence of neither acid nor *t*-BuOH is required for H_2O_2-based oxidation of 2,3,6- and 2,3,5-TMP to TMBQ [4]. Hydroperoxo complex **II** is supposed to be the active species responsible for the formation of TMBQ.

The kinetic regularities and estimated rate constants acquired from the kinetic study on PC oxidation with H_2O_2 are in good agreement with the theoretically predicted reaction mechanism where peroxo complex **I** is the main species responsible for the aromatic ring hydroxylation.





DFT structure of peroxo complex $[\gamma\text{-}PW_{10}O_{38}V_2(O_2)]^{3-}$.

4 Conclusions

Polyoxometalate $(Bu_4N)_4H[\gamma\text{-}PW_{10}V_2O_{40}]$ catalyzes the selective oxidation of PC with aqueous H_2O_2 to produce either 2,4,5-/2,3,5-TMP (ca. 7:1) or TMBQ, depending on the substrate to oxidant ratio. The oxidation of 2-MN proceeds with unusual regioselectivity toward 6-MNQ. Both kinetic and DFT studies on the PC oxidation implicate peroxo complex $[\gamma\text{-}PW_{10}O_{38}V_2(O_2)]^{3-}$ as the key intermediate leading to 2,4,5-/2,3,5-TMP.

Keywords: nanostructured oxides, sol-gel, gold nanoparticles, benzyl alcohol, oxidative esterification

1 Introduction

The oxidation of alcohols is one of the most challenging reactions in synthetic organic chemistry. The resulting carbonyl compounds are widely used in various fields of the chemical industry. For example, methyl esters find a commercial use as solvents, diluents, extractants and flavoring agents [1-4]. Gold nanoparticles (NPs) are considered to be promising catalysts for the aerobic oxidation of alcohols, which involve O_2 as an oxidant, due to their high activity and stability. However, most of the gold systems reported for the oxidative esterification of alcohols require the presence of base (usually NaOH or K_2CO_3) and only a few catalysts based on AuNPs were found capable to promote a direct transformation of alcohols to esters using molecular oxygen as an oxidant in the absence of any base additive.

In the present work, the performance of AuNPs supported on nanostructured unitary Al_2O_3 and CeO_2 and binary Ce-Al-O oxides was studied in the liquid-phase aerobic oxidation of benzyl alcohol and benzaldehyde in methanol solutions under neutral conditions, for the first time as far as we know.

2 Experimental/methodology

Nanostructured Ce-Al-O mixed oxides with different content of ceria (10 and 30 wt. %) were prepared by sol-gel method using organometallic precursors as described previously [5]. Commercial CeO_2 (Alfa-Aesar) was used as a support as well. Gold catalysts (3 wt. % Au) were synthesized by deposition-precipitation route using urea as precipitation agent as in [5]. The structural and electronic properties of gold samples were studied by N_2 adsorption, XRD, TEM, XPS and UV-Visible spectroscopy under temperature-programmed reduction or oxidation. Obtained materials were catalytically studied in the oxidative esterification of benzyl alcohol and benzaldehyde. The reactions were carried out in a homemade stainless steel reactor equipped with a magnetic stirrer. In a typical run, a mixture of the substrate (2.5 mmol), solvent (3 mL), and the catalyst (10 mg; 0.9 – 2.0 μmol of Au) were transferred into reactor. The reactor was pressurized with oxygen to the total pressure of 10 atm and placed in an oil bath; then the solution was intensively stirred at 110 °C for the reported time. The reactions were followed by gas chromatography (GC) (Shimadzu 17 instrument fitted with a Carbowax 20 M capillary column and a flame ionization detector). At appropriate time intervals, stirring was stopped and

after catalyst settling aliquots were taken and analyzed by GC.

3 Results and discussion

Gold catalysts supported on Ce-Al-O mixed oxides showed better performance in the liquid-phase oxidative esterification of benzyl alcohol and benzaldehyde without usage of any base promoter than gold supported on individual oxides. The strong synergetic effect of ceria and alumina can be explained by the enhanced oxygen storage capacity of the materials prepared from mixed oxides as compared to pure alumina and ceria. Thus, the introduction of ceria nanospecies into alumina facilitates the oxygen activation by AuNPs and strongly improves their performance in the oxidation processes.

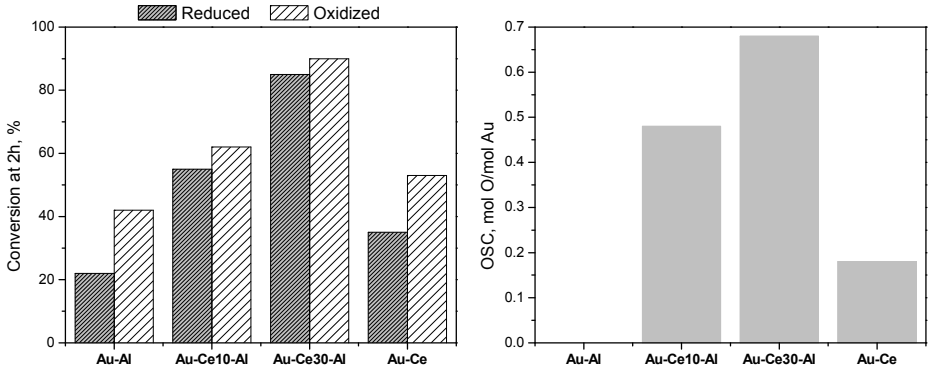

Fig. 1. Conversion of benzyl alcohol at 2 h of reaction over Au catalysts supported on various nanostructured oxides after different pre-treatments (left). Oxygen storage capacity (OSC) measured via oxygen adsorption at room temperature over the same reduced gold catalysts (right) [5].

4 Conclusions

Gold nanoparticles supported on Ce-Al-O mixed oxides prepared by sol-gel route demonstrates higher activity in the liquid-phase aerobic oxidative esterification of benzyl alcohol and benzaldehyde than gold supported on unitary ceria and alumina. The thermal pre-treatment in oxygen resulted in more active catalysts than pre-treatment in hydrogen. The order of the catalytic activity is as following: $Au/Al_2O_3 < Au/CeO_2 < Au/Ce(10)\text{-}Al < Au/Ce(30)\text{-}Al$. The data obtained in this work may be applied for the development of new effective catalysts for industrial application in the oxidative esterification of a wide variety of alcohols using environmentally benign molecular oxygen in the absence of any co-catalysts or additives.

Keywords: titanium silicalite, phenol hydroxylation, hydrogen peroxide

1 Introduction

Selective oxidation in the liquid phase is currently applied in the chemical industry for manufacturing a wide variety of chemicals ranging from commodities to high-value-added fine chemicals. Heterogeneous catalysts only started to play a significant role in this area at the beginning of the 1980s with the synthesis and the industrial applications of titanium silicalite-1 (TS-1). The successful design of TS-1 by Enichem (1) as an oxidation catalyst for environmentally benign industrial oxidation reactions with hydrogen peroxide comprises one of the most important innovations in heterogeneous catalysis over the last thirty years. This zeolitic-type material of the MFI-type incorporates titanium in the framework and displays unique catalytic properties for oxidation reactions of alkanes, alkenes and aromatic hydrocarbons, with the hydrogen peroxide system replacing oxygen as the oxidation agent, at moderate reaction conditions and with water as the main by- product of the oxidation.

The unique performance of this MFI-type zeolite catalyst, which is isomorphous with the ZSM-5 zeolite and silicalite-1, is attributable to the specific features of isolated Ti4+ active sites incorporated in the silica structure of the zeolite framework. These were shown to be able to efficiently promote activity and selectivity in oxidation reactions with hydrogen peroxide. In contrast, non-isolated titanium, such as segregated titanium dioxide, TiO2, forms an "Anatase-like" phase, which not only is inactive for these reactions but also imposes severe diffusion limitations to oxidation over TS-1 zeolites by filling the pores of with inactive material. Further, depending on the conditions of preparation, some extra-framework titanium exists which forms an amorphous TiO2 phase in the pores. This may be partially removed by a diluted acetic acid wash or by other means prior to the use of the zeolite for the catalytic reaction.

This paper, describes the synthesis, characterization and activity- testing of a series of Ti-silicalite catalysts (TS-1) using the hydroxylation of phenol as the test reaction. In addition, high-silica ZSM-5 zeolites and silicalite-1, comprising isomorphous zeolite systems of the MFI-type were also produced and characterized and their textural and structural properties were compared with those of the TS-1 zeolite.

2 Experimental section

For the synthesis of TS-1 titanium-silicalite nanocrystals standard methods based on the hydrothermal synthesis of zeolites as described in the literature (1 - 3) were used. These comprise the use of organic precursors such as tetraethyl orthosilicate (TEOS) and tetra butyl ortho titanate (TBOT). In our case, we have predominantly used colloidal silica (Ludox® HS 30%) as the silica source and tetrapropyl ammonium hydroxide (TPAOH) as the template. Experiments with the use of tetrapropyl ammonium bromide (TPABr) were successful in the synthesis of ZSM-5 zeolites; however, the TS-1 produced with this combination (using ammonia as the base) did not crystallize very well. For the hydrothermal synthesis of a series of ZSM-5 zeolites, silicalite-1 and titanium silicalite (TS-1), 1–litre, stirred, high-pressure SS 316 autoclaves and other smaller, high pressure, teflon-lined SS vessels (50 ml, 100ml and 200 ml) without stirring were used.

For characterization, the zeolite nano catalysts were tested with XRD, SEM, TEM, FTIR, and

UV-VIS. Results from Raman spectroscopy are still outstanding. The spatial distribution of the titanium and silicon in the TS-1 micro particles was studied with EDS. Finally, N2-adsorption isotherms were obtained, in order to determine the textural properties of the nano catalysts.

For the preparation of theTS-1 zeolite precursor gel [2] Solution A, comprising 45g TEOS in a flask was placed in an iced bath under argon atmosphere, and 2.4g Ti (OBu)4 was added under intensive stirring. A clear solution was formed. Thereafter, Solution B, consisting of 100 g of aqueous solution of 20% TPAOH was added to Solution A in a drop wise process under stirring, with the aim to maintain a clear solution; the temperature was allowed to rise to 60^0C. The final pH was adjusted to 12. Thereafter, the mixture was placed in a teflon-lined, one-litre autoclave and was allowed to crystallize at 175^0C, under stirring. After crystallization was completed (96 hours), calcination followed using a procedure similar to that for the ZSM-5 zeolite. The molar composition of the precursor gel was nSiO2: nTiO2: nTPAOH: nH2O = SiO2: 0.027 TiO2: 0.36TPAOH: 35H2O. The ratio of Si:Ti was 24.

To evaluate the catalytic performance of the synthesized TS-1, the hydroxylation of phenol with hydrogen peroxide was carried out as the test reaction. The batch oxidation procedure was as follows: 18.g g of phenol was dissolved in 64 ml methanol or acetone solvent inside a round-bottomed, 250 ml flask, equipped with a thermometer, dropping funnel and a stirrer. 1.88g TS-1 catalyst (10% to phenol) was added. Finally, 20g of 30% H2O2 was slowly added when the temperature had reached 70oC. Overall reaction time was 6 hours. Samples of the reaction mixture were regularly withdrawn and analyzed using gas chromatography with a capillary column.

3 Results and discussion

Fully crystalline TS-1 zeolite nano crystals were obtained at a temperature of 175^0C and a time period of 96 hours, and above, in both autoclave systems. The XRD pattern was identical with that of the isomorphous MFI zeolites, namely ZSM-5 and silicalite-1. The patterns at 2Θ = 7.96, 8.91, 14.00, 14.87, 20.92, 23.28, 23.97, 24.52, 26.66 are typical for the ZSM-5 zeolite and its isomorphous zeolites. TS-1 catalyst crystallizes in the orthorhombic system; the crystallites were calculated to be in the range of 20 – 40 nm, whereas the pore size amounts 0.53 x 0.56nm as in the case of ZSM-5 zeolites.

SEM, XRD, FTIR, EDS and UV-vis techniques were used to illustrate the effects of the preparation procedure on the structure and the morphology of each of the three series of zeolites obtained (TS-1, silicalite and ZSM-5). The existence of isolated Ti4+ active sites incorporated in the silica structure was clearly demonstrated with the strong band appearing in the FTIR spectra at 960 cm-1with the stretching vibration of [SiO4] units influenced by the presence of adjacent Ti-atoms incorporated in the framework. Neither pure silicalite-1, nor the ZSM-5 zeolites show a band at around this frequency and thus this band at 960 cm -1 is considered a “fingerprint” for the existence of titanium in the zeolite matrix.

The catalytic results obtained, showed that using the TS-1 with methanol as solvent, considerable conversion of the phenol substrate was achieved within only a few hours (2 h, conversion of phenol> 40%) and the selectivity results towards the catechol and hydroquinone were above 60%. These results were dependent on the solvent; when acetone was used, the conversion was lower (residence time: 2h; conversion only 25% ; selectivity:40%).

4 Conclusions

It was demonstrated that the TS-1 catalysts prepared at our laboratories have textural and structural properties similar to those described in the literature [1-3] and that they display significant catalytic activity in the hydroxylation of phenol. The product selectivities obtained were also high, however they were dependent on the solvent used.

Keywords: phosphorylation, catalysis, transition metal complexes

1 Introduction

Relevance of the methods of C-H phosphorylation of aromatic compounds with metals and their complexes is an important research direction that is little studied to date. The review published in recent years devoted to developments in the field of formation CP bonds in various catalytic reactions, almost without considering the examples of aromatic C-H phosphorylation bonds [1-3].

2 Results and discussion

Therefore, the development of catalytic methods especially with regard to the requirements of "green chemistry" is fundamentally important today.

The aim of this work is to find new reactions capable to activate and transform catalytically inert C-H bonds in organic molecules to carbon-phosphorus functional groups using redox -activated metals Co, Mn, Fe, Ni and their complexes.

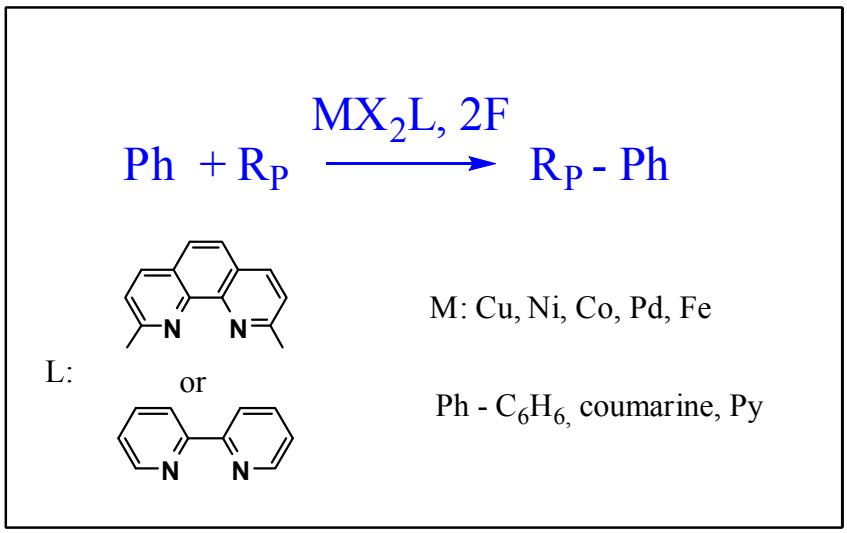

Fig. 1. Schematic representation of studied processes

3 Conclusions

Within this work it was shown that the electrochemical activation of metal complex to M (III) oxidation state (apart from Ag) allows to add the dialkylphosphite to the aromatic substrates (benzene, pyridine, coumarine) successfully. Silver nitrate yields to monoalkylphosphonate in th same electrochemical conditions.

Keywords: isobutylene, hydroalcoxycarbonylation, metalcomplex catalysis, biological active esters

1 Introduction

Hydroalkoxycarbonylation of olefins with carbon monoxide and alcohols under condition of homogeneous catalysis with transition metal complexes allows facile one-step synthesis of practically useful carbon acid esters. Many of them have biological activity and are constituents of drugs or valuable intermediate products in drug synthesis. Hydroalkoxycarbonylation of isobutylene with carbon monoxide and alcohols in the presence of catalytic systems based on Palladium Phosphin Complexes ($Pd(PPh_3)_4$-PPh_3-TsOH, $Pd(Acac)_2$-PPh_3-TsOH) was applied for preparing of biological active isovaleric acid esters: l-menthylisovalerate (main active component of the spasmolytic medicine “Novovalidolum”), ethylisovalerate (intermediate product for obtaining sedative and spasmolytic medicines “Ethyl ether of α-bromisoveleric acid” (EEBIA) and “Corvololum-K”), cyclohexylisovalerate (bactericide activity against Staphylococcus aureus, Escherichia coli, Pseudomonas aeruginosa; antifungus activity against Candida albicans), benzylisovalerate (bactericide activity against Escherichia coli, Staphylococcus aureus) and monoglyceryde of isovaleric acid (bactericide activity against Escherichia coli, Pseudomonas aeruginosa; and antifungus activity against Candida albicans).

2 Experimental/methodology

The reaction were performed in a stainless-stell autoclave. The reaction was performed without solvent. The [alcohol]:[isobutylene]:[Pd]:[PPh_3]:[p-TsOH] ratio was 435:565:1:7:12. The autoclave at room temperature was charged with the catalytic system and alcohol. The autoclave was hermetized, purged in duplicate with carbon monoxide for deaeration, and charged with olefine, after which required carbon monoxide pressure was effected, and stirring and heating were started. The reaction products were isolated by fractional distillation.

3 Results and discussion

Hydroalkoxycarbonylation reaction of isobutulene with carbon monoxide and alcohols (ethanol, cyclohexanol, l-menthol, benzyl alcohol, glycerol) in the presence Palladium Phosphin Complexes carried out at conditions: temperature 100^0C; CO pressure 2,0 MPa; reaction time 4 h. [1-3]. The yields of the products were 57,0-96,0%. The selectivity in linear reaction products was 100%. Such a high regioselectivity is apparently provided both by the structure of the starting alkene (isobutylene) and by the reaction mechanism. The most probable is a hydride mechanism.

New efficient technologies for preparation of drugs (Novovalidolium, EEBIA and Corvalolum-K) are based on isovaleric acid esters were worked out. Novavalidolum – is a spasmolytic (sedative) medicine; it has a sedative effect on the nervous system and a moderate reflex vaso-dilating effect. EEBIA possesses sedative and spasmolytic properties; it is included in Corvalolum-K composition and may be used for producing other medicines. Corvalolum-K is

a combined medicine and consists of EEBIA, phenobarbital, sodium hydroxide, peppermint oil, ethyl alcohol and water. Corvalolum-K possesses anetic and spasmolytic properties.

Due to the more advanced technology of production the Medicines will have better qualitative characteristics. The cost of production of the Medicines with the use of new technologies is 2-3 times lower as compared to the medicines produced by existing at the present traditional technologies.

4 Conclusions

Biological active isovaleric acid esters were synthesized by isobutylene hydroalkoxycarbonylation in the presence of catalytic systems based on Palladium Phosphin Complexes.

New, efficient technologies for preparation of drugs are based on the isovaleric acid esters – "Novovalidolum", "Ethyl ether of α-bromisovaleric acid" and "Corvalolum-K" – were worked out.

Keywords: selective hydrogenation, hexanoic acid, hexanol, platinum, rhenium, atomic dispersion

1 Introduction

Liquid-phase hydrogenation of carboxylic acids is a crucial component of a number of strategies for the conversion of biomass into fuels and chemicals. The reaction products, alcohols, are widely used in industry as nonionic surfactants, running resins, plasticizers, cosmetics, etc. This process is catalyzed by bimetallic Pt-Sn and Ru-Sn catalysts occurred under severe reaction conditions ($T \leq 300°C$ and $P \leq 300$ bar) with an alcohol selectivity of only 40-75% [1]. Recently, the novel Pt and Pd catalysts promoted with rhenium showed a higher selectivity (*ca*. 90%) in hydrogenation of acids to alcohols under milder conditions [2,3]. A more pronounced performance was shown by the metal-organic pincer-type complexes demonstrating at $T \leq 100°C$ and $P \leq 50$ bar the 100% alcohol selectivity due to heterolytic activation of the molecular hydrogen to form metal hydride [4]. Here, we tried to stabilize on the titania surface the Pt-ReO_x species of atomic dispersion and to test in hydrogenation of hexanoic acid under reaction conditions similar to that of the highly selective homogeneous catalyst. Moreover, the kinetics assisted reaction mechanism was proposed.

2 Experimental/methodology

Commercial anatase titania (Hombifine N) was used as a support. The catalyst preparation profile included consecutive deposition of rhenium and platinum via incipient wetness impregnation from their water solution of ammonium perrhenate and platinum amine complexes with further thermal decomposition and reduction under controlled gas media. The chemical composition of the catalysts, order of metal deposition, and temperature of redox treatments were optimized. The size, metal charge and chemical composition of the Pt-ReO_x species were characterized by means of HRTEM, STEM-HAADF with line EDX analysis, XPS and FTIR. The hydrogenation process in dodecane or dioxane as a solvent was performed in a Parr reactor with GC analysis at P_{H2} = 25-75 bar and T = 110-150°C.

3 Results and discussion

The key approaches for stabilizing the highly dispersed Pt-ReO_X species on the TiO_2 surface were 1) the formation of low-valence and low-coordinated ReO_X clusters ($x \leq 1$) due to strong interaction of the Re precursor with the support under inert gas media and 2) a further formation of Pt-O-Re centers due to strong interaction of the Pt precursor with the formed ReO_X species, which are able to dissociate heterolytically the molecular hydrogen similar to that of the homogeneous metal-organic catalyst. Indeed, the highly dispersed particles of *ca*. 0.5 nm in size were observed on the titania surface, where the Re:Pt ratio followed from line EDX analysis of rhenium and platinum was close to 2:1 (Fig. 1A). In addition, according to XPS and FTIR data, Pt is metallic, while Re is in the partially oxidized (Re^{1+} or Re^{2+}) states. The kinetic study confirmed that the reaction rate constant linearly increases with number of Pt-ReO_X centers, and

the highest activity was achieved at Re:Pt = 2 (Fig. 1B, see the cross-point) which is in agreement with EDX data. A further adding of superstoichiometric platinum did not increase the reaction rate because of large low-active Pt particles were formed only. We believe that, as for the *Ru-NPy* pair in pincer complexes, the neighboring *Pt–O* atoms are able to activate molecular hydrogen with generation of Pt hydride for efficient hydrogenation of the carbonyl group of acid.

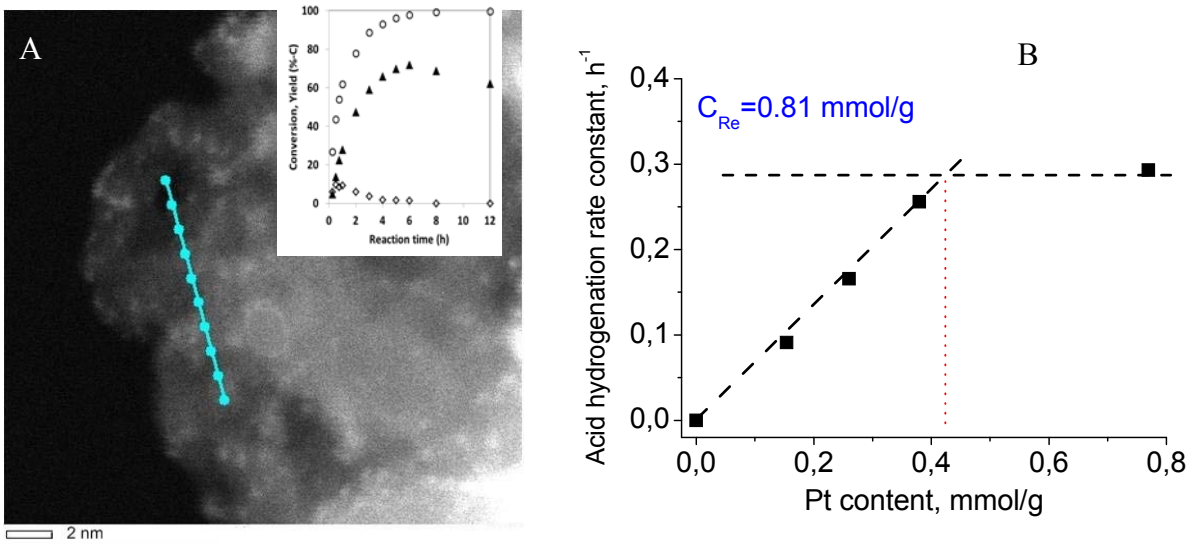

Fig. 1. (A) STEM-HAADF image of the 5% Pt-15% Re/TiO_2 sample with line EDX analysis of Pt and Re (the inset); (B) the hydrogenation rate constant *vs* the Pt content in catalysts with monolayer coverage by renium (0.81 mmol/g).

It was shown that the side reaction of acid esterification with hexanol catalyzed by acid itself is homogeneous and decreases noticeably the hexanol selectivity. The use of dioxane as a solvent allowed us to significantly suppress esterification, so that the selectivity reached 99% which is close to that of the homogeneous catalyst. The TOF value of 40 h^{-1} is one order higher than those known from the literature. The first order kinetics towards target and side reactions described well the kinetic data obtained in a wide range of reaction conditions. Finally, the Pt-ReO_X/TiO_2 catalyst revealed high stability during at least 5 recycles for 20 hours.

4 Conclusions

The Pt-ReO_X species ($x \leq 1$) of atomic dispersion were stabilized on the titania surface. It was shown that these centers with the atomic ratio Re/Pt = 2 are highly active and selective in hydrogenation of hexanoic acid to hexanol. The first order kinetic model of the hydrogenation process described well the kinetic data obtained in a wide range of reaction conditions. High TOFs (up to 40 h^{-1}) and selectivities (up to 99%) and stability were demonstrated under mild reaction conditions.

Keywords: epichlorohydrin, epoxidation, titanium-containing zeolite, hydrogen peroxide, epoxy, resins

1 Introduction

Epichlorohydrin is an important product of basic organic synthesis. The main method for production of epichlorohydrin is dehydrochlorination of glycerol α,β-dichlorohydrins in an alkaline medium. However, this method has low efficiency, poorly utilizes the starting reagents, and is ecologically unsafe.

At present, one of promising techniques for production of epichlorohydrin is the liquid-phase oxidation of allyl chloride with hydrogen peroxide in an organic solvent on a heterogeneous catalyst, titanium-containing zeolite. However, evidence about physicochemical aspects of this process can hardly be found in the literature.

The goal of our study was to examine the influence exerted by various factors on the process of liquid-phase oxidation of allyl chloride with an aqueous solution of hydrogen peroxide on a titanium-containing zeolite. In particular, the effect of the amount of the solvent, temperature, and reagents ratio was analyzed.

2 Experimental

The epoxidation of allyl chloride was studied in a laboratory batch reactor equipped with an electromagnetic rabble and a system maintaining a constant temperature. To maintain the components in the liquid state, an excess pressure of 0.5–1.5 atm was used.

3 Results and discussion

Allyl chloride was epoxidized with an aqueous solution of hydrogen peroxide on a titanium-containing zeolite in the presence of an organic solvent. Alcohols, ketones, and ethers can be used as solvents. Our studies have shown that methanol provides the highest epoxidation rates and high yield of epichlorohydrin. In this process, the solvent serves as a homogenizer of allyl chloride and hydrogen peroxide, thereby providing their interaction at the surface of the solid catalyst. It should be noted that the amount of the solvent strongly affects the basic aspects of the process. Because the ternary system constituted by allyl chloride, methanol, and water has a limited solubility region, the choice of the solvent concentration is limited by the possibility of obtaining a homogeneous reaction mixture, on the one hand, and by the inadvisability of its strong dilution complicating the subsequent isolation of epichlorohydrin, on the other.

To study the effect of the solvent concentration on the process of allyl chloride epoxidation, we carried out a set of experiments at various methanol : allyl chloride molar ratios. The solvent concentration was varied in the range 50–80 wt %, which lies within the mutual solubility region of the allyl chloride–methanol–water ternary system.

It was found that, as the content of the solvent in the reaction mass is lowered, the initial rate of epichlorohydrin formation grows, with this relationship being linear. Variation of the methanol content within the range 50–80 wt % only slightly affects the yield of epichlorohydrin,

which remains constant: 94–96% at a hydrogen peroxide conversion of 96–98%. Thus, it is advisable to perform the epoxidation process at a solvent content close to 55–65 wt %, which corresponds to a methanol : allyl chloride molar ratio of (4–6) : 1. Lower solvent concentrations are undesirable because of the possible transition of the system from a homophase to a heterophase state, despite the possible increase in the initial rate of the process. Solvent contents exceeding 65 wt % fails to provide a desired increase in the process selectivity, and only diminishes the epoxidation rate and largely complicates the subsequent stage of epichlorohydrin isolation because of the strong dilution of the reaction mass. At a solvent content of 55–65 wt %, the epoxidation rate is sufficiently high and an effective heat removal is provided, which rules out reaction mass overheating leading to undesirable consequences.

To evaluate the effect of the initial allyl chloride : hydrogen peroxide ratio on the basic aspects of the process, we carried out a set of experiments at various initial ratios between these reagents. The allyl chloride : hydrogen peroxide molar ratio was varied within the range (1–6) : 1. An increase the concentration of hydrogen peroxide (decrease in the initial allyl chloride : hydrogen peroxide ratio) results in that the initial rate of epichlorohydrin formation grows.

It should be noted that variation of the initial allyl chloride : hydrogen peroxide ratio also strongly affects the yield of epichlorohydrin. For example, an increase in the initial ratio from 1 : 1 to 3 : 1 at a constant conversion of 95% makes the yield of epichlorohydrin higher. Further increase in the concentration of allyl chloride fails to raise the yield of the target product. The reason is that the rate of the target process decreases with increasing initial allyl chloride : hydrogen peroxide ratio, and, as a consequence, a longer residence time is necessary for reaching high conversions of hydrogen peroxide. This leads to an additional development of undesirable processes of successive transformations of epichlorohydrin. Thus, the optimal initial allyl chloride : hydrogenperoxide molar ratio for synthesis of epichlorohydrin is 3 : 1.

To evaluate the effect of temperature, we carried out a set of experiments in the temperature range 30–60°C. Raising the temperature within this range results in that the initial rate of the process becomes 3.5 time higher. It should be noted that raising the temperature at which epichlorohydrin is synthesized intensifies not only the target reaction, but also a number of side transformations, which is confirmed by the decrease in the yield of epichlorohydrin. Thus, the final choice of the optimal temperature for synthesis of epichlorohydrin will be determined by the formation rate of the target product and the process selectivity, as well as by the demand for the by-product formed. In the authors' opinion, the range of optimal temperatures for the process of allyl chloride epoxidation is 40–50°C.

To evaluate the influence exerted by the amount of the catalyst, we performed a set of experiments with the catalyst content in the range 0–32 g/l. It was found that this amount strongly affects the process rate. The initial rate of the epoxidation process linearly depends on the amount of the catalyst, which confirms that the reaction occurs under kinetic control. Variation of the catalyst content has no effect on the yield of epichlorohydrin, which remains nearly constant. Thus, the amount of the catalyst used in epoxidation in a batch reactor will primarily affect the process rate, and, therefore, its content should be determined by the design of the reactor unit, and for the most part by its ability to remove the released heat.

4 Conclusions

The following process conditions are suggested for epoxidation of allyl chloride with aqueous solutions of hydrogen peroxide in an organic solvent in a batch reactor: solvent methanol, temperature 40–50°C, allyl chloride : hydrogen peroxide molar ratio 3 : 1, solvent concentration 55–65 wt %. Experiments performed under nearly optimal conditions can produce epichlorohydrin in 96–97% yield at a quantitative conversion of hydrogen peroxide.

Keywords: lactulose, lactose, isomerization

1 Introduction

Selective synthesis of lactulose from lactose is one of the important reactions for pharmaceutical and food applications due to lactulose prebiotics properties [1]. Moreover lactose is a large-scale, low cost substrate of dairy industry: annually, million tons of lactose are produced worldwide and its isomerization to lactulose can be a possible way to obtain valuable products [1, 2]. There are several catalytic methods for lactulose syntheses including homogeneous catalytic isomerization by strong acids [1, 3], strong bases, amphoteric catalysts (hydroxyls, sulphites, borates); heterogeneous catalytic isomerization (ion exchange resins, alumosilicates) [4, 5]; biocatalytic isomerization by galactosidases and isomerase enzymes [6-8] and electrocatalytic isomerization. Lactose isomerization is a complex chemical process characterized by the formation of numerous side products such as epilactose, galactose, glucose, fructose and isosacharinic acid along with lactulose.

2 Experimental

Catalyst synthesis.

7.2 g of iron chloride (III) was dissolved in 100 ml of water. The solution prepared was added to 150 ml of 1M sodium hydroxide solution. Precipitated iron hydroxide (III) was separated by centrifugation and washed with distillated water. After that the precipitate was calcined at 300 °C for 3 hours and stored under air. 0.1M solutions of boric acid in water were prepared under nitrogen, 5 ml of boric acid solution was added to iron oxide suspension and the suspension was shaken for 2 hours under nitrogen. After this catalyst was filtrated from solution, washed by methanol and water and dried at 60^0C. The filtrate was analyzed on borate ions absence by adding Alizarin Red solution in sulfuric acid.

Lactose isomerization methodology

The isomerization was conducted batchwise in a Parr 4561 autoclave. The reactor was equipped with a heating jacket, a cooling coil, a filter in a sampling line and a substrate chamber (for placing lactose solution without mixing with the catalysts), hollow shaft concave blade impeller to ensure efficient mixing. The effective liquid volume was 50 ml (total volume 150 ml). The reactor was operated at ambient pressure under nitrogen and temperature between 70 and 90 °C. Samples of the reaction mixture were periodically removed for the analysis. The reaction in the samples was stopped by placing the sample in an ice-bath and adding a few drops of HCl to neutralize pH.

HPLC analysis

The analysis of the reaction solution was performed using ULTIMATE-3000 HPLC chromatograph. Ion exchange 250*4 mm tungsten column characterized by a theoretical plate number of 82000 was chosen for sample analysis. Reprogel H (7 mkm) served as a stationary phase, whereas a 0.1 $mmol.L^{-1}$ sulfuric acid solution in deionized water was used as the mobile phase. The flow rate was held constant as 0.5 $mL.min^{-1}$ at 80 bar and 30 °C. The refractometer detector was used for components detection. The concentrations of lactose, lactulose, glucose, fructose, galactose, epilactose and isosacharinic acid were determined using external standards.

NMR analysis

NMR spectra were recorded on a Bruker AM300 500 MHz NMR spectrometer (Moscow, A.

N. Nesmeyanov Institute of Organoelement Compounds of Russian Academy of Sciences). 1H chemical shifts were referenced to the residual solvent signal at δ 4.70 (D_2O) The spectra were recorded once with 30 mg of lactulose, lactose and dried reaction mixture dissolved in 700 μL of D_2O.

3 Results and discussion

The performance of synthesized and traditional catalysts was evaluated under the following reaction conditions: lactose initial concentration 0.3 mol/l, reaction temperature 70°C and catalyst concentration 0.1 mol/l and pH=11.

Table 1. Catalysts activity characteristics in lactose isomerization process

Catalyst	TOF*, $s^{-1}*10^2$	Conversion, %	Selectivity, %
NaOH	0.51	48	55
$Na_2B_4O_7$	1.25	95	88
$NaAlO_2$	0.84	72	78
Fe_3O_4-2-BO_3	0.82	75	80
Fe_3O_4-4-BO_3	0.84	77	82
Fe_3O_4-6-BO_3	0.90	82	85

The HPLC and NMR analyses showed formation of lactulose and the main side products – glucose, fructose, galactose which were detected for all catalyst, and isosacharinic acid, epilactose were detected in traces. The highest TOF (Table 1) was found to be 0.0125 s^{-1} for conventional $Na_2B_4O_7$ catalysts, while for the most active Fe_3O_4 based catalyst the TOF was 0.0093 s^{-1} and for the most active iron oxide Fe_2O_3-6-BO_3 based catalyst the TOF was 0.9 s^{-1}. The highest lactose conversion and the process selectivity for the most active HPS based catalyst was found to be 82% and 85% respectively, however it is lower compared to commonly used $Na_2B_4O_7$ catalyst.

4 Conclusions

A series of borate modified catalysts based on magnetic nanoparticles (III) were synthesized. The catalysts activity strongly depends on surface concentration of borate ions. The catalytic properties of the synthesized catalysts have been examined under a wide variety of reaction conditions in lactose isomerization process. The most active catalyst providing the highest lactulose yield was found to be Fe_3O_4-6-BO_3, however the catalytic activity of the synthesized catalyst is lower compared to the most active sodium tetraborate homogeneous catalyst and higher compared to conventional heterogeneous catalysts. Nevertheless the possibility of heterogeneous catalysts easy magnetic separation from the reaction mass has a lot of advantages for the industrial implementation.

Selective Synthesis of Butadiene from Ethanol over ZrBEA Catalysts

Sushkevich V.L.*, Ivanova I.I.

Lomonosov Moscow State University, Moscow, Russia

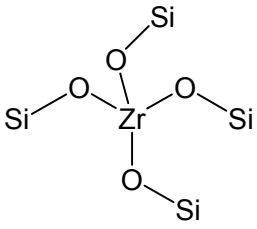
* vitaly.sushkevich@gmail.com

Keywords: butadiene, ethanol, Zr beta, infrared spectroscopy, DFT

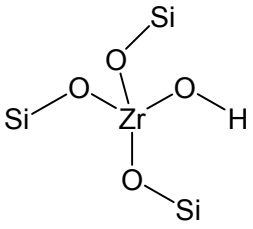
1 Introduction

The recent developments render the ZrBEA zeolite as a material with very high potential as catalyst in such processes as Lewis acid-catalyzed transformation of levulinic acid to γ-valerolactone, etherification of alcohols, the Meerwein–Ponndorf–Verley–Oppenauer (MPVO) oxidation-reduction reactions, and butadiene synthesis from ethanol. The latter reaction is very important for the diversification of the industrial routes of synthesis of butadiene, which is an important monomer for the rubbers and elastomers production. Recent assessment of the economic, environmental, health, safety and operation aspects of naphtha-based and ethanol-based routes suggested the alternative ethanol to butadiene conversion process as a promising sustainable substitute for the dominant naphtha-based method, which can contribute to decreased use of fossil fuel reserves.

However, the nature of its active sites, which is a necessary prerequisite for understanding mechanisms of reactions and design of new catalysts, has not been fully investigated. Experimental and theoretical data suggests that ZrBEA should possess two distinctive types of Lewis sites, designated herein as “closed” and “open” Zr(IV) sites. However, the real configuration of the present sites, and which of those sites are catalytically active, remains unknown. Another open question is how the Zr loading and distribution affects the ratio between closed and open Zr(IV) sites, and their respective activity.



"Closed" site



"Open" site

All these open questions motivated the present study on the determination of the structure of active sites for selective ethanol transformation into butadiene over ZrBEA by combination of infrared spectroscopy and DFT calculations.

2 Experimental

ZrBEA catalysts with Si/Zr ratio within 100-800 were synthesized using the procedure described elsevere [1]. For catalytic tests in the reaction of ethanol transformation into butadiene all the catalysts were modified with 1 wt% of silver.

The catalysts were characterized by N_2 adsorption, FTIR spectroscopy of adsorbed probe molecules, TEM, XPS, XRD. The catalytic tests were performed under atmospheric pressure in flow-type fixed-bed reactor. The weight hourly space velocity (WHSV) was varied within 0,1-0,6 h^{-1}, reaction temperature was 593K.

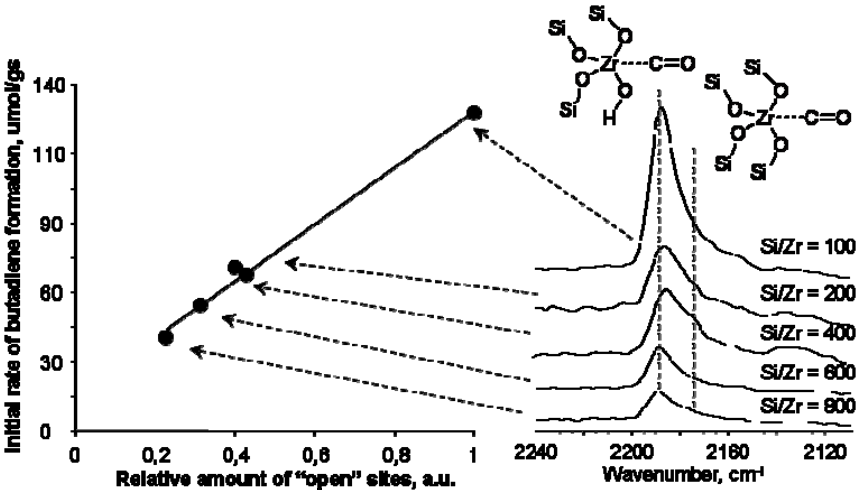
For quantum chemical calculations the geometries of the structures obtained by adsorption of CO on the cluster models were optimized within the DFT framework with the hybrid functional B3LYP using a LANL2DZ effective core potential basis set for Zr and the standard 6-31G(d, p) basis set for C, O, Si, and H atoms. Vibrational spectra have been calculated within the

harmonic approximation.

3 Results and discussion

Ethanol conversion into butadiene is a complex process involving at least four consequitive reaction steps: (1) ethanol dehydrogenation into acetaldehyde; (2) aldol condensation of acetaldehyde into crotonaldehyde; (3) Meerwein–Ponndorf–Verley-Oppenauer (MPVO) reaction between crotonaldehyde and ethanol leading to crotyl alcohol and acetaldehyde and (4) dehydration of crotyl alcohol into butadiene. On metal containing oxide catalysts steps (2) and (3) were demonstrated to be rate determing steps [2].

The increase of Zr content in ZrBEA up to 2 wt% leads to the significant enhancement of the butadiene formation rate from 36 to 132 μmol/g·s due to the increase of the amount of Zr Lewis sites responsible for steps (2) and (3). However, the catalytic activity does not show direct correlation with the total amount of Zr sites. FTIR data of adsorbed CO shows coexistence of two Lewis sites, which basing on the results of DFT calculations were attributed to "open" (2185 cm^{-1}) and "closed" (2176 cm^{-1}) sites (see Figure below). Whereas the amount of closed sites does not show any relationship with the catalytic activity of difference ZrBEA samples in the ethanol conversion into butadiene, the "open" sites demonstrated linear correlation with the initial rate of butadiene formation. Such selective activity of open sites could be attributed to the higher acid strength of open sites, as well as their better steric accessibility compared to the closed sites.



4 Conclusions

Combination of the results of the FTIR and the DFT calculations suggests that the Zr(IV) Lewis acid sites in ZrBEA catalysts are represented by isolated Zr atoms in tetrahedral positions of the zeolite crystalline structure linked with four ("closed" site) and three ("open" site) silicon atoms. The catalytic activity in butadiene synthesis form ethanol isshown to correlate with the amount of "open" sites. High efficiency of the "open" sites can be rationalized in terms of higher acid strength and better steric accessibility of such sites.

Gamogen-Catalytic Vinylation of Aromatic Acetylene Alcohols

Ziyadullaev O.E.*, Turabdjanov S.M., Ikramov A.I., Irgashev Yo.T.

Tashkent Chemical Technological Institute, Tashkent, Uzbekistan

* bulak2000@yandex.ru

Keywords: gamogeneous catalysis, aromatic acetylenic, alcohols, acetylene, a solvent product outlet, intermediate and auxiliary connections

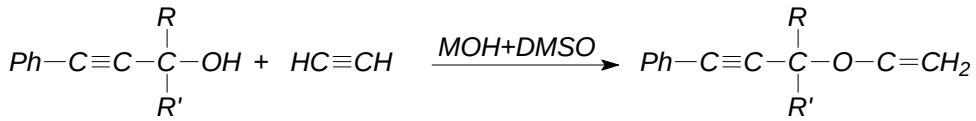
1 Introduction

Vinyl ethers in the industry, as initial products they are used to obtain acetals, corotinoida, oligonucleotides, citrals, herbal preparations, polymers, heteropolymers, glue, lacquer, emulsion, paint, alkyd resins, artificial leather, plasticizers, oil additives [1, 2].

2 Experimental

Vinylation reaction with aromatic acetylenic alcohol (AAA) gamogeneous methods. The influence of the nature and amount of catalyst, the molar ratio of the starting materials during the reaction temperature on the yield of the product. Definitely purity, structure, elemental composition and physical constants and quantum chemical calculations of the synthesized compounds. The optimal conditions for the synthesis of a product with a high yield.

Vinylation reaction of aromatic acetylene alcohols (AAA) containing phenyl group in its molecule in the presence of acetylene has been investigated and properly vinyl ethers (VE) have been synthesized [3].



$R = -CH_3$, $R^I = -C_2H_5$; $R = -CH_3$, $R^I =$ izo $-C_3H_7$, $R = -CH_3$, $R^I = -C(CH_3)_3$; $R = -CH_3$, $R^I = -C_6H_3$, $Ph = -C_6H_5$.

The influence of temperature, catalyst and solutions nature on the yield of AAA VE has been studied systematically and analyzed. On the basis of received results DMSO solution in the presence of catalyst KOH, when acetylene influences on AAA at temperature 120^{0}C, for 6 hours it has been determined that VE comes out with highest yield.

Theoretically, when the temperature rises, it can be explained the decrease of AAA VE yield as follows. Orientation polarity of hydrogen positive charged in AAA hydroxyl group towards triple bond of acetylene depends on the exchanging of catalysts metal cations with active hydrogen of acetylene and acetylenes forming. It is known, it is determined the fall down in the product yield on account of the orientation polarity, having decreased alongside with rising of temperature, intensifying of acetylene molecule motion, as a result, on account of the damage of its special regulated arrangement. It has been determined the decrease of solubilization of alcoholates alongside with the increase of their molecular weight, and this opposes acetylene joining and it has been observed the decrease in the formation of VE. Acetylene and solution are sent into the system with extra amount for the purpose of increasing product yield it will bring to rise in price of the cost of the product synthesizing. Extra expenditure of acetylene and solution causes lasting of reaction duration and recycling demands to implement complicated technological processes.

3 Conclusions

To sum up, it has been observed the decrease in vinyl ethers productivity owing to the

formation of acetylenes reacting with metals and their hydrolysis, the increase of alcoholates stability formed by joining AAA containing ethyl, isopropyl and triple radicals with metals.

The Gold Particle Catalysed Mechanism for the Oxidation of Hydroxymethylfurfural to 2,5-Furandicarboxylic Acid: a DFT Study

Thomas L.M.[1], Lee A.F.[2], Wilson K.[2], Willock D.J.[1*]

1 - Cardiff University, Cardiff, UK
2 - Aston University, Birmingham, UK

* thomasl63@cardiff.ac.uk

Keywords: biomass, DFT, gold nanoparticle, oxidation, HMF

1 Introduction

Hydroxymethylfurfural (HMF), (figure 1) is obtained from dehydration of sugars such as glucose, fructose and xylose[1]. This biomass derived molecule is the subject of great interest as it can be used as a platform to replace traditional chemical feedstocks used within industrial processes. This versatility has seen HMF labelled a "top 10" molecule by the United States department of energy[2]. One such molecule obtained from HMF is 2,5-furandicarboxlyic acid (FDCA), (figure 1), which is obtained via an oxidation reaction. FDCA being a dicarboxylic acid can undergo polymerization to form polymers suitable for usage within the packaging industry, therefore replacing crude oil derived terephthalic acid. It is reported this oxidation to FDCA can be performed using heterogeneous gold nanoparticles as catalysts under mild reaction conditions[3]. There is some debate within the literature regarding the oxidation route and therefore computational modelling is required to shed light on this reaction.

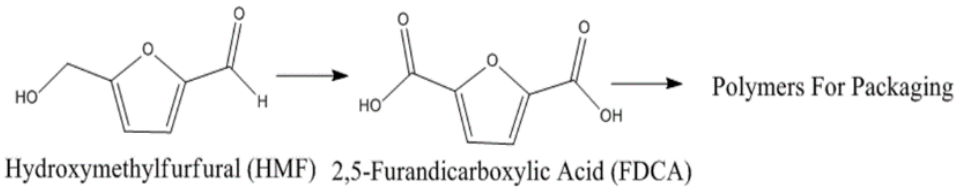

Figure 1. Pathway for conversion of HMF to polymers for packaging materials.

2 Experimental/methodology

Here a detailed computational (DFT) study is presented discussing the interaction of HMF with gold clusters various sizes (Figure 2). The effect of alloying gold particles with palladium is presented along with the influence of the following particle supports: Fe_2O_3, and TiO_2. Dispersion interactions have been included within calculations and the importance of accounting for dispersion within mechanistic studies will be presented.

Keywords: high-throughput, biorefineries, chemocatalysis, biocatalysis, hybrid catalysis

1 Introduction

Catalysis under all of its forms (heterogeneous, homogeneous or biocatalysis) is of upmost interest in crucial domains such as Environment, Food, Health, Energy, which are at the inner core of the current societal demands. The development of new catalysts with improved performances is therefore a highly strategic issue.

Innovation in catalysis is based, on the one hand, on forefront fundamental research to develop new catalytic concepts and, on the other hand, on an experimental phase devoted to the synthesis, characterization of the catalytic formulations and on the measurement of their properties/performances. The experimental part of the development of a new catalyst is time- and money-consuming, as traditional "trial and error" methods for synthesizing and testing catalysts are still needed. "*A priori*" theoretical prediction of optimal catalyst composition, structure and conditions of preparation for a given reaction is actually not yet possible. Therefore, there is a strong need for rapid preparation, characterization and screening of catalytic systems.

2 Description of the REALCAT platform

The main objective of the REALCAT project (French acronym standing for 'Advanced High-Throughput Technologies Platform for Biorefineries Catalysts Design') (Fig.1), which will be presented in details in this communication, is to set up a highly integrated platform devoted to the acceleration of innovation in all the fields of industrial catalysis with an emphasis on emergent biorefinery catalytic processes. In this extremely competitive field, REALCAT consists in a versatile High-Throughput Technologies (HTT) platform (Fig. 2) devoted to innovation in heterogeneous, homogeneous or biocatalysts and their combinations under the ultra-efficient very novel concept of hybrid catalysis.

Fig. 1. The REALCAT logo

The REALCAT platform, representing a 10 M€ funding from the French government, is a complete, unique, and top-level HTT workflow including (i) robots for the automated synthesis of

catalysts and novel biocatalysts, (ii) rapid characterization tools and (iii) a series of versatile parallel continuous and batch reactors - for gas phase, liquid phase or three phases reactions - combined with ultra-fast analytical tools at the top of the state-of-the-art for the analysis of the products in the reactors effluents. Moreover, within the frame of the REALCAT project, methodological developments will also be carried out in partnership with private companies in order to develop innovative HTT tools for catalysis not yet available on the market. This will ensure that the REALCAT platform remains the most advanced level of HT equipment for catalysis in the world in the future.

Fig. 2. The REALCAT platform

Three laboratories, all located on Lille University's campus (North of France) have gathered their forces to design such a challenging project: UCCS, specialized in homogeneous and heterogeneous catalysis; Institut Charles Viollette (ProBioGEM team), specialized in biocatalysis and CRIStAL, specialized in computer engineering, data treatment, bio-informatics, modelling and analysis of biologic systems. This integrated combination of skills is of outstanding importance for the optimization of the different operations of the platform. This will make REALCAT a major actor of high-level R&D catalysis programs on hot topics such as biorefinery, energy, environmental, food and health applications.

3 Conclusions

In this lecture the REALCAT platform will be described in details and the first results issued from it will be presented. A focus will be put on the potential of the platform and on the possibilities for external users to get an access to REALCAT.

Acknowledgements

The REALCAT platform is benefiting from a governmental subvention administrated by the French National Research Agency (ANR) within the frame of the 'Future Investments' program (PIA), with the contractual reference 'ANR-11-EQPX-0037'. The Nord-Pas-de-Calais Region and the FEDER as well as the Centrale Initiatives Foundation are thanked for their financial contribution to the acquisition of the equipment of the platform.

Pd-Catalyzed Selective Hydrogenolysis of γ-Ketoamides as a New Approach to the Synthesis of 5-Alkylpyrrolidin-2-Ones or Linear Carboxylic Acid Amides

Turova O.V.*, Berezhnaya V.G., Starodubtseva E.V., Vinogradov M.G.

N. D. Zelinsky Institute of Organic Chemistry of the Russian Academy of Sciences, Moscow, Russia

* turova@ioc.ac.ru

Keywords: Pd-catalyzed hydrogenolysis, γ-ketoamides, pyrrolidin-2-ones, linear carboxylic acid amides

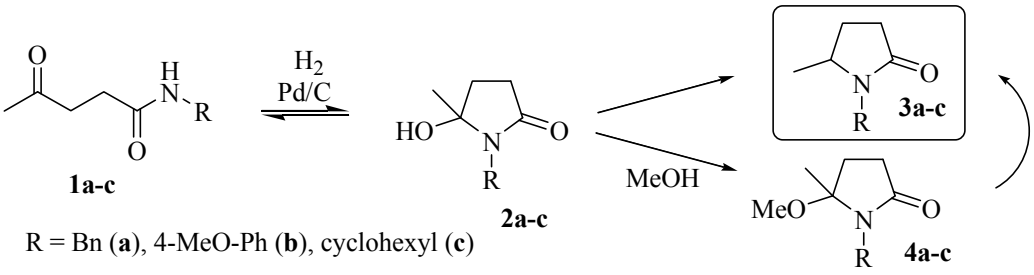
1 Introduction

Synthesis of 5-alkyl- and 5-arylpyrrolidin-2-ones based on the Pd-catalyzed C-O bond hydrogenolysis of hydroxy lactams has been recently elaborated by us [1]. At the same time, difficulties can be occurred to prepare individual hydroxy lactams from the effect of ring-chain tautomerism. In the present work, possibility of using available γ-ketoamides in the open form as convenient starting substrates is first demonstrated.

2 Experimental/methodology

Under conditions of the Pd-catalyzed C-O-hydrogenolysis in the presence (if needed) acid cocatalyst (see Table 1), the model open amides **1** are converted *in situ* to form **2**, a precursor of the target heterocycles **3** (Scheme 1).

Scheme 1



R = Bn (**a**), 4-MeO-Ph (**b**), cyclohexyl (**c**)

Table 1. Hydrogenolysis of levulinic acid amides **1a-c** in MeOH[a]

Entry	Ketoamide	**1**/HCl	Conversion, %	Products, %	
				3	**4**
1[b]	**1a**	-	90	80	20
2	**1a**	-	80	100	0
3	**1a**	100/1	83	100	traces
4	**1a**	100/10	94	100	0
5	**1b**	100/10	100	100	0
6	**1c**	100/10	60	70	30

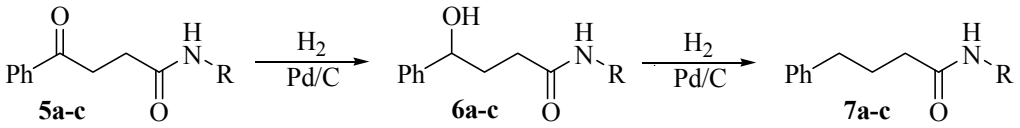
[a] **1**/Pd = 100, 60 °C, 6 h. [b] 50 °C, 24 h.

3 Results and discussion

In MeOH, which is preferable solvent, the methoxy derivative **4** may be also formed as the by-product (see table 1, entry 1). However, increasing the temperature to 60 °C and the use of HCl as co-catalyst allowed to achieve 100% selectivity at the almost complete conversion of substrates **1a**,**b** (entries 2-5). The third substrate **1c** showed the lesser reactivity and

hydrogenolysis selectivity (entry 6).
In contrast to levulinic acid amides **1**, Pd-catalyzed hydrogenolysis of 3-benzoylpropionic amides **5** proceeds exclusively with participation of ketogroup via the intermediate hydroxy amide **6** (scheme 2).

Scheme 2



R = Bn (**a**), Bu (**b**), *tert*-Bu (**c**)

4 Conclusions

The Pd-catalyzed hydrogenolysis of N-alkyl(aryl)substituted γ-ketoamides has been first realized using levulinic and 3-benzoylpropionic amides as model substrates. In most cases, the process takes place selectively with participation of cyclic (hydroxylactam) or the open tautomeric form of substrate to yield, correspondingly, substituted pyrrolidin-2-ones or linear amides.

Insights on the Mechanism for the Transformation of Ethanol on Basic Oxides (Lebedev and Guerbet Reactions)

Velasquez Ochoa J.[1*], Chieregato A.[1], Bandinelli C.[1], Fornasari G.[1], Cavani F.[1], Mella M.[2]

Keywords: surface, intermediates, DRIFTS, Guerbet mechanism, Lebedev theoretical modelling

1 Introduction

In line with the increasing interest in generating higher value chemicals from bio-alcohols such as ethanol, we felt necessary to review the mechanism of upgrading of these compounds. In particular, it is of great importance to understand the surface reactions occurring when ethanol interacts with oxides having basic properties, which are ubiquitous ingredients in catalysts to produce higher alcohols (Guerbet reaction), olefins (Lebedev process), or ethyl acetate (Tishchenko reaction) [1]. Our review highlighted that the accepted mechanism of ethanol transformation still contained several aspects lacking a robust support; these are discussed in this work and alternatives are proposed based on reactivity tests, spectroscopy (in-situ diffuse reflectance infrared) and computational calculations. Interestingly, it was possible to exclude the role of the acetaldol as the key intermediate in the formation of both butanol and butadiene. As a consequence, a novel mechanistic theory was proposed to explain not only the present results, but also most of the scientific literature on the Lebedev and Guerbet chemistry. This new approach provides a rational description of the intermediates shared by the two reaction pathways as well as a different perspective on the catalysts properties that are necessary to direct the reaction pathway toward the higher alcohol or the olefin [2]. A reference catalyst made of MgO was used for experiments.

2 Experimental

MgO catalyst was prepared by precipitation from an aqueous solution of $Mg(NO_3)_2 \cdot 6H_2O$. The solid was calcined at 450°C for 8 h in air. The surface area was 86 m^2/g. Reactivity experiments were carried out using a continuous flow glass reactor. Inlet feed molar ratio was constant (2 mol% of Ethanol in N_2). Downstream products were monitored by on-line gas-chromatography analysis.

DRIFTS-MS: The sample was pre-treated at 450°C in a He flow and then cooled down to room temperature. Ethanol was fed at 0.6 $\mu l.min^{-1}$ until saturation. After the evacuation of physically adsorbed ethanol, the temperature program was run (until 450°C at 10°C min^{-1}). Selected mass spectrometry signals (m/z) were monitored continuously in time and temperature.

DFT-calculations: The modelling was carried out employing gas phase electronic structure calculations by means of the Gaussian09 suite at the Density Functional Theory (DFT) level. Specifically, the B3LYP DFT functional together with the 6-31++G(d,p) basis set were used to optimize relevant stationary points along the reaction paths.

3 Results and discussion

Ethanol reactivity tests performed at 250 and 400°C over MgO varying residence time showed that 1-butanol was a primary product, as well as acetaldehyde and ethylene; also crotyl alcohol was among the main products. C_4 aldehydes (3-hydroxybutanal, crotonaldehyde and butyraldehyde) and C_4 olefins (butenes and butadiene) were only detected as secondary products at high temperature.

In situ DRIFT spectroscopy showed the evolution of the surfaces species with the temperature (see Figure 1). In this way, it was possible to detect the intermediates of the ethanol transformation; these included an activated form of the ethanol (a carbanion) and an adsorbed form of crotyl alcohol.

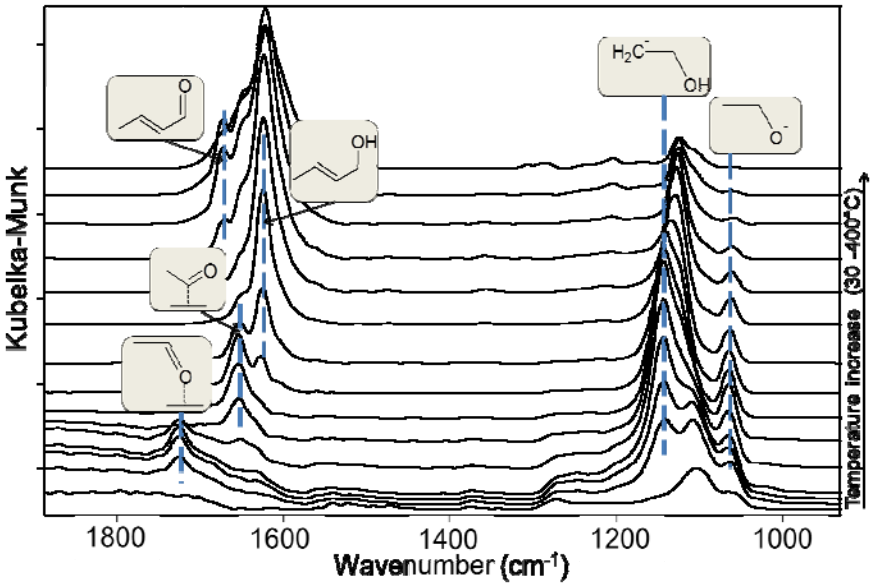

Figure 1. DRIFT spectra of ethanol adsorption on MgO and its transformation with temperature.

DFT calculations confirmed that the formation of carbanion species was less energetically demanding than ethanol dehydrogenation, the latter leading to acetaldehyde (on Mg3C sites). Further calculations on the reactivity of this carbanion specie showed that it could easily form ethylene, which formed in large amounts even over this basic catalyst. Moreover, it could either attack acetaldehyde to form a precursor of the crotyl alcohol - which then dehydrated to form butadiene - or another ethanol molecule to form 1-butanol. These results made clear that the formation of crotonaldehyde by aldolic condensation, supposedly favoured by the basicity properties of the catalysts, was not the key reaction to explain the products distribution as it has been stated in the literature [3]. Instead, we proposed that crotonaldehyde is formed after crotyl alcohol; In fact, the tests carried out by feeding some of the possible intermediates showed that the alkenol produces a similar product distribution to that one obtained with the ethanol.

4 Conclusion

The proposed new mechanism for the transformation of ethanol into C_4 compounds over MgO made it possible to draw a unifying picture of the different routes leading to either 1-butanol (Guerbet reaction), butadiene (Lebedev process), or ethylene. The suggested mechanism discards the key role of both acetaldol and crotonaldehyde as the reaction intermediates, usually accepted as being shared between the two pathways leading either to the alcohol or the diolefin.

Catalysis by the Noble Metals in the Process of Obtaining New Biologically Active Compounds

Vereshchagina N.V.*, Antonova T.N., Kopushkina G.Yu., Shelekhova A.I.

Yaroslavl State Technical University, Chemical Engineering Department, Yaroslavl, Russia

* nadezhda.vereshagina@bk.ru

Keywords: dicyclopentadiene, dicyclopentene, catalysts of hydrogenation

1 Introduction

The synthetic medication, which include biologically active compounds of aromatic and/or a cyclic structure with functional groups have a large share among the medication in the pharmaceutical industry.

As a potential source of biologically active compounds oxygen-containing derivatives of dicyclopentadiene, having the structure close to the frame, can be used, for example, mono- and diketones: 3-oxotricyclo[5.2.1.$0^{2.6}$]decane, 3,4-dioxotricyclo[5.2.1.$0^{2.6}$]decane.

We proposed to use dicyclopentene, as hydrogenated analogue dicyclopentadiene, for preparation this compounds with a high degree of purity.

2 Experimental/methodology

The hydrogenation reaction of dicyclopentadiene with hydrogen in the liquid phase in the presence of catalysts on the bases of noble metals used for obtaining of dicyclopentene.

3 Results and discussion

It is established that the most activity showing finely dispersed catalyst (1 % Pd/C). It allows selective formation of dicyclopentene under mild conditions (atmospheric pressure, temperature of 40 to 80 °C) at full conversion of the original dicyclopentadiene. The high activity of this catalyst is determined by its structure. The catalytic activity in the structure of palladium deposited on charcoal give its clusters small size (2-3 nuclear). Carbon matrix prevents to formation clusters of large size.

Selective obtaining of dicyclopentene in the process of hydrogenation of dicyclopentadiene in the presence of 1 % Pd/C is possible in result the sequence of saturation of double bonds dicyclopentadiene (tricyclo[5.2.1.$0^{2.6}$]decadiene-3,8). Double bond of bicycloheptene fragment its molecule saturated as the first and obtained dicyclopentene have a structure as tricyclo[5.2.1.$0^{2.6}$]decene-3.

The use of finely dispersed catalyst under conditions of intense mixing converts three-phase system in a state of pseudohomogeneous. As a result, the hydrogenation process can be realized in the reactor, simulating the ideal mixing reactor. The catalyst is easily separated from the reaction products and can be reused without prior activation.

3 Conclusions

A new way of obtaining oxygen containing products based on dicyclopentadiene (for example, 3-oxotricyclo[5.2.1.$0^{2.6}$]decane and 3,4-dioxotricyclo[5.2.1.$0^{2.6}$]decane) for pharmaceutical synthesis are proposed and studied.

Keywords: aromatization, propane, H-Ga-Al-catalysts

1 Introduction

The use of the components of natural and associated petroleum gas as a feedstock for production of valuable chemical products acquires an ever-increasing importance, which is particularly critical due to a gradual depletion of oil reserves. In this case, production of aromatic hydrocarbons from light alkanes attracts not only manufacturers, but also researchers solving the fundamental problems of catalysis [1]. The efficiency of aromatization of light alkanes strongly depends on the catalyst and the conditions of its application. Typical aromatization catalysts are systems consisting of the supporter – H-form of pentasil and the modifying components, mainly zinc, gallium, platinum, or palladium [2-4]. To increase the yield of aromatic hydrocarbons, a thermal or chemical modification of zeolites is used. The main methods of their chemical modification are ion exchange, impregnation with solutions of salts and isomorphous substitution of framework aluminum atoms.

The aim of this work is to establish the relationship between the localization of gallium introduced into a zeolite by different methods and the catalytic activity of the resulted contacts in the course of propane aromatization.

2 Experimental/methodology

We have investigated the Ga-containing zeolite catalysts prepared by different methods. Modification of the zeolite with gallium was carried out by impregnation, ion exchange, mechanical mixing, and isomorphous substitution. The concentration of gallium oxide in the sample was 1.85 wt%. The acidic properties of Ga-containing catalysts were tested by the method of temperature programmed desorption of ammonia (TPD). The specific surface area and the pore size distributions were determined using a Micromeritics ASAP 2020 instrument (USA). HR TEM images were obtained in a Jeol JEM-2010 electron microscope (Japan).

The catalysts under study were tested in the course of propane conversion in a flow-type reactor at atmospheric pressure, the reaction temperature 400-600 ^{o}C, and the feed space velocity 500 h^{-1}. The reaction products were analyzed by GLC using a Chromatek-Kristall 5000.2 chromatograph. In order to estimate the catalytic activity of the samples, the degree of propane conversion was estimated. The yield and formation selectivity of the gaseous and liquid products were also calculated.

3 Results and discussion

The studies have shown that the Ga-containing zeolite catalysts prepared by different methods are characterized by virtually the same total catalyst activity (estimated from the degree of propane conversion) but different aromatization activities. The highest activity and selectivity towards formation of aromatic hydrocarbons from propane was exhibited by the catalyst produced by impregnation of zeolite. For this sample, the propane conversion and the yield in aromatic hydrocarbons at 550 °C are 95 and 44.5 %, respectively (Table 1).

The zeolite manufactured by the method of hydrothermal synthesis differs only slightly in its selectivity towards formation of aromatic hydrocarbons from the sample prepared by impregnation. This indicates that both methods result in the formation of an approximately equal number of active sites in the zeolite structure. These centers, having nearly similar structure activate the propane molecules and promote their subsequent conversion into aromatic hydrocarbons. The lowest activity of propane aromatization is exhibited by zeolites modified with gallium by the methods of ion exchange and mechanical mixing. For example, the yield in aromatic hydrocarbons over the Ga-containing zeolite manufactured by ion exchange at 550 °C is 37.8% for a propane conversion 95%.

Table 1. Characteristics of the process of propane conversion over Ga-containing catalysts (T = 550 °C)

Method of gallium introduction	X, %	S_1, %	S_2, %	S_3, %	S_4, %	Y, %
isomorphous substitution	95	5.7	47.0	2.7	43.8	41.7
impregnation	95	5.2	45.4	2.4	46.9	44.5
ion exchange	95	5.3	51.3	3.3	40.0	37.8
mechanical mixing	93	5.4	51.1	3.1	40.1	37.3

Note. X is the conversion of propane; S_1, S_2, S_3 and S_4 is the selectivity towards a formation of hydrogen, C_1-C_2 alkanes, C_2-C_4 alkenes and aromatics, respectively; Y is the yield of aromatic hydrocarbons.

Using TEM data, it was found out that gallium in a zeolite catalyst produced by isomorphous substitution is in a cation- dispersed state. Under high magnification, the zeolite impregnated with gallium was observed to contain particles measuring 2-4 nm on the on the surface of the zeolite crystals, which provided a higher contrast. For the Ga-containing zeolite prepared by ion exchange no GaL signal was present in the EDX spectrum from a large number of particles, which may be due to the low Ga content in this sample and an insufficient sensitivity for the spectrometer to detect any signals from Ga. On the other hand, there still were some particles (very few) measuring about 3 nm on the surface of certain crystals. These particles are similar to those detected in the sample prepared by the impregnation method. The method of ion exchange appears to be unsuitable for fixation of gallium on the zeolite surface. Large GaOx aggregates with disordered structure were observed in the sample, containing gallium introduced by mechanical mixing, which were localized on the surface of the sample. Moreover, the surface contained pores and asperities due to mechanical processing.

4 Conclusions

Thus, the investigations have shown that the Ga-containing ZSM-5 zeolite catalysts, prepared in different ways, differ in their physical, chemical and acid properties due to local inhomogeneities in the distribution of aluminum and gallium in the crystalline aluminosilicate framework. The Ga-containing zeolite catalyst prepared by impregnation has been observed to demonstrate the highest catalytic activity and selectivity for formation of aromatic hydrocarbons from propane.

Dehydration of Biodiesel-Derived Crude Glycerol into Acrolein over HPW Supported on Cs-Modified SBA-15

Liu R., Wang T.*, Jin Y.

Beijing Key Laboratory of Green Reaction Engineering and Technology, Department of Chemical Engineering, Tsinghua University, Beijing, China

* wangtf@tsinghua.edu.cn

Keywords: crude, glycerol, dehydration, acrolein, alkaline, metal, ions, SBA-15, tungstophosphoric, acid

1 Introduction

Acrolein has broad industrial and agricultural applications, and is used in the production of acrylic acid and its esters. The current technology for producing acrolein is based on the selective oxidation of propylene over the complex multi-component $BiMoO_x$-based catalysts [1]. However, this technology will become less competitive as the crude oil price increases. The development of selective dehydration of pure glycerol provides a route to the sustainable production of acrolein. Nowadays, the price of refined glycerol is 900−1000 US$/ton, while crude glycerol is available at only ~150 US$/ton [2]. This makes the sustainable production of acrolein from crude glycerol much more competitive compared with that from pure glycerol reported in our previous work.

2 Experimental

The HPW/Cs-SBA catalyst was prepared using the two-step vacuum impregnation method reported in our previous work [3]. In the first step, an aqueous solution of Cs_2CO_3 (Alfa Aesar) was introduced under vacuum. Then HPW was impregnated using $H_3PW_{12}O_{40}{\cdot}nH_2O$ (Alfa Aesar) aqueous solution in a similar way to form $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ with a 50 wt% loading of HPW. The final catalyst samples were denoted as HPW/Cs-SBA.

Glycerol solution with different feed composition was used to study the effect of impurities. The aqueous solutions were prepared with pure glycerol ($C_3H_8O_3$, ultrapure, HPLC Grade, Alfa Aesar) or crude glycerol. The synthetic crude glycerol contained one of the following impurities: methanol, FFA (linoleic acid), FAME (methyl oleate), glycerides (glycerol monostearate), Na^+ (NaCl) and K^+ (KCl). The weight percent of impurity in each synthetic crude glycerol was 5wt%. Desalted plant crude glycerol was also used as feedstock. Ion exchangers was used in the desalination process [4]. A commercial ion-exchange resin D001-CC provided by Tianjin Bohong Resin Technology Co. Ltd was used to remove the alkli metal ions.

The experiments of glycerol dehydration were carried out at 300 ^oC under atmospheric pressure in a fixed bed reactor (10 mm i.d.) using 0.5 g catalyst.

3 Results and discussion

Several kinds of synthetic crude glycerol with methanol, methyl stearate or alkli metal ions were prepared and used to study the influence of different impurities on the product distribution. Among the impurities commonly contained in crude glycerol, only the alkli metal ions caused catalyst deactivation and decrease in acrolein selectivity. The reason was that alkli metal ions deposited on the HPW/Cs-SBA catalyst surface to form alkaline salts of HPW by neutrilization and decreased the effective medium Brønsted acid sites.

In order to increase the stability of HPW/Cs-SBA during the catalytic conversion of plant crude glycerol, the alkli metal ions were removed by glycerol desalination with ion-exchange resin. Figure 1 shows the glycerol conversion and product selectivity as a function of the

reaction time with 20 wt% aqueous solution of plant crude glycerol and desalted crude glycerol at 300 °C. It can be seen that the glycerol conversion decreased from 100% to 90% and the acrolein selectivity decreased from 86% to 79% after 40 h of reaction with plant crude glycerol. In comparison, the acrolein yield kept stable at 86% when desalted crude glycerol was used, which was similar to that with pure glycerol. To investigate the thermal stability of the catalyst for desalted glycerol dehydration, the reaction was carried out after 3 h regeneration of the catalyst at 500 °C in the air. The HPW/Cs-SBA catalyst showed good thermal stability and gave the same activity and selectivity as before regeneration. These results showed that it was feasible to use desalted crude glycerol to efficiently produce acrolein. Because the desalination process was much cheaper than the whole purification process for refined glycerol production, this approach significantly enhanced the competitiveness of acrolein production from glycerol.

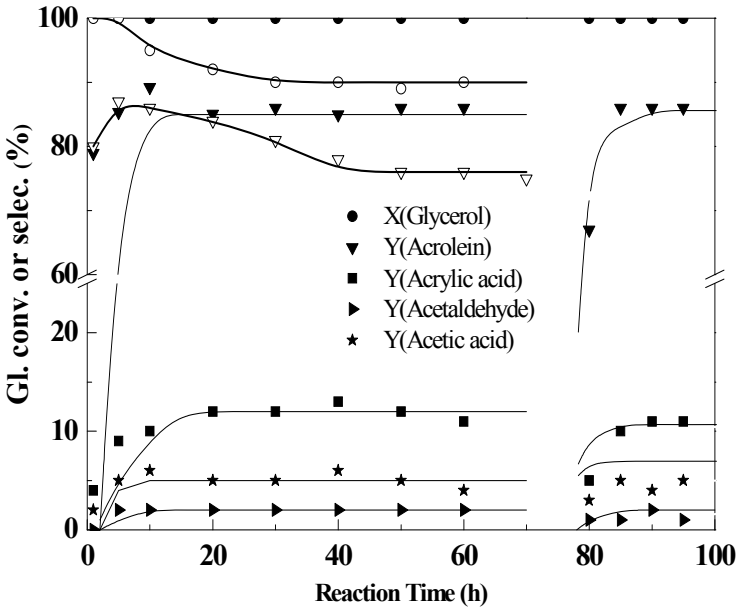

Fig. 1. Glycerol conversion and product selectivity with 20 wt% plant crude glycerol (open symbol) and desalted crude glycerol (closed symbol) at 300 °C before and after in situ regeneration at 500 °C for 3 h.

4 Conclusions

The feasibility of using crude glycerol as feedback for the acrolein production by dehydration reaction was explored in this work. When using crude glycerol for dehydration to acrolein, the HPW/Cs-SBA catalyst showed good resistance to organic impurities such as methanol and fatty acid. But the alkaline metal ions such as Na^+ and K^+ converted the medium acid sites to weak acid sites and significantly decreased the yield of acrolein. Among all the impurities, only the alkaline metal ions need to be removed before the dehydration reaction. After desalination of the plant crude glycerol with ion-exchange resin, the catalyst gave 86% acrolein yield, which was as high as that with pure glycerol. The catalyst showed good stability after coke-burning regeneration process. Our work provides a green and efficient route to produce acrolein from crude glycerol, which is a promising alternative and complement to the petroleum-based production of acolein due to its economic and environmental benefits.

Keywords: methane, oxidation, nickel-based, catalys, synthesis, gas

1 Introduction

The partial oxidation of methane into synthesis gas has created significant interest for researchers in the field of petrochemistry, because we will be able to use natural gas for at least 100-150 years as one of basic resources of the petrochemical industry. Synthesis gas is also known to be an important material connecting methane with petrochemistry and can be directly converted to methanol which is a useful raw material for various chemicals; i.e., ethanol, formaldehyde, acetic acid, and methyl esters and at.al [1]. In order to achieve a practical application of the oxidative conversion of methane, the development of highly active, stable, selective, and cost-effective catalysts are desired [2].

The most effective and economic catalysts for steam reforming and autothermal reforming have been known to be Ni based catalysts, especially Ni/ γ-Al_2O_3 catalysts, because novel metals are expensive even though their high activity [3]. However, as well known, Ni based catalysts suffer from fast deactivation and poor process ability due to high coke deposition. In order to solve this problem, many attempts have been tried by researchers. Introduction promoting additives in the Ni catalyst is one of the effective ways to reduce the formation of the coke [4].

In this study, we investigated the effects of promoting additives (Co_2O_3, CeO_2, La_2O_3) on the performance and the physicochemical characteristics of the nickel catalysts.

2 Experimental/methodology

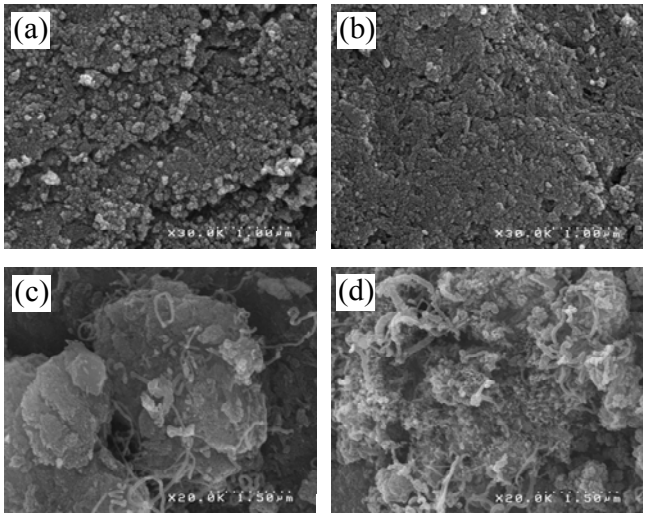
Experiments to test the efficiency of the catalysts were carried out using an automated flow catalytic device (FCI-1 LLC). The device consists of three main parts; the preparation of the initial gas mixture, a quartz flow-type reactor, and a gas chromatograph for the product analysis. The reaction was performed at atmospheric pressure and the temperature was studied in the range of 600-900 ^oC. The amounts of the reaction products were determined by an absolute calibration method using a gas chromatograph equipped with a thermal conductivity detector (GC-1000 LLC "Chromos"). The catalysts were prepared by the impregnation of γ-Al_2O_3 (S_{BET} = 190 m^2/g) with a solution of $Ni(NO_3)_2 \cdot 6H_2O$, drying at 350 ^oC (for 2 hours), and then calcination at 500 ^oC for three hours. Morphology of the catalysts was observed by a scanning electron microscope (SEM) using S-4100 (Hitachi High-Technologies Corporation) and a transmission electron microscope (TEM) using Technai G220 (FEI Company).

3 Results and discussion

The Ni/γ-Al_2O_3 catalyst was modified with oxides of cobalt, cerium, and lanthanum. The catalysts were evaluated during the reaction at the W = 4500 h^{-1} and the ratio of the reaction mixture was CH_4: O_2: Ar = 2:1:3.6. The modification of the Ni/γ-Al_2O_3 catalyst reduced the yield of CO_2 in the reaction products with the increasing CO yield. Among the tested catalysts, the NiLa/ γ -Al_2O_3 catalyst was the most effective one for the formation of synthesis gas because of the decreasing CO_2 content from 2.5 to 0.1%. For the reaction using the La-modified catalyst,

the H_2 yield also increased from 81% to 83%.

The SEM photographs of the Ni-M/γ-Al_2O_3 (M = La, Ce, and Co) catalysts used for 30 h indicated a different situation for the coke formation (Figure 1). The Ni/γ-Al_2O_3 and NiCo/γ-Al_2O_3 catalysts formed a significant amount of the tube- or yarn-like cokes, whereas no significant amount of coke was observed on the surface of the NiCe and NiLa/γ-Al_2O_3 catalysts. The addition of cerium and lanthanum in nickel-based catalyst enhances the catalytic activity via increase of the active component. Also having the high ability for oxygen storage allows regulating the oxygen concentration on the surface of the catalysis.



(a) NiLa/γ-Al_2O_3, (b) NiCe/γ-Al_2O_3,
(c) NiCo/γ-Al_2O_3, (d) Ni/γ-Al_2O_3

Fig. 1 SEM photographs of M-Ni/γ-Al_2O_3 catalysts after reaction at 750 ºC for 30 h

These results suggested that the addition of La and Ce improved the surface properties of the Ni/γ-Al_2O_3 catalyst. We tried to determine the amount of coke on the Ni/ γ -Al_2O_3 (after the reaction for 30 h at 750 ^oC) by TG-DTA measurement, however, no significant amount of coke was detected.

4 Conclusions

The addition of modifiers (Co, Ce, and La) to the Ni/γ-Al_2O_3 catalyst increased the yields of H_2 and CO with the decreasing CO_2 content in the reaction products. We successfully developed the most effective NiLa/ γ -Al_2O_3 catalyst, which showed a high stability for 30 hours with excellent selectivities such as 83% to hydrogen and 99% to carbon monoxide at the 95% methane conversion. Determined, that the introduction of additives of cerium and lanthanum in Ni/γ-Al_2O_3 catalyst increases its stability to coke formation.

Catalytic Hydrogenation of Dienone for Getting Vitamins and Odorous Substances

Suyunbayev U., Yergaziyeva G.*, Zhumagazin A.

Institute of Combustion Problems, Almaty, Kazakhstan

* ergazieva_g@mail.ru

Keywords: hydrogenation β-ionone, dehydro β-ionone, citral, citronellal

1 Introduction

Catalytic hydrogenation in a liquid phase is one of significant methods of receiving various organic compounds. Feature of liquid-phase processes is possibility receiving the composite connection under comparatively mild conditions of temperature.

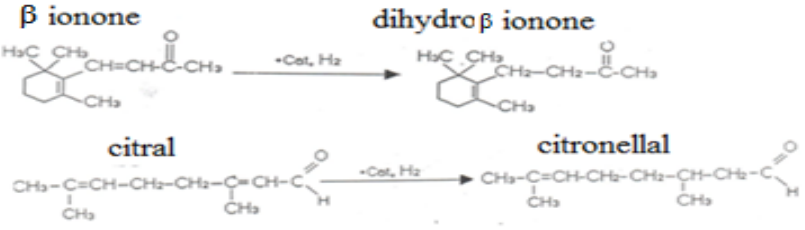
Carrying out processes of catalytic hydrogenation of organic compounds is of great importance for production of products in the pharmaceutical, food and perfumery industry. The modern industrial production of odorous substances is based mainly on chemical and timber-chemical raw materials, some odorous substances receive from essential oils. World release of odorous substances is 100 thousand tons. In everyday use odorous substances play a very important role, since it is difficult to present modern life without toilet soap, cologne, perfume, cosmetic products, detergents, medicines, etc. In industry, many odoriferous substances (citronellal, etc.) receive a batch process, the replacement of this method to a new environmentally friendly and economically effective way flow will allow increasing productivity of the process.

It should be noted that in literature and also on production almost completely there are no data about hydrogenation of organic substances with the conjugated olefinic linkage on stationary catalysts in a liquid phase [1-3]. Thus, systematic research of influence of different parameters on selectivity of hydrogenation of odorous substances in a periodic duty is of interest in two aspects. On the one hand, these data provide new information that expand ideas about general regularities of this process, complementing and clarifying the existing theoretical views on this question. On the other hand - allow to pick up optimum stationary catalysts and conditions for a periodic and continuous way of the hydrogenation of organic substances.

In this paper, the aim is studying of reaction of a hydrogenation β-ionone and citral in the presence of metals VIII of group in a wide variation of experimental conditions in a periodic duty and further development of the continuous way of hydrogenation β-ionone in dihydro - β-ionone and citral in citronellal.

2 Results and discussion

The following reactions are taken as a basis of process:



Experiments were made on kinetic installation of high pressure at a variation a process

condition: Tr=373-773 K, P=0,1 - 9,8 MPa, $T_{red.}$ catalyst = 393-893 K. The results are presented in figure 1. Figure 1 shows a change of composition of getting products of reaction hydrogenation β-ionone over metals VIII of group in 96% ethanol at 2,0 MPa and temperature 303 K. Determined, that the nature of metal has essential effect on row saturation of unsaturated bonds in the molecule β-ionone.

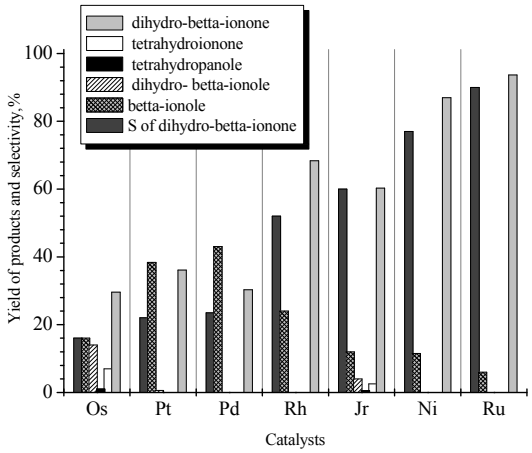


Figure 1. Effect of the metals nature on products yield

On selectivity of hydrogenation β-ionone in dihydro-β-ionone the studied catalysts settle down in the following row: Ru>Ni>Pd>Rh>Jr>Pt>Os. The nickel, ruthenium and palladium can be used as selective catalysts for hydrogenation β-ionone in dihydro-β- ionone by the continuous process.

Considering a number of indexes of profitability and availability in our next researches, nickel supported catalysts were used for hydrogenation β-ionone and citral. Studying of hydrogenation of citral into citronellal over nickel containing catalyst showed that the selectivity for citronellal of 86-87%.

The Spectral Analysis of Hydrocarbons in the Oil from the Well1311 of Surakhani Field

Yolchuyeva U.C.*, Jafarova R.A., Rzayeva N.A., Abbasova N.A.

Institute of Petrochemical Processes named after Y.G.Mammadaliyev, Baku, Azerbaijan

* ulviyya.yolcuyeva@gmail.com

Keywords: oil, Surakhani field, polycyclic, aromatic, hydrocarbons, the method of IR spectroscopy, UV spectroscopy

1 Introduction

It is known that the study of the properties of the oil , its various branches of the national economy, including its efficient use in petrochemical industry, as well as allows the study of its genetics.

2 Experimental

In various kinds of oils the amount of aromatic hydrocarbons (AH) varies from 15% to 50%. AH in petrochemical industry is a very important raw material.Thus,using the reactions of the alkylation,oxidation,dehydrogenation,isomerization and other of aromatic hydrocarbons,there are obtained substances for different purposes on basis which are manufactured important products to the national economy.

The oils which producedin the oilfields of Azerbaijan have the unique properties.With their low low sulfur,low resin,light-coloured,rich with fractions are being light oils ,they have a high biological activity.Surakhani oil can be attributed to such oils.Sorakhani oil is being white oil (kerosene) is rich in saturated paraffin-naphthene hydrocarbons and it has been using in folk medicine for a long time.Studies have shown that there are considerable amount of the rasig the biological activity relic hydrocarbons in Surakhani oils.

The composition and properties of Surakhani oil fractions have been studied in previous researches.The crude oil (Surakhani oil well № 1311)in comparision due to another numbers of the wells in the same fields has a relateviely high density(r=842.5 kq/m3) .

Silicosis gel (AEC) a solvent hexane, hexane-benzene (1: 1), benzene, ethyl-benzene (1: 1) are used as adsorbents in the shown process. The results are presented in the table:

№	Components group	The amount, weight of percent	Beam refraction coefficien, n_d^{20}	Density 20^0 S, kq/m^3
1	Methane-naphthene	75.42	1.4550	0.8250
2	I Aromatic	5.87	1.5108	0.8368
3	II Aromatic	3.68	1.5357	0.8695
4	III Aromatic	6.23	1.5768	0.9026
5	IV Aromatic	4.7	1.5990	0.9848
6	Resin	4.1	–	1.0031

As shown in the table the component of oil well number 1311 includes paraffin-naphthene, I, II, III, IV group of aromatic hydrocarbons,resinous compounds.The separate group of hydrocarbons has been studied by the method of the IR and UV spectroscopy.

In IR spectra the absorption bands were observed in the following:
724, 1459, 2924, 1375, 2856 sm^{-1} spectral field of the CH2 group C-H mathematical relation in accordance with deformation of valence vibrations and absorption lines are arranged. 960, 1032 sm^{-1} in spectral field is arranged naphthene, and in 3011 sm^{-1} is arranged the benzene ring C-H bonds at, 1604 sm^{-} C=C, and in 702, 779, 812, 879 sm^{-1} field is located the replaced absorption lines in accordance with aromatic hydrocarbons.

UV- spectrum analysis shows that , I, II, III, IV groups The composition of the aromatic fractions, especially 1, 2 və 3 are are multilink aromatic hydrocarbons. In the fractions composition is found 4 and 5 multilink aromatic hydrocarbons in small quantities.

Oligopeptide Modified Mesoporous Silica Catalyts for Direct Aldor Reaction

Yoshida A.*, Takasaka T., Ebi Y., Sato R., Naito S., Ueda W.

Kanagawa University, Yokohama, Japan

* ayoshida@kanagawa-u.ac.jp

Keywords: mesoporous silica, peptide catalyst, direct aldol reaction

1 Introduction

Mesoporous silicas have been regarded as potential support materials for catalysts and adsorbents. However, its applicability is still limited because their inner surfaces are covered with silanol groups, which are rather inert to promote reactions while it can act as effective hydrogen boding donors/acceptors. The vast number of researches has been reported to introduce catalytically active components, such as metal nanoparticles, enzymes and organic functionalities inside porous structure [1]. Oligopeptide is also nice candidate for investing with asymmetric catalytic activity to mesoporous silicas, because immobilization of oligopeptide on solid surfaces is an established technique as the solid phase peptide synthesis. In this work, the Pro-Pro-Asp tripeptide molecules, which are reportedly effective homogeneous catalyst for direct aldol reaction [2], were immobilized on the surfaces of various mesoporous silica supports and investigated the cooperative characteristics of peptide molecules and silanol groups.

2 Experimental

Mesoporous silicas of SBA-15, MCM-41 and KIT-6 were prepared according to the standard methods. Prior to the peptide introduction, NH_2 functionalities were introduced on mesoporous silica surfaces by using the silane coupling agent of 3-aminopropyltriethoxysilane derivative which has the bulky protecting group on the nitrogen atom for providing high dispersion of NH_2 groups on silica surfaces [3]. Pro-Pro-Asp tripeptide molecules were immobilized on NH_2 groups on silica surface by sequential introduction of the corresponding amino acids applying a solid phase peptide synthesis technique (Fig. 1). Microporous silica and aminomethyl polystyrene resin were also modified with the tripeptide using the same procedure. The obtained Pro-Pro-Asp tripeptide-modified catalysts are denoted as PPA-catalysts. The direct aldol reaction was carried out under the following conditions. To dispersions of PPA modified catalysts (containing 25 μmol of peptide) in 3 mL of acetone, *p*-nitrobenzaldehyde (151 mg, 1 mmol) and the internal standard material of *o*-dichlorobenzene (20 mg) were added. The suspensions were stirred at ambient temperature for 48 h with periodical sampling for determining the yield of the aldol product by HPLC analyses.

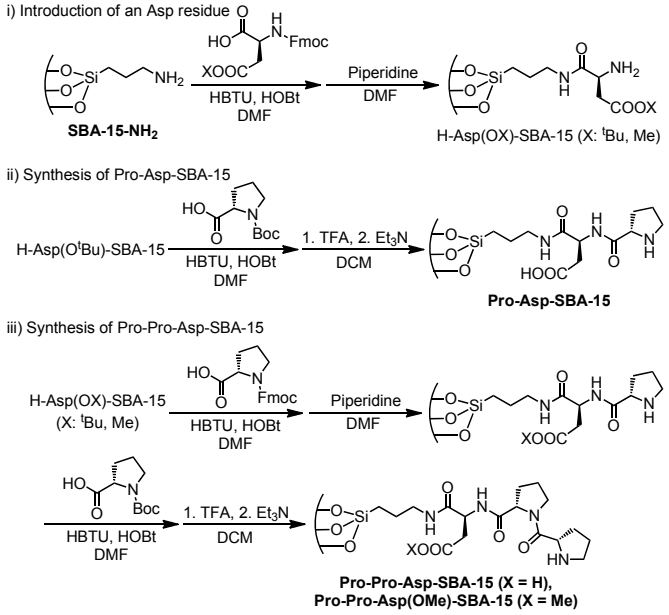

Fig. 1. Synthetic procedure for tripeptide-modified SBA-15.

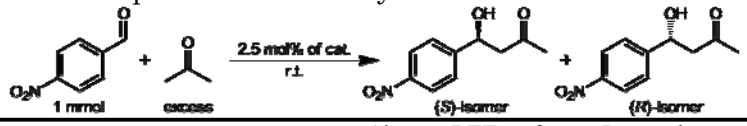
3 Results and discussion

The results of the aldol reaction, N_2 physisorption analyses and loading amount of peptide are summarized in Table 1. N_2 physisorption analyses revealed that the PPA-mesoporous catalysts maintained its quite large surface area and pore volume even after immobilization of the tripeptide. Mesoporous structure and large pore volume may provide those catalysts for accessibility of substrate molecules to the catalytically active PPA peptide molecule. The loading amount of PPA peptide on mesoporous silicas are in the range of 0.11~0.15 mmol/g, suggesting that averagely 6 ~ 10 nm^2 of the surfaces are allowed for each PPA peptide molecules. Those values indicate that each peptide molecules are well dispersed on the mesoporous silica surface. The direct aldol reaction of 4-nitrobenzaldehyde and acetone was conducted using various PPA tripeptide modified catalysts. PPA-MCM-41 exhibited the highest catalytic activity among the prepared catalysts. 68% of the aldol product was yielded for 8 h with 18 % of *e.e.* The maximum yield of 81% was achieved at 24 h. The other peptide modified mesoporous silica catalysts of PPA-SBA-15 and PPA-KIT-6 also showed higher catalytic activity than the PPA-silica and PPA-resin catalysts. Those results show that mesoporous silica supports with wide surface area and large pore volume facilitate diffusion of reactants and products to/from catalytically active peptide molecules immobilized on the supports. Interestingly, the enantioselectivity of PPA-mesoporous and microporous silica catalysts are inverted comparing to those of PPA-resin and reported result at homogeneous conditions [2]. The silica based supports afforded *R* enantiomer predominantly whereas the resin support and free peptide molecules in homogeneous conditions afforded *S* enantiomer. The PPA-resin catalyst with selective protection of the carboxylic group on the side chain of the Asp residue exhibited inverted enantioselectivity to afford *R* enantiomer with 16% of e.e., suggesting that the carboxylic group dominates enantioselectivity. The observation of almost identical enantioselectivity to the silica based supports indicates that the carboxylic group was inactivated when the PPA molecule is immobilized on the silica surfaces. This inactivation of carboxylic group is probably caused by formation of hydrogen bonding with surface silanol groups.

Table 1. Direct aldol reaction of 4-nitrobenzaldehyde and acetone catalysed by tripeptide-modified mesoporous silica catalysts



Catalysts	Time / h	Yield / %	*ee* / %	Abs. Conf.[b]	BET surface area / $m^2 \cdot g^{-1}$	Pore volume / $cm^3 \cdot g^{-1}$	Loading amount of PPA / $mmol \cdot g^{-1}$
PPA-MCM-41	8	68	18	*R*	833	0.73	0.13
PPA-SBA-15	8	35	17	*R*	545	0.90	0.15
PPA-KIT-6	8	26	15	*R*	642	0.44	0.11
PPA-silica	8	17	17	*R*	276	1.20	0.08
PPA-Resin	9	2	26	*S*	<5	-	0.55

[a]All values and the absolute configuration were determined using HPLC analyses. [b]Absolute configuration of the predominatly formed enantiomer.

4 Conclusions

The catalytically active PPA peptide was successfully heterogenized by using solid phase peptide synthesis technique. The mesoporous silica supported catalysts exhibited superior catalytic activity to the microporous silica and resin supported catalysts. Wide surface area and mesoporous structure may facilitate diffusion of reactants and products to/from catalytically active peptide molecules immobilized on the support surfaces.

The Method of Dealumination of Zeolite Ferrierite with Ammonium Hexafluorosilicate

Zalyaliev R.F.*, Mukhambetov I.N., Lamberov A.A.

The Kazan (Volga) Federal University, Kazan, Russia

* zalyaliev.r@gmail.com

Keywords: dealumination, zeolite, ferrierite, skeletal isomerizationn, isobutene

1 Introduction

Interest in the zeolite ferrierite is caused mainly due to the relevance of obtaining isobutene skeletal isomerization of n-butenes. Ferrierite exhibits high activity in the isomerization reaction at relatively low temperatures (400-450 ºC), but has weak initial selectivity (< 50 %). For him known methods of modifying based on different techniques of dealumination that lead to an increase in selectivity. Removing the aluminum cations may be carried out acid treatment, the influence of chelators, hydrothermal dealumination, as well as interaction with ammonium hexafluorosilicate (AHFS).

2 Results and discussion

Effective dealumination of ferrierite succeeded spend only by hydrothermal treatment. Herewith during the hydrothermal treatment, the aluminum cations deposited in the zeolite channels and are the cause the low stability of catalysts. Therefore development of zeolite with high module remains actual problem.

This paper investigates the interaction AHFS with zeolite ferrierite at the temperature higher than 200 ºC and considering the possibility dealuminating of the zeolite by replacement of aluminum on silicon in order to obtain high-silicon zeolites with SiO_2/Al_2O_3 more than 55.

3 Conclusions

The obtained samples (SiO_2/Al_2O_3 = 64, 74) were investigated by TPD of ammonia, low temperature nitrogen adsorption, ^{29}Si, ^{27}Al NMR, X-ray analysis, IR spectroscopy. Optimal samples of has the following catalytic performance: conversion – 40 %, selectivity – 87 % (at the temperature 450 ºC).

Paramagnetic Nickel Complexes in the Catalytic Carbon-Carbon Bond Formation Reactions

Flid V.R., Shamsiev R.S., Zamalyutin V.V.*

Moscow State Academy of Fine Chemical Technology (MITHT), Moscow, Russia

* zamalyutin@mail.ru

Keywords: Paramagnetic, Nickel, Complexes, Norbornadiene, Cross-coupling, Aryl, Halides

1 Introduction

The interest in transition metal complexes, including nickel, with uncharacteristic degree of oxidation is largely due to their ability to participate in catalytic processes. Paramagnetic complexes Ni(I) and Ni(III) are present in a homo- reactions and cross-coupling of aryl halides [1], the oligomerization of ethylene and propylene [2], dimerization of norbornadiene (NBD) [3]. However, their role in catalysis still remains unclear.

2 Results and discussion

When interacting $NiAll_2$ (all-C_3H_5, 1-$CH_3C_3H_4$, 2-$CH_3C_3H_4$, 1-$C_6H_5C_3H_4$) NBD with fixed paramagnetic nickel(I) complex was discovered, which was with triaxial anisotropy of the g-factor at 77 K characterized. Such complexes are observed in the system containing no conventional stabilizing ligands for the first time. On the contrary, their presence leads to the disappearance of paramagnetic particles. The formation of Ni(I) is provided to reduce the positive charge of nickel in $NiAll_2$. When interacting with NBD $NiAll_2$ stationary relative concentration of Ni(I) differ significantly, assuming at 298 K the value range of 10^{-3} - 10^{-6} of the total nickel concentration.

Obviously, the nickel(I) complex includes a NBD molecule as a stabilizing ligand. Dependence of the concentration of paramagnetic particles from the structure $NiAll_2$ indicates possible involvement of allyl ligand in the formation of Ni(I). The mechanism of formation of Ni(I) is based on the reaction of stoichiometric allylation NBD, and $NiAll_2$ and $Ni(NBD)_2$. counterdisproportionation. The main stages was gained both experimental and theoretical confirmation of the use of model systems.

Probably, an important role in the formation of the Ni(I) complex plays nickel hydride. Experimentally proved its presence in the reaction system. At the same time, compounds observed in ESR spectra could not be related to hydride compounds. Probably, paramagnetic nickel hydride posesses very labile and easily implement NBD to the Ni-H bond. π, σ- nickel NBD complexes formed in this case significantly more stable and dominate among the compounds Ni(I).

Through the use of DFT/PBE method, the "hydride" route in the catalytic dimerization of NBD theoretically was sounded. However, its contribution to the overall process is probably unsignificant.

Our results do not allow definitely to establish the role of the paramagnetic nickel complexes in catalysis. Nevertheless, there is no doubt in that Ni(I) forms due to the extraordinary ability of the NBD to stabilize unstable compounds in the valence states which are not specific for them.
A series of highly effective and available catalysts for homocoupling of aryl halides based on nickel complexes with diazabutadiene ligands. New catalysts being used in low concentrations allow to obtain high yields of biaryls various types, including sterically hindered, as well as compounds containing various substituents in the aryl fragments. For the first time through the method of ESR spectroscopy discovered and investigated paramagnetic nickel(I) complex, the

most likely intermediate compound in the catalytic reaction. Based on the spectral, kinetic and calculated quantum-chemical data the mechanism of aryl halides homocoupling based on nickel complexes was proposed. The process is based on the traditional for metal complex catalysis stages.

The initiation of the process begins with initial nickel(II) salt reduction by zinc in the presence of diazabutadiene derivative. A formed nickel(0) complex starts the catalytic cycle and at the first stage molecule coordinates ArX as π-ligand, and then carries out its oxidative addition. The process then continued with one-electron reduction of the complex Ni(II). The resulting compound is involved in the process of oxidative addition of a new ArX molecule to form an active intermediate diaryl $L_2XNi(III)Ar_2$. Its decay is accompanied by reductive elimination and biaryl formation of a new Ni(I) intermediate. Regeneration of the catalyst may occur by the one-electron reduction with zinc to the initial Ni(0). Since the method of forming fixed ESR nickel(I) intermediate with a high concentration, apparently, the rate-limiting step is one-electron reduction of the complex Ni(I) with DAB, under the action of metallic zinc.

3 Conclusions

The results obtained in this work did not conclusively establish the role of paramagnetic complexes of Ni-catalyzed processes of norbornadien dimerization and homocoupling of aryl halides. However, on the basis of kinetic, spectroscopic and calculated quantum-chemical data corresponding mechanisms was suggested. Through the usage of the DFT/PBE method theoretically was proved "hydride" route in the catalytic dimerization of NBD. The second process is based on the traditional metal complex catalysis stages.

Keywords: 3-picoline, oxidation, heterogeneous, vapor-phase catalysis, microwave heating, vanadium–titanium oxide system

1 Introduction

One-step heterogeneous gas-phase oxidation of 3-picoline over vanadium-titanium oxide catalysts using air as an oxidizing agent is a better and cleaner way to obtain nicotinic acid (vitamin B_3) [1]. In this investigation to heat a catalyst to 250-270°C, conventional energy was applied. Due to high energy consumption some alternative energy sources can be considered. One of the promising substituents is microwave (MW) irradiation that is becoming increasingly popular as a clean, cheap, convenient method of heating, increasing yields, and decreasing reaction times while using less power input [2]. Microwave irradiation is a way of applying energy directly to the reaction system rather than through other media. The conversion of electromagnetic energy in heat occurs simultaneously and evenly by heating a solid catalyst while microwave transparent materials (insulation, reactor wall and gas phase) are penetrated without energy consumption. The aim of this work is to investigate the influence of microwave energy on heterogeneous vapor-phase oxidation of 3-picoline over V-Ti-O system.

2 Experimental

Binary V-Ti-O catalysts and vanadia were prepared by spray drying of a mixture of titanium dioxide (anatase form) and vanadyl oxalate solution followed by calcination at 450°C for 4 h [1,3]. Microwave "Discover" system with "Open vessel" option (CEM Corporation) was used to heat the catalyst. A sample of the catalyst (0.25-0.50 mm) mixed with quartz was placed on a frit support in a tubular quartz reactor (diameter 15 mm, length 50 mm) with a coaxial thermocouple pocket. A non-metallic Fiber Optic Thermocouple was used to control and measure the temperature in a catalyst layer. The set parameter ranges were: microwave power 18-160 W, temperature 170-220°C. For comparison, some experiments were performed in a conventional oven. The initial components and reaction products were analyzed by Gas Chromatography (Shimadzu GC-8A) equipped with Porapak-Q, Carbowax, Molecular Sieves, and Equity Columns.

3 Results and discussion

By using both sources of energy, conventional and MW, vanadia-titania catalysts produce the same products: nicotinic acid, 3-pyridinecarbaldehyde, 3-cyanopyridine, and CO_2.
Fig. 1 represents the rate of 3-picoline transformation calculated per square meter and the selectivity for nicotinic acid as a function of a catalyst composition in conventional and MW systems. All experiments in conventional oven shown in this figure were performed at 250 °C, and conversion (X) of about 40%. Experiments in MW heated reactor were performed at the

measured temperature of about 180 °C, and at a conversion range of 30–50%.

It can be seen (Fig. 1a) that by conventional heating, the binary catalysts are noticeably more active than individual oxides. The highest activity was observed over the binary catalysts containing 20–75% of vanadium oxide. By microwave heating, the dependence is entirely different: vanadium oxide reveals the highest activity. The higher is the percentage of vanadium oxide in the binary catalyst, the higher is the rate of the 3-picoline transformation. Titanium oxide as the less active catalyst was observed in microwave oven as well.

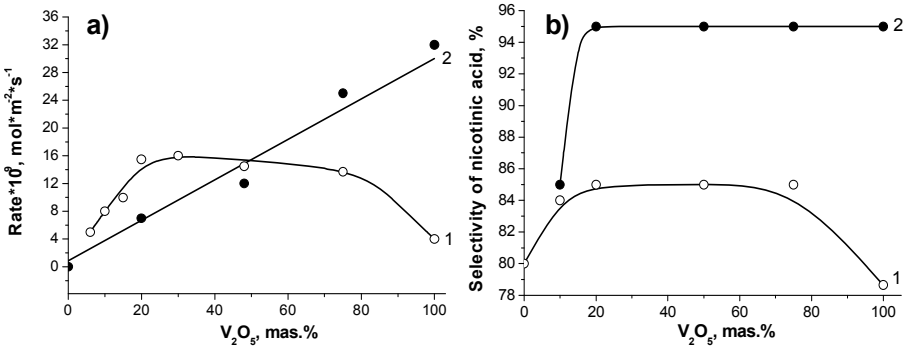

Fig. 1. a) - Rate of 3-picoline transformation as a function of catalyst composition.

b) - Selectivity for nicotinic acid as a function of catalyst composition.

1–conventional heating: 250°C, X ~ 40%; 2–microwave heating: 180°C, X = 30-50%.

Selectivity for the nicotinic acid versus catalysts composition is given in Fig.1b. As can be seen, microwave assisted 3-picoline oxidation is more selective toward nicotinic acid than a traditional conventional method. Selectivity for nicotinic acid is 95% for the binary catalyst samples containing 20–75% of V_2O_5. This is 10% higher than selectivity for nicotinic acid obtained in conventional heated reactor. Individual V_2O_5 is much more selective when heated in microwave oven. Selectivity for 3-pyridinecarbaldehydeis is lower in MW system than in conventional oven on all catalysts. Selectivity for CO_2 is lower in MW system as well. For binary catalysts containing 20–75% of V_2O_5, selectivity for CO_2 ranges between 2 and 3%. Different behavior of individual vanadium oxide in two systems, MW and CH, can be explained by considering a sufficient distinction between MW and CH. Temperature profiles in the particle of a catalyst heated by each individual source are entirely different. Due to specific temperature distribution, the lattice oxygen in the microwave effective dielectric vanadium oxide becomes more mobile inducing the rate of 3-picoline oxidation to nicotinic acid.

4 Conclusions

Application of microwave energy as a remote heating source to the heterogeneous vapor-phase oxidation of 3-picoline has several new advantages. This method consumes less energy and creates an optimal temperature profile in vanadium-containing catalyst particles making a positive contribution to the selectivity and capacity of the green method of nicotinic acid synthesis.

Pt Based Bimetallic Catalysts Prepared by Conventional Impregnation and Deposition and Reduction in Liquid Phase Methods for Selective Hydrogenation of Citral

De Miguel S., Rodriguez V., Scelza O., Stassi J., Vilella I., Zgolicz P.*

Instituto de Catálisis y Petroquímica, UNL-CONICET, Santa Fe, Argentina.

* pzgolicz@fiq.unl.edu.ar

Keywords: Pt-based, bimetallic catalysts, carbon nanotubes, selective hydrogenation of citral

1 Introduction

In the fine chemical industry, supported bimetallic catalysts are frequently used, because such systems exhibit interesting yields with regard to their applications. An important example of application is the selective hydrogenation of the carbonyl group (C=O) of α,β-unsaturated aldehydes into α,β-unsaturated alcohols (UA) [1]. However, the challenge in the development of bimetallic catalysts for this type of reaction is to achieve the hydrogenation of the C=O without affecting the C=C olefinic bond, since, the hydrogenation of the C=C is thermodynamically more favorable than the hydrogenation of the C=O, and usually, low yields are obtained with typical monometallic catalysts of hydrogenation [1,2]. In this sense, bimetallic nanoparticles allow a better tailoring of the electronic and catalytic properties. The final selectivity of these bimetallic nanoparticles depends both on the second metal/noble metal ratio and the interaction between the active metal and the reduced or ionic species of the second metal, which act as Lewis acid sites to promote the hydrogenation of the carbonyl group [1]. However, both the interaction between the metals and the type of promoter species formed strongly depend on the nature of the support and the preparation method. In this work, Pt-based bimetallic catalysts multi-walled carbon nanotubes-supported were prepared by two methods (conventional impregnation followed of a reduction step in H_2 flow (CI) and deposition-reduction in liquid phase (RLP)) in order to study and compare their performances in the citral hydrogenation.

2 Experimental/methodology l

Commercial carbon nanotubes (MWNT, 211m^2/g, purity>95%) were purificated by successive treatments with aqueous solutions with inorganic acids. The purificated support (CNP) were used to prepare Pt based bimetallic catalysts (5wt%) using an aqueous solution of H_2PtCl_6/promoter (promoter: $FeCl_3$, $SnCl_2$, $GaNO_3$, or $InNO_3$). Two types of reduction were carried out: under H_2 flow at 350 ºC and reduction in liquid phase using $NaBH_4$ at low temperature. Additionally a thermal treatment with N_2 at high temperature (700ºC) were carried out on the reduced samples. The metallic phase of the catalysts was characterized by temperature programmed reduction (RTP), test reactions (cyclohexane dehydrogenation-CHD, cyclopentane hydrogenolisis-CPH and benzene hydrogenation-BH), XPS, and TEM. The hydrogenation of citral (3,7-dimethyl-2,6-octadienal) was carried out in a discontinuous volumetric reaction equipment with a device for sampling the reaction products using 2-propanol as a solvent, P atm, 70ºC and 1400 rpm.

3 Results and discussion

Characterization results. From TPR results for catalysts prepared by CI, it is was observed that the Pt reduction peaks of PtSn, PtIn, PtGa samples, showed a shift to higher or lower temperature and a higher area than that corresponding to the TPR profile of the monometallic one. This fact together with the lower H_2 consumption observed at the temperatures where the

promoter are reduced, would be indicating that a co-reduction between Pt and promoter metals occurs. On the contrary, the higher H_2 consumption observed at high temperatures in catalysts prepared by RLP, evidence a poorer interaction between metals in these catalysts. XPS results evidenced the presence of a high P^o/P^{ionic} ratio (P: Sn, Ga, In) in bimetallic catalysts prepared by CI while for catalysts prepared by RLP this ratio is inverted. PtFe catalysts prepared on both methods showed only the presence of ionic species. Besides, the results from test reactions (CHD and CPH) for catalysts prepared by CI treated and untreated with nitrogen evidenced the presence of mainly electronic effects in PtSn, PtGa, and PtIn catalysts and geometric ones in the PtFe catalyst. However, since the change in the activation energy with respect to the monometallic catalysts is opposite for PtSn (higher) and PtGa and PtIn (lower) catalysts, a different electronic modification is suggested. For catalysts prepared by RLP the change in the initial reaction rate depend on the nature of promoter, but any case, the Ea_{BH} value does not change significantly. Thus, these characterization results show that the addition of a second metal modifies the structure of Pt particles, but different effects, such as dilution, blocking or decorating of particles would prevail according to the electronic state (ionic, reduced or alloyed) and the nature of the promoter and the preparation method. The characteristics of the metallic phase were correlated with the catalytic behavior in the citral hydrogenation. Table 1 shows the results of activity and selectivity. The addition of a second metal significantly improves the selectivity to UA in all the bimetallic catalysts prepared by CI due to both the activation of the C=O and the poisoning of acid sites of the support. Except for PtFe catalyst, the catalysts prepared by RLP do not show a significant change in the selectivity to UA with respect to the monometallic one. These results can be related to the higher and ordered modification of the Pt metallic phase in catalysts prepared by CI than those prepared by RLP. Besides, the lower activities in the last catalysts, also evidence a higher blocking effect in these samples. The results found with PtFe catalysts prepared by both methods would be related to the formation of PtFe complexes which help to explain the high interaction of the metals in the final catalyst. Besides, the N_2-thermal treatment do not increase the particle size as it was expected in catalysts prepared by CI, but improve the selectivity in PtSn and PtGa catalysts probably due to the formation of a more adequate bimetallic phase. Only the PtSn-RLP catalyst treated with N_2 showed a better selectivity to UA. For the other catalysts prepared by RLP neither the activity or selectivity to UA were improved after the thermal treatment probably due to an even higher blocking effect in these catalysts with respect to those untreated.

Tabla 1. Hydrogenation Results: S_{UA}: selectivity UA, T: reaction time at 95 % of citral conversion

Catalyst (CI)	**S_{AI} (%)**	**T (h)**
Pt	7.0	7.2
PtFe(2.5%wt)	93 **(95)**	7.5 **(20)**
PtSn(1.0%wt)	89 **(97)**	3.0 **(7.0)**
PtGa(1.8%wt)	91 **(98)**	0.8 **(>20)**
PtIn(2.5%wt)	97 **(95)**	0.5 **(0.13)**
Catalyst (RLP)	**S_{AI} (%)**	**T (h)**
Pt	16.0	3.5
PtFe(2.5%wt)	92 **(89)**	20 **(>24)**
PtSn(1.0%wt)	4 **(79)**	2 **(12)**
PtGa(1.8%wt)	28 **(26)**	6 **(>24)**
PtIn(2.5%wt)	46 **(-)**	6.5 **(-)**

*values in bold and brackets correspond to results obtained for the catalysts submitted to the N_2-thermal treatment

4 Conclusions

Pt metallic phase is more strongly modified in bimetallic catalysts prepared by CI than in those prepared by RLP. Besides, phases more adequated for selective hydrogenation were obtained in catalysts prepared by CI or PtFe catalysts probably due to the presence of more highly ordered metallic phases. In consequence, the hydrogenation results highly depended on the catalyst preparation method, the thermal treatment and the nature of the second metal.

Study of the Reaction Network of Fischer-Tropsch Synthesis by Multicomponent Steady-State Isotopic Transient Kinetic Analysis

Ledesma C.[1*], Yang J.[2], Blekkan E.A.[1], Holmen A.[1], Venvik H.J.[1], Chen D.[1]

1 - Norwegian University of Science and Technology, Trondheim, Norway
2 - SINTEF Materials and Chemistry, Trondheim, Norway

* cristian.l.rodriguez@ntnu.no

Keywords: Fischer-Tropsch synthesis, isotopic labeling, kinetics, reaction, mechanism

1 Introduction

Fischer-Tropsch synthesis (F-T) is one of the most important processes to transform a mixture of carbon monoxide and hydrogen (also called synthesis gas) into hydrocarbons and liquid fuels by using catalytic systems. The wide variety of products that can be obtained points out the complexity of the reaction mechanism, which is known to be a polymerization like mechanism, but the nature of the main intermediates corresponding to paraffin and olefin formation as well as in chain growth are still in debate. Steady-State Isotopic Transient Analysis (SSITKA) is considered a powerful technique to investigate reaction mechanisms by labelling isotopically at least one of the reactants [1]. This technique has been employed with other methods (i.e. DFT, transient methods) in order to create a model to describe the transient curves of the main intermediates of Fischer-Tropsch synthesis [2]. However, these methods are not capable to determine the rate constants involved or describe the effect of reaction conditions or catalyst composition in the reaction step to explain the performance of the catalyst. In this work, a new method based on multicomponent SSITKA measurements allowed mapping the kinetic parameters of the Fischer-Tropsch synthesis over a Co-Re/CNT catalyst under methanation conditions at 210°C and 1,85 bar.

2 Experimental/methodology

CO hydrogenation reaction has been performed using a fixed-bed quartz reactor (4 mm i.d.). The 20% wt. Co and 0.5% wt. Re over carbon nanotubes (CNT) catalyst has been diluted inert silicon carbide to improve the isothermal conditions along the catalyst bed. Prior to reaction, the catalyst was reduced in 10 NmL/min H_2 at 623 K. After 16 h of reduction, the catalyst was cooled down to 483 K, H_2/CO/Ar (15/1,5/33,5 NmL/min) mixture was introduced and the pressure was adjusted to 1,85 bar. Once the steady state was achieved after 6 hours on stream, SSITKA experiments were carried out by switching between $H_2/^{12}CO$/Ar and $H_2/^{13}CO$/Kr. The reaction order of the reactants has been determined by varying their partial pressure. The transient responses of Ar, Kr, ^{12}CO, ^{13}CO, $^{12}CH_4$ and $^{13}CH_4$ were monitored with a Balzers QMG 422 quadrupole mass spectrometer (MS). The concentrations of H_2, CO, Ar and C_1-C_6 hydrocarbons were analysed with a GC-MS (Agilent GC7890B – MSD5977A) equipped with multiloop, TCD, FID and MSD detectors. The isotopic distribution of C_2, C_3 and C_4 hydrocarbons were calculated as a linear combination of the fragmentation patterns of the corresponding isotopic products [3].

3 Results and discussion

The measured site coverage of the various intermediates on the catalyst surface obtained under F-T synthesis allows the elucidation of their nature by testing kinetic dependences of the

intermediate concentration with the different carbon numbers on the corresponding olefin and paraffin formation rate. The paraffin ($r_{t,n}$) and olefin formation ($r_{o,n}$) reactions have been evaluated as a function of the H_2 partial pressure, in order to investigate the reaction order towards this reactant (Figures 1a and 1b). Chain propagation reaction ($r_{p,n}$) has been evaluated as a function of the carbon number, as depicted in Figure 1c.

$r_{t,n}=k_{t,n}\theta_{Cn}(\theta_{H2})^2$ $r_{o,n}=k_{o,n}\theta_{Cn}\theta_{H2}$ $r_{p,n}=k_{p,n}\theta_{Cn}\theta_{C*}$

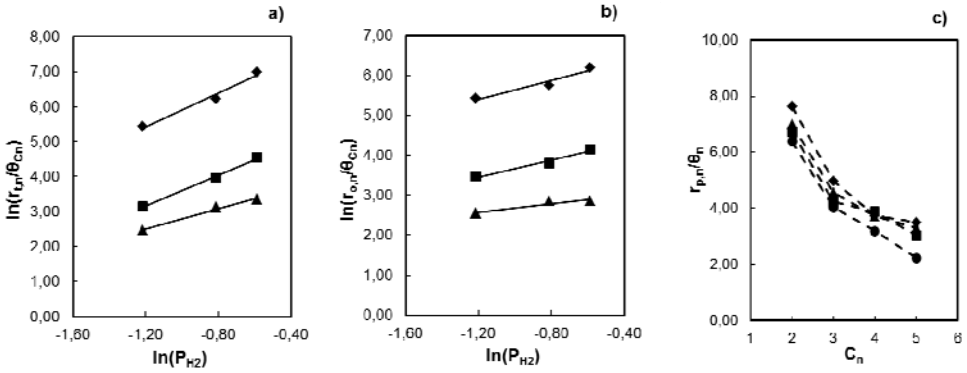

Fig. 1. Hydrogen reaction order in paraffin formation (a) and olefin formation (b) reactions at different carbon number: ■: C_2; ♦: C_3, ▲: C_4; c) Chain growth rate and site coverage as a function of the carbon number at different P_{CO} and P_{H2} (in bar): ♦: P_{CO}=0,06, P_{H2}=0,56; ■: P_{CO}=0,11, P_{H2}=0,56; ▲: P_{CO}=0,06, P_{H2}=0,44; ●: P_{CO}=0,06, P_{H2}=0,30.

Figures 1a and 1b show a H_2 reaction order towards paraffin and olefin formation of 2 and 1, respectively for C_2 and C_3 intermediates. This reaction order can only be explained by the presence of hydroxycarbene like intermediates. However, the lower reaction order in C_4 compound indicates that alkylene like intermediates may also be present. Chain propagation reaction rate (figure 1c) decreases with the carbon number, as expected. The similar trends obtained at different conditions demonstrate that the nature of the growing monomer is the same for all the conditions tested. Besides, the different values obtained at each carbon number indicate that the growing monomer depends on CO and H_2 partial pressures.

4 Conclusions

This work shows a powerful method to identify the kinetic mapping of the FT reaction network over a Co-Re-based catalyst by analysing the site coverage of the main intermediates obtained by multicomponent SSITKA. This methodology can be an effective tool to study the effect of catalytic properties, such as promotion, particle size or support characteristics in the reaction mechanism.

Keywords: acrolein, glycerol dehydration, niobium, oxide, phosphoric acid

1 Introduction

The depletion of fossil fuels along with other environmental concerns has led to increased interest in new avenues for renewable energy. Biodiesel, which is produced via trans-esterification reactions with the oils of plants, animals, algae, etc., is emerging as an alternative energy resource. The amount of glycerol is about 10 wt% of total biodiesel yield [1]. The techniques for utilizing surplus glycerol are interesting and many research groups have been studying the transformation of glycerol to valuable chemical products [2]. Acrolein, which is produced by the dehydration of glycerol, is used for not only producing acrylic acid but also various other chemicals [3]. Various solid acid catalysts, such as zeolites, niobium, zirconium, titanium, silica-alumina, are used in the production of acrolein. In this study, we conducted gas phase glycerol dehydration reactions using phosphoric acid-loaded niobium oxide catalysts.

2 Experimental/methodology

We synthesized PO_4/Nb_2O_5 catalysts by simple impregnation method, wherein we mixed the required amount of H_3PO_4 with powdered niobium oxide and stirred the solution at 70 °C for 1 h. Subsequently, the water was evaporated, under low vacuum conditions, using a rotary evaporator. After evaporation, the PO_4/Nb_2O_5 samples were dried at 100 °C for 24 h. Finally, the dried samples were calcined at 400 °C for 4 h. The catalysts were denoted as x-PO_4/Nb_2O_5(x = Phosphoric acid wt%).

A gas phase glycerol dehydration reaction was carried out, under atmospheric pressure, using a PO_4/Nb_2O_5 catalyst. 10 wt% of glycerol solution was fed using an HPLC Pump. Ar was used as the carrier gas. The liquid phase was evaporated by passing through an evaporator maintained at 310 °C. The vapor was then fed into a quartz reactor tube (length 350 mm, i.d. 8.8 mm) maintained at 300 °C using an electric split furnac; 0.4 g of the catalyst was supported on the quartz wool. The gaseous product was condensed using an ice trap maintained at –5 °C and collected on an hourly basis for analysis using GC17A and GCMS-QP5000 equipped with a Petrocol capillary column. The condensed product was analyzed after 2 h.

3 Results and discussion

Above 40 wt% of phosphoric acid in PO_4/Nb_2O_5, the crystalline pattern of $NbPO_5$ was confirmed at 20.542°, 28.985°, 35.846°, and 56.027°. This pattern indicates an orthorhombic $NbPO_5$ diffraction pattern (JCPDS PDF-1 #40-0124). It was reported that the $NbPO_5$ crystal was synthesized on loading niobium oxide with phosphoric acid by the impregnation method given in the reference [4].

The elemental binding energy and metal concentration on the catalyst surface were

investigated by XPS analysis. In our results, increasing the phosphoric acid loading led to a relative reduction in niobium concentration. This could imply that phosphate covers the niobium surface. In the used catalyst, the concentration of phosphorous and niobium decreased. This could be explained by a loss of elements and carbon deposition that occurs during the reaction. For binding energy, we propose that an increase in phosphoric acid loading leads to a decrease in the niobium binding energy. In the fresh 50 wt% PO_4/Nb_2O_5 catalyst, the binding energy of Nb $3d_{5/2}$ was 206.21 eV. This binding energy indicates the presence of NbO_2. Therefore, the $NbPO_5$ crystal could be synthesized by adding phosphoric acid.

The crystallinity of the catalysts was observed using transmission electron microscopy. We confirmed that fresh Nb_2O_5 and 20 wt% PO_4/Nb_2O_5 catalysts were amorphous. In the fresh 50 wt% PO_4/Nb_2O_5 catalyst, the $NbPO_5$ crystal was observed; however, its crystallinity was not very high. The used Nb_2O_5 and 20 wt% PO_4/Nb_2O_5 catalyst were amorphous. Moreover, deposited carbon, in the form of crystalline graphite, was also not observed. In the used 50 wt% PO_4/Nb_2O_5 catalyst, we observed that the $NbPO_5$ crystal grew well.

We carried out gas phase glycerol dehydration using a PO_4/Nb_2O_5 catalyst. In our experiment, the best catalytic performance was obtained using 20 wt% PO_4/Nb_2O_5. We believe that 20 wt% PO_4/Nb_2O_5 has the appropriate BET surface area and acidity, resulting from its amorphous state, for gas phase glycerol dehydration.

Table. 1. Binding energies of the fresh catalyst determined by XPS

Catalyst	Binding energy (eV)		
	Nb $3d_{5/2}$	Nb $3d_{3/2}$	P 2p
20 wt% PO_4/Nb_2O_5	207.63	210.36	132.26
50 wt% PO_4/Nb_2O_5	206.21[a]	208.99	132.61

a. NbO_2 binding energy

4 Conclusions

In this work, we synthesized PO_4/Nb_2O_5 catalysts using a simple impregnation method and produced acrolein through gas phase glycerol dehydration. Above 40 wt% of phosphoric acid in PO_4/Nb_2O_5, nanosized $NbPO_5$ crystals were formed. We confirmed the presence of this crystal through XRD, XPS, and TEM analysis. The $NbPO_5$ crystal is formed because an increase in phosphoric acid loading decreases the niobium binding energy. The best performing catalyst was 20 wt% PO_4/Nb_2O_5. From our results, it is evident that the appropriate BET surface area and acidity are important, which differs from our previous work on liquid phase dehydration [2].

Keywords: Fischer-Tropsch synthesis, Co-based catalyst, Al-SBA-15, mesoporous, materials

1 Introduction

Fischer-Tropsch Synthesis (FTS) is regarded as a key technology in GTL-FPSO process which produces liquid fuels such as gasoline, diesel and wax from the synthesis gas [1-3]. The use of mesoporous silica as supports for FTS catalyst has been explored. Mesoporous molecular sieves not only allow for higher active metal dispersion but also make uniform pore size distribution. Zeolite materials are also used in FTS reaction and because of the acid site which improves isomerization during the reaction under way, it was preferred to use in upgrading and FTS reaction. However there are some reports about silanol groups in zeolite which lead to retard the reduction of metallic cobalt [4]. Furthermore by the Anderson–Schulz–Flory (ASF) distribution of FTS reaction, it is inherently found to have a wide-range of hydrocarbon distribution from methanol to heavy waxy product. Moreover, the hydrocarbon selectivity towards gasoline range products is generally known to be limited to a maximum of 48 mol% [5]. In this work, we synthesized Co-based catalyst supported on the modified SBA-15 to obtain the mild reduction condition and selective products with certain carbon number distribution.

2 Experimental/methodology

For the comparison of the acid site on the catalyst support, modified SBA-15 was prepared with the molar ratio of Si/Al= 0, 5, 7 and 10 and ZSM-5 was also measured against SBA-15. Supports were prepared by conventional method with the use of tetraethyl orthosilicate (TEOS) and aluminum isopropoxide as a silica and aluminum precursors, respectively [6]. Nonionic triblock copolymer $EO_{20}PO_{70}EO_{20}$ (P123, Aldrich) was used as surfactant. Catalysts were prepared by impregnation method using cobalt nitrate as an active metal precursor, and were characterized by N_2 physisorption, NH_3-TPD, TPR, XRD, TGA, SEM and TEM. During the reaction, product gases (C_1-C_9) were analyzed by online GC, and higher hydrocarbons (C_5-C_{44}) were analyzed by offline GC and GC-MS.

Table 1. Physical Properties of Prepared Catalysts

Catalysts	BET S.A. (m^2/g)	Total Pore Volume (cm^3/g)	Average Pore Diameter (nm)	Micro/MesoPorous
SBA-15	857	1.02	5.8	Mesoporous
10-Al-SBA-15	690	1.14	6.6	Mesoporous
7-Al-SBA-15	403	1.03	10.9	Mesoporous
5-Al-SBA-15	371	1.08	11.6	Mesoporous
Co-ZSM-5	174	0.24	5.55	Microporous

3 Results and discussion

The physical properties of prepared supports were obtained by the N_2 physisorption analysis. With increase in the ratio of the amount of alumina to SBA-15 materials, the BET surface area was decreased and the average pore diameter was increased. Interestingly, the total pore volume of catalysts was almost the same throughout the SBA-15 series catalysts despite the change in alumina ratio. Reducibility of prepared catalysts was measured by using the H_2-TPR method. It was found that the Co-SBA-15 and Co-ZSM-5 catalysts have similar reduction profiles. However, in case of the alumina added SBA-15 catalyst, much broader and blunt reduction peaks were shown due to the formation of segregated cobalt and alumina support. By controlling the amount of alumina, we can obtain the catalyst which has the prop-er reducibility and appropriate interaction between the cobalt and support materials.

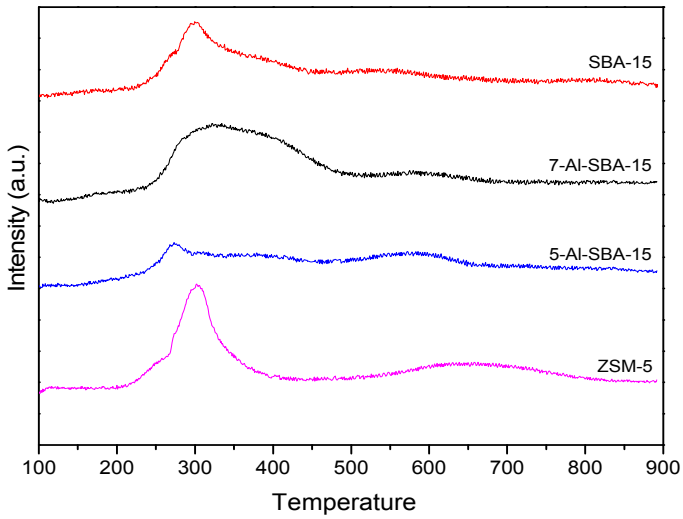

Fig. 1. H_2-TPR of prepared catalysts.

4 Conclusions

It was found that with the increase of the Si/Al ratio, the interaction between cobalt metal and support was increased. It was considered that the strong interaction between the active metal and support makes the catalysts hardly reducible materials. Indeed, by adding the alumina to SBA-15, the weak acid site was also increased and the isomerization during the reaction was activated. Therefore it showed relatively middle range hydrocarbon distribution compared with the catalyst which uses SBA-15 as a support.

Keywords: glycerol steam reforming, hydrogen catalyst, nickel, kinetics

1 Introduction

In recent years, hydrogen energy has received much attention as an alternative energy. Therefore, extensive research has been conducted to find sustainable sources for hydrogen. Biomass is a promising candidate for hydrogen production because it has relatively high hydrogen content, and nontoxic. During the production of biodiesel, glycerol by-product is formed approximately 10% [1-2]. Some studies have been carried out on glycerol steam reforming by the different metal and nobel metal catalysts [3]. Previous studies have shown that Cerium and iron increased the reducibility of the Ni-based catalysts [4-5]. In this paper, we examined the kinetics of glycerol steam reforming and investigated the glycerol reaction order and activation energy using Ni-Fe-Ce/Al_2O_3 catalyst.

2 Experimental/methodology

The Ni-Fe-Ce/Al_2O_3 catalyst was prepared by impregnation method and as follows. First, Al_2O_3 was impregnated with ferric nitrate and cerium nitrate solutions, dried at 100 °C for 24 h, and calcined at 500 °C for 5 h in air. Secondly, the Fe-Ce/Al_2O_3 catalysts were further impregnated with a Ni nitrate solution, dried, and then calcined again using the method described above.

This experiment, the glycerol steam reforming, was conducted in a 6-mm ID fixed-bed quart reactor containing 0.03g Ni-Fe-Ce/Al_2O_3 catalyst at atmospheric pressure and temperature of 723-823K.

Ar gas was used as carrier gas. 12-30 wt.% glycerol solution (corresponding to $\frac{W}{F_{A0}}$ of 0.65-2.03) was used as feed to ensure stoichiometrically excess steam. The glycerol solution was fed into the reactor by an HPLC pump, vaporized in a preheater (563K) and passed over the catalyst inside the reactor. Reactor outlet gases were separated into a liquid phase and a gas phase in a condenser. The gaseous products were analyzed on-line by gas chromatography.

3 Results and discussion

The experimental data is obtained in kinetically controlled reaction regime of negligible mass transport limitations. In this paper, internal transport in the reaction system was ignored, because commercial 1-mm ball-type was employed. External transport as minimized by selecting suitable total flow rate, and there was no significant change in glycerol conversion when the total flow rate exceeded over 300ml/min.

The values of activation energy and reaction order based on the power-law model calculated with experiment data. Fig. 1 shows the relation between glycerol conversion rate and glycerol

solution concentration. Fig. 2 is Arrhenius plot. Thought these plots, the activation energy and reaction order were found to be 40.81 kJ/mol and 0.349, respectively.

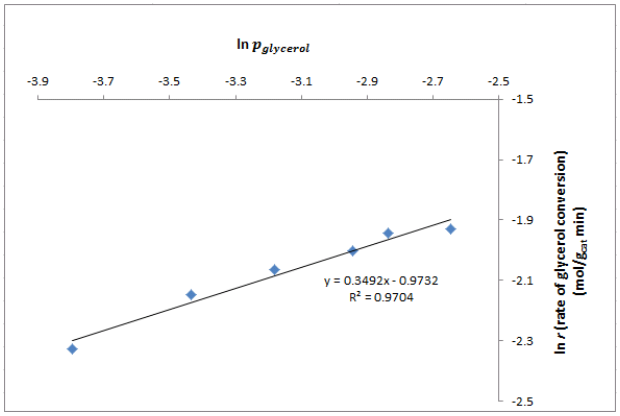

Fig. 1. A plot of ln *r* vs. ln$P_{glycerol}$ at 723K

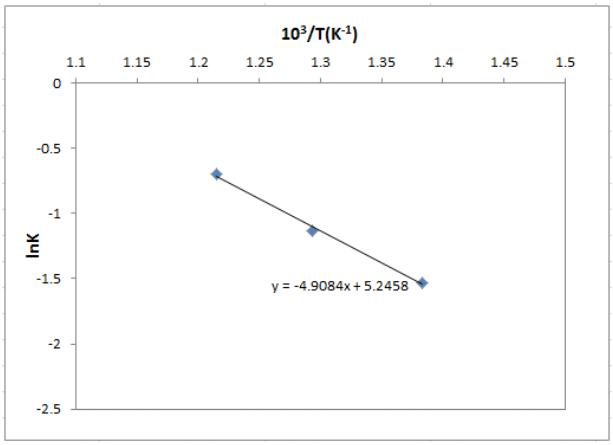

Fig. 2. A plot of 1000/T vs. *ln K* at atmospheric pressure

4 Conclusions

The experimental data is obtained in kinetically controlled reaction regime. The activation energy and the reaction order for the glycerol steam reforming reaction using Ni-Fe-Ce/Al_2O_3 catalyst were found to be 40.81 kJ/mol and 0.349, respectively, based on a power-law model.

Keywords: biocatalysts lipase' activity, nanocarbon-in-silica, matrix, interesterification, biodiesel

1 Introduction

Nowadays, considerable attention has been given to the lipase-active biocatalysts for industrial scale implementation because these enzymes are powerful tools for catalyzing not only hydrolytic breakdown of fats and oils with subsequent release of free fatty acids, diglycerides, monoglycerides, and glycerol, but various reverse reactions of synthesis – triglycerides' esterification, interesterification, as well as acidolysis, alcoholysis, aminolysis. Therefore, R&D of commercially attractive heterogeneous biocatalysts, as well as proper selection of strategy to improve their properties (enzyme activity and stability) by appropriate procedure of lipase' immobilization is still an exciting goal. It has been argued that the using the whole or partially destroyed microbial cells as active components for biocatalysts and preparation of the whole-cell biocatalysts are more profitable for industry.

This research was devoted to the preparation of heterogeneous biocatalysts by entrapment of lipase-active components, such as whole cells or cells' lysates of an *Escherichia coli* recombinant strain (r*E.coli*/lip), inside silica xerogel, as well as inside {nanocarbon-in-silica} composites. Nanocarbons such as multiwalled carbon nanotubes and carbon nanospheres were included inside SiO_2-matrix together with lipase-active components. The properties (enzyme activity and stability) of the biocatalysts were studied in dependence of physical-chemical characterictics of the nanocarbons included. The prepared lipase-active biocatalysts were examined for oil triglycerides' hydrolysis and interesterification.

2 Experimental

Heterogeneous lipase-active biocatalysts were prepared by entrapment of lipase-active components r*E.coli*/lip inside silica xerogel and {nanocarbon-in-silica} composites as described in [1–3]. Multiwalled carbon nanotubes (CNT) with different tubes' diameters (Ø9–11 nm, S_{sp}=320 m^2/g, "thin" and Ø20–22 nm, S_{sp}=140 m^2/g, "thick") and carbon nanospheres with bulbous structure (Ø5–6 nm, S_{sp}=485 m^2/g, "nano-onion") were included as functional additives. CNTs were included both as aggregates larger than 150 nm obtained in a pyrolytic installation and as suspension after dispersion using ultrasonic disintegrator. The prepared biocatalysts had the following optimal compositions, in wt% of dry substances: r*E.coli*/lip cells or cells' lysates – 20–40, nanocarbons – 0–10, maltodextrin – 0–20, SiO_2 – balance to 100. The moisture of dried granules of biocatalysts (0.1 to 2 mm in size) averaged between 7–10 wt%.

The activity of prepared biocatalysts was determined in a periodic batch reactor or in a continuous packed-bed reactor. The emulsified tributyrine was used as substrate for hydrolysis at 20°C. Oil-fat blends of vegetable oils (⅔) and of fully hydrogenated one (⅓) were used as substrates for interesterification at 60–75°C. The triglycerides' esterification for the methyl- or ethyl fatty acids' esters (biodiesel) was carried out with participation of methyl- or ethyl-acetate at 40–50°C, hexane being used as solvent.

3 Results and discussion

Triglycerides' hydrolysis by the silica- and {nanocarbon-in-silica} biocatalysts was studied. It was found that the activities of the prepared biocatalysts depended strongly on the characteristics of nanocarbons included inside SiO_2-xerogel, in particular their specific area and dispersity. The biocatalysts with included aggregates of "thick" CNT were the 1.3–2 folds more active in comparison with the reference {no carbon-in-silica} biocatalysts; whereas the biocatalysts prepared with dispersed "thin" CNT possessed the lowest activity.

Silica- and {nanocarbon-in-silica} biocatalysts prepared by entrapment of r*E.coli*/lip lysates were studied in the process of interesterification in oil-fat blends. In this case, basing on the effect on conversion (*x*,*%*) in the 1st reaction cycle the included nanocarbons can be arranged in the following order: no nanocarbon (*50%*) > aggregated "thick" CNTs (*35%*) ≈ aggregated "thin" CNTs (*35%*) > dispersed "thin" CNTs (*25%*) > "nano-onion" (*20%*). After 4th reaction cycle, the {"nano-onion"-in-silica} biocatalyst deactivated completely, as well as the {CNTs-in-silica} biocatalysts retained up to ~30% of initial activity.

It was found that the prepared biocatalysts exhibited high operational stability in the process of biodiesel production by interesterification of sun flower oil and methyl- or ethyl-acetate and operated for more than 1000 h, the half-life time being equal to 720 h at 40°C (Fig.).

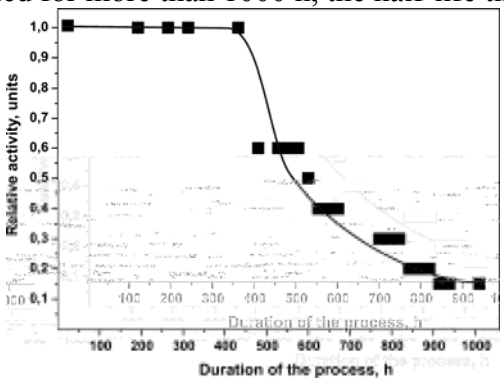

Fig. Interesterification' activity of the lipase-active biocatalyst during the process of biodiesel production

Conditions: 40°C, 0.1 M vegetable oil and 2.3 M ethyl-acetate in hexane, a batch reactor, 150 rpm

4 Conclusions

Lipase-active heterogeneous biocatalysts were prepared by entrapment of recombinant r*E.coli*/lip whole cells or their cells' lysates inside silica xerogel, as well as inside {nanocarbon-in-silica} composites. The study on the effect of the included nanocarbons, in particular multiwalled carbon nanotubes (CNTs) with different diameters and dispersity, as well as nanospheres on the initial activity of the prepared biocatalysts was carried out in the processes of triglycerides' hydrolysis and interesterification. It was shown that the use of aggregated "thick" CNTs yielded the biocatalysts with the highest initial activity in the tributyrine' hydrolysis; 250 U/g and 1000 U/g for entrapped whole cell and cell' lysates respectively. The lowest activities of the biocatalysts were determined using dispersed "thin" CNTs and "nano-onion" uniformly distributed inside biocatalysts; 50 U/g and 400 U/g for entrapped whole cell and cell' lysates respectively. In the case of triglycerides' interesterification, the {no carbon-in-silica} biocatalysts prepared by entrapping r*E.coli*/lip lysates and maltodextrin inside pure SiO_2-xerogel (no carbon) possessed the highest triglycerides' interesterification activity, half-life time being more than 70 h and 720 h at 75°C and 40°C respectively.

Keywords: selective oxidation, liquid-phase oxidation, ethylbenzene, i-propylbenzene, cymene, N-hydroxyphtalimides, mathematical models

1 Introduction

During oxidation of some alkylaromatic hydrocarbons, in particular, ethylbenzene, i-propylbenzene, cymene, the corresponding hydroperoxides are formed and widely used in industry as a basis for initiation additives or intermediates in synthesis of valuable products of chemical engineering. To accelerate the liquid-phase oxidation of hydrocarbons to hydroperoxides various catalytic systems have been proposed. However, these processes are still carried out in industry without catalysts. The problem of catalytic oxidation of the corresponding hydrocarbons is connected with the fact that known catalytic systems indeed increase the rate of their oxidation, however, they do not provide adequate selectivity towards hydroperoxides. This can result in uncontrollable decomposition of hydroperoxides at the strengthening stage followed by thermal explosion.

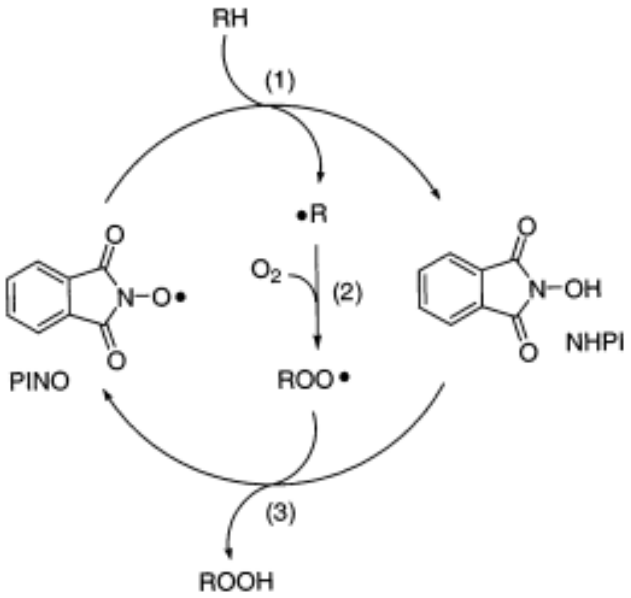
The research carried out both in Russia and abroad has demonstrated that some derivatives of N-hydroxyphtalimides are highly active and selective catalysts of hydroperoxide formation in oxidation of alkylaromatic hydrocarbons, including i-propylbenzene, ethylbenzene and cymene. They provide new opportunities for intensification of existing processes in industry.

2 Experimental

In the present work the results of model tests of the process of hydrocarbons oxidation in conditions close to industrial process are shown. Technical hydrocarbons, which were not additionally purified, were used as a feed. Basic experiments were carried out in the presence of hydroperoxides, which were specially released from industrial oxidate of the corresponding hydrocarbon via sodium salt. N-hydroxyphtalimides were synthesized using hydroxylamine and corresponding phthalic anhydride according to our method. The purity of obtained catalysts was determined using spectral methods. Analysis of oxidation reaction mass was carried out iodometry and chromatography methods. The off-gases containing O_2, CO, CO_2, H_2, CH_4 and heavier hydrocarbons were analyzed chromatographically. Catalytic oxidation of i-propylbenzene has been widely studied, and the results obtained give the ground to apply them in industry.

3 Discussion

High selectivity of hydroxyperoxide formation in the presence of phtalimide systems even at high conversions of i-propylbenzene (30-40%) demonstrate that phtalimides do not practically participate in hydroperoxide decomposition, i.e. strengthening of oxidate under these conditions is technologically reasonable. A number of researchers consider that high rate and selectivity of hydroperoxide formation are connected with proceeding of the main reactions (1) – (2) – (3) according to the following scheme:



Another important aspect of intensification of i-propylbenzene industrial oxidation process in the presence of phtalimide systems, in particular, N-hydroxyphtalimide, is high conversion of the feed per single run. 40% i-propylbenzene conversion was achieved at 130 ^{o}C per 1 h, which is two times higher compared to industrial process. It is noteworthy that selectivity towards i-propylbenzene remains above 90 %. If i-propylbenzene oxidation is carried out with 17-20 % conversion (typical for industrial process), selectivity reaches 94-96 %. If applied industrially, the obtained results may provide significant economic impact, in particular, in co-production of phenol and acetone, styrene and propylene oxide due to increase in reactor productivity, significant off-loading in oxidate fractionation node as well as reduction of production wastes.

In the present work a comparative results of kinetic studies of catalytic oxidation of ethylbenzene and i-propylbenzene are shown. Mathematical models of the processes have been developed taking into account the parameters of instrumentation of industrial processes. Technical-and-economic indices of corresponding processes in the case of oxidation catalysts based on hydroxyphtalimides have been determined. The only limitation for application of new method in existing industry is connected with possible difficulties to provide heat removal in oxidation reactors. To overcome the problem one should increase the heat-exchange surface of built-in coils and use fractional air supply to different levels of reactor. The calculation results demonstrate that process performance in accordance with proposed method, in particular, production of hydroxyperoxide, would allow using only one fractioning step instead of two in the currently used method, reduce energy intensity of production by 40±5 %, increase the productivity of reactor section by 60-70 %. This may result in significant economic effect. Higher economic effect could be reached, if one develops new oxidation reactors operating in different hydrodynamic modes taking into account kinetics of i-propylbenzene oxidation in the presence of phtalimide catalysts.

4 Conclusions

The fundamentals of industrial oxidation of ethylbenzene, i-propylbenzene, cymene and other hydrocarbons are quite similar, thus, one can expect high economic effect for these processes. However, to make final decision on their application in industry it is necessary to carry out pilot tests and develop all technological steps of production and separation of corresponding products taking into account the backflow recycle and catalysts. Results of pilot tests can support the propositions on high effectiveness of application of new catalytic systems and provide required information to prepare initial data for design basis.

Keywords: photocatalysis, TiO_2/SiO_2, composite, pollutants degradation, supported nanoparticles, UV radiation, visible light

1 Introduction

Industrial growth causes increasing problems connected to pollution of water streams but common purification techniques such as biochemical oxidation and physical treatment processes have several disadvantages. Since the discovery of the photocatalytic properties of TiO_2 by Fujishima and Honda in 1972 [1], relevant research efforts focussed on photocatalysis as an efficient alternative for the degradation of pollutants. The decrease of the size of the active phase to the nanoscale is a powerful approach to enhance photocatalytic activity [2]. However, nanoparticles suffer from agglomeration during the reaction, which leads to loss of surface area and of accessibility of the active phase. Here, we present an original strategy to stabilise TiO_2 nanoparticles by embedding them in a porous silica matrix while fully preserving their accessibility by ensuring their location at the surface of the material.

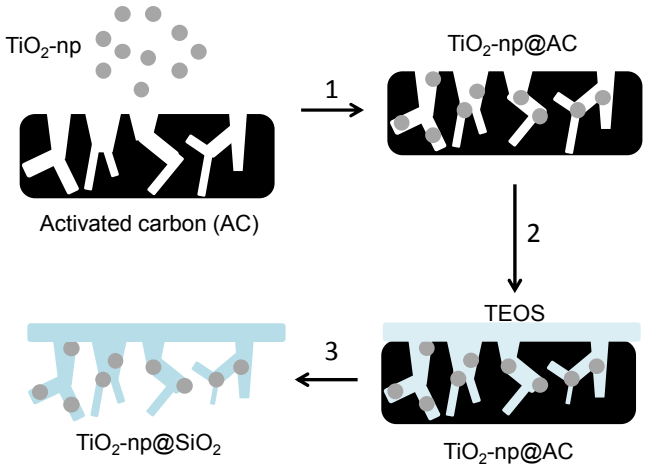

Fig. 1. The multi-step synthesis method used to produce a photocatalyst with highly accessible TiO_2 nanoparticles.

2 Experimental section

TiO_2 nanoparticles were embedded at the surface of SiO_2 through a multistep synthesis procedure (Fig. 1). First, the desired amount of TiO_2 nanoparticles was deposited on activated carbon (1). Then, the TiO_2-carbon composite was impregnated with TEOS (2). Finally, the material was calcined to burn off the carbon support and to produce TiO_2-SiO_2 photocatalysts with fully accessible nanoparticles and high surface area (3). A series of materials with different ratios between TiO_2 and SiO_2 was prepared following this method. The photocatalytic activity

was tested in the degradation of phenol and rhodamine B (1 mg/ml of photocatalyst, 200 ppm aqueous solution of pollutant). The mixture was stirred for 1 h in the dark to achieve adsorption/desorption equilibrium before irradiation for the selected time (typically 3 h).

3 Results and discussion

Characterisation by means of TEM (Fig. 2), N_2-physisorption and XRD indicated that the composite TiO_2-SiO_2 materials display high surface area and discrete TiO_2 nanoparticles dispersed on the SiO_2 support. Both these properties are fundamental for the photocatalytic performance. Indeed, the composite materials showed higher photocatalytic activity compared the TiO_2 P25 benchmark in the degradation of different types of probe molecules (phenol and rhodamine B) under UV radiation. The highest degree of photocatalytic degradation of the pollutants was obtained with the composite with a 60% loading of TiO_2, which reached 72% degradation of rhodamine B compared to 45% obtained with TiO_2 P25 under the same conditions (Fig. 2). Remarkably, these photocatalysts are also active under visible light due to the presence in the structure of residual C atoms from the carbon template. The TiO_2-SiO_2 photocatalysts could be efficiently recycled in consecutive tests.

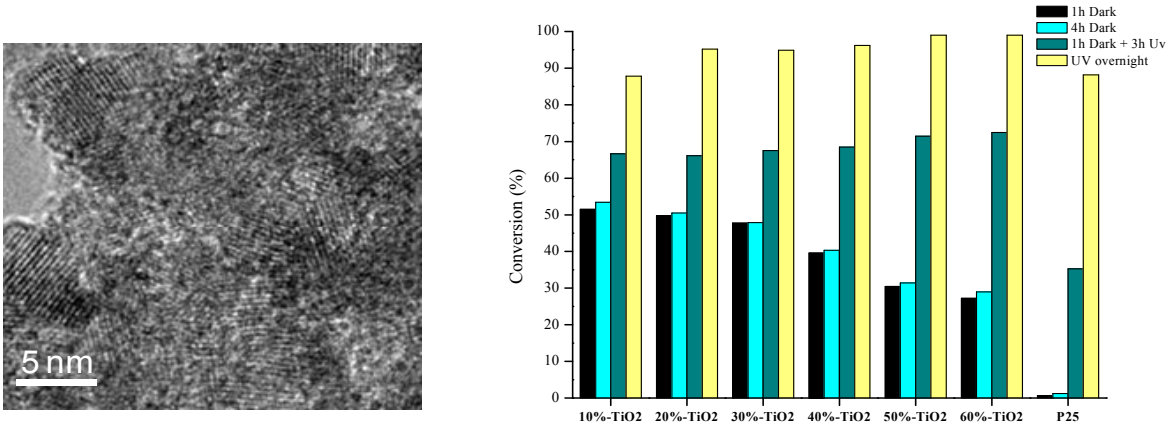

Fig. 2. TEM image of the composite material showing individual and crystalline TiO_2 nanoparticles embedded on a SiO_2 support (left). Photocatalytic degradation of Rh.B under UV radiation (right).

4 Conclusions

A new synthesis method was developed to prepare a series of TiO_2/SiO_2 composites in which TiO_2 nanoparticles are embedded at the surface of SiO_2. The obtained materials display high surface area and well-dispersed, highly accessible TiO_2 domains. These features led to an excellent photocatalytic activity in the degradation of pollutants. This synthesis method is of general applicability and can be promising for preparing supported nanoparticles with different composition.

Keywords: photocatalysis, titanium dioxide, uranyl, nitrate, visible light, volatile organic compounds

1 Introduction

Photocatalysis is known as a promising method for destruction of various toxic pollutants. TiO_2 was selected as the most active metal oxide semiconductor among heterogeneous photocatalysts and today it plays an important role in many industrial and technological processes, environmental and biomedical applications. However pure TiO_2 photocatalysts are active only under the mild UV irradiation with photon energy equal or higher than its band gap (3.2 eV). On the other hand, ultraviolet or near-ultraviolet radiation (λ<400 nm) occupies only about 4% of the solar light spectrum [1]. In order to utilize solar light efficiently in the visible region (λ>420 nm) which covers large range of the solar spectrum, the development of visible-light-driven photocatalysts has started over last decades [2].

It is well known that uranyl ions in water could be synthesized by visible light and after excitation the oxidizing potential of uranyl ions becomes as high as 2,6-2,7 V [3]. At the same time the gas phase photocatalytic oxidation of organic species with uranyl-modified photocatalysts was weakly investigated. The influence of spectral characteristics, uranyl quantity and nature of the support were not investigated. These questions were the subject of current research.

2 Experimental/methodology

In the current work photocatalyst samples were synthesized by incipient wetness impregnation method with the use of TiO_2, γ-Al_2O_3 and SiO_2 as support. The $UO_2(NO_3)_2$ content was varied from 0.2 to 10 wt.%.

The activity of catalysts was measured in the reaction of acetone and ethanol vapor photooxidation in the static reactor at room temperature. The high pressure Xe-lamp and the 450 nm LED were used as the light sources. The visible regions of the spectrum was cutoff with the Optical glass filter ZhS-11 were used to cutoff the visible region (λ > 420 nm) from the Xe-lamp irradiation. Ethanol, acetaldehyde and CO_2 gas concentration were measured with the gas chromatograph equipped with FID and with the FTIR spectrometer equipped with gas cell.

UV-VIS spectroscopy with the diffuse reflectance attachment, XPS spectroscopy and fluorescence methods were used for additional photocatalysts characterization.

3 Results and discussion

Results of investigation demonstrated that:

All the synthesized photocatalysts oxidize ethanol and acetone even under the visible light with wavelength higher than 470 nm. Acetaldehyde was registered as the intermediate of C_2H_5OH photocatalytic oxidation whereas CO_2 was registered as the final products of both ethanol and acetone vapor PCO (Figure 1, **a**).

Although pure unmodified TiO_2 was not active under visible light (λ>420 nm) it was found to be the best support for uranyl nitrate and the $UO_2(NO_3)_2/TiO_2$ sample demonstrated highest photooxidation rate up to 470 nm incident light wavelength (Figure 1, **b**) [4].

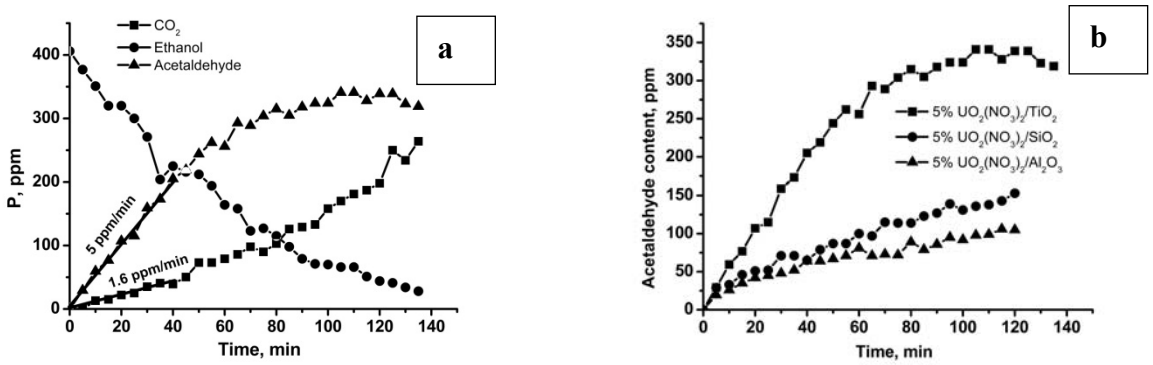

Fig. 1. (**a**) Kinetic curves of the ethanol vapor removal and CO_2 and acetaldehyde accumulation during the PCO of ethanol vapor in the static reactor under visible light; (**b**) Kinetic curves of the acetaldehyde accumulation during the ethanol PCO on the $UO_2(NO_3)_2/TiO_2$, $UO_2(NO_3)_2/SiO_2$ and $UO_2(NO_3)_2/Al_2O_3$ samples under visible light (λ > 420 nm)

Photocatalytic activity of all uranyl modified photocatalysts depended on the uranyl content and the type of support (Table 1).

Table 1. Photocatalytic activity of the uranyl modified catalysts with different $UO_2(NO_3)_2$ content under visible light (λ>420 nm) in the ethanol vapour PCO.

Sample	U content, wt. %	Rate of acetaldehyde formation, ppm/min	Rate of CO_2 formation, ppm/min
0.5% $UO_2(NO_3)_2/TiO_2$	0.41	1.6	0.25
2% $UO_2(NO_3)_2/TiO_2$	1.7	3.0	0.63
5% $UO_2(NO_3)_2/TiO_2$	3.9	5.0	1.6
5% $UO_2(NO_3)_2/SiO_2$	-	0.91	0.01
5% $UO_2(NO_3)_2/Al_2O_3$	-	0.73	0.23

Additional experiments were conducted to investigated the optical properties of the uranyl modified TiO_2. UV-VIS diffuse reflectance spectra revealed that the most active $UO_2(NO_3)_2/TiO_2$ sample absorbs even lower amount of visible light than uranyl modified silica and alumina. Also the luminescence intensity of the $UO_2(NO_3)_2/TiO_2$ is much lower than of the uranyl modified silica and alumina samples.

4 Conclusions

The possible explanation of the increase of uranyl photocatalytic activity when it is deposited onto the TiO_2 surface is its photophysical interaction with the TiO_2 energy states.

Keywords: photocatalysis, nitrate reduction, groundwater purification, tin-palladium bimetal

1 Introduction

Pollution of groundwater with nitrate (NO_3^-) is serious problem in the world. Since NO_3^- is toxic in human body, the World Heath Organization recommends the concentration of NO_3^- in drinking water below 0.8 mmol dm^{-3}. In the present study, we propose a photocatalytic reaction system combining a semiconductor photocatalyst (Pt/TiO_2) and a supported bimetallic non-photocatalyst ($SnPd/Al_2O_3$) dispersed in water. In this photocatalytic system (Pt/TiO_2-$SnPd/Al_2O_3$ system), H_2 is formed by a photocatalytic reaction over Pt/TiO_2 with the aid of a sacrificial compound, and the formed H_2 is consumed as a reductant for non-photocatalytic reduction of NO_3^- in water over $SnPd/Al_2O_3$ [1]. Here we applied the photocatalytic system for the purification of real groundwater and investigated the effects of compounds in the groundwater on the photocatalytic and non-photocatalytic performances [2].

2 Experimental

Pt/TiO_2 with 0.5 wt% Pt was prepared by photodeposition method using TiO_2 (Evonik P25), and $H_2PtCl_6 \cdot 6H_2O$ in aqueous methanol solution. $SnPd/Al_2O_3$ was prepared by incipient wetness method using Al_2O_3 (Aerosil Alu C), aqueous $PdCl_2$ solution, and aqueous $SnCl_2$ solution. Loading amount of Sn and Pd were fixed to 2.3 wt% and 4.2 wt%, respectivety. Photocatalytic reduction of NO_3^- in water was carried out in a Pyrex reaction vessel connected to a closed gas circulation system. The catalyst powder of Pt/TiO_2 (500 mg) and $SnPd/Al_2O_3$ (100 mg) were dispersed in the reaction solution (250 cm^3, $[NO_3^-]$ = 1.0 mmol dm^{-3}) with 1.0 mmol dm^{-3} glucose and then the suspension was irradiation with a 300 W Xe lamp ($\lambda > 300$ nm). The products in liquid and gas phases were analyzed by using two ion-chromatographs and a gas-chromatograph, respectively. Groundwater polluted with NO_3^- was obtained from a well in Kitami, Hokkaido, Japan (GW).

3 Results and discussion

The Pt/TiO_2-$SnPd/Al_2O_3$ system effectively and selectively promoted the photocatalytic reduction of NO_3^- to N_2 in aqueous NO_3^- solution (KNO_3-aq), whereas Pt/TiO_2 or $SnPd/Al_2O_3$ alone showed little or no activity under the reaction conditions (Table 1). The photocatalytic activity and selectivity to N_2 for the system were higher than those for the $SnPd/TiO_2$.

Table 1 Photocatalytic reduction of nitrate in water in the presence of various catalyst [1]

Entry	Catalyst	Conversion [%]	Selectivity [%]		
			NO_2^-	NH_4^+	gas[f]
1	Pt/TiO_2	0	---	---	---
2	$SnPd/Al_2O_3$	2	0	31	69

3	Pt/TiO_2 + $SnPd/TiO_2$	39	0	10	90
4	$SnPd/TiO_2$	19	0	23	77

Fig. 1 shows time courses for the photocatalytic reduction of NO_3^- over the Pt/TiO_2-$SnPd/Al_2O_3$ system. In case of KNO_3-aq, complete decomposition of NO_3^- was obtained after 36 h. On the other hand, elevation of the NO_3^-conversion was almost stopped after 12 h in the real groundwater (GW), indicating that the catalysts were deactivated during the reaction in GW. This was due to the negative effect of the compounds in GW on the activities over Pt/TiO_2, $SnPd/Al_2O_3$, or both.

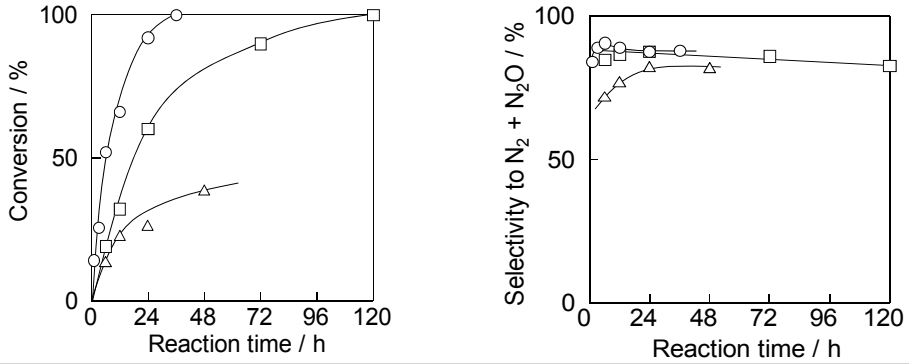

Fig. 1 Time courses for photocatalytic reduction of NO_3^- in (△) GW, (□) GW-Ox, and (○) KNO_3-aq in the Pt/TiO_2-$SnPd/Al_2O_3$ system.

To investigate the effects of the organic compounds in GW on the photocatalytic performance of the Pt/TiO_2-$SnPd/Al_2O_3$ system, we treated GW with photocatalytic oxidation in the presence of Pt/TiO_2 to decompose the organic compounds and conducted the photocatalytic reduction of NO_3^- in the treated solution (GW-Ox) over the Pt/TiO_2-$SnPd/Al_2O_3$ system. The decomposition rate of NO_3^- in GW-Ox was nearly twice that in GW, and NO_3^- was completely decomposed at 120 h. At 100% conversion, the selectivity to N_2 + N_2O was 83%, which was almost the same as that in KNO_3-aq. Thus, removing the organic compounds from GW makes it possible to decompose NO_3^- selectively to N_2 and N_2O. However, the reaction rate for NO_3^- decomposition in GW-Ox was slower than that in KNO_3-aq, indicating that compounds other than the organic ones in GW negatively affected the catalytic performance of the Pt/TiO_2-$SnPd/Al_2O_3$ system.

Thus we further investigated the influence of ionic compounds in GW on the Pt/TiO_2-$SnPd/Al_2O_3$ system. Chloride ion in KNO_3-aq did not affect the conversion of NO_3^- and selectivity. When SO_4^{2-} or SiO_3^{2-} was present in KNO_3-aq, the conversion of NO_3^- significantly decreased. This was because poisoning of Pt/TiO_2 with SO_4^{2-} and SiO_3^{2-}, and that of $SnPd/Al_2O_3$ with polymerized silicate ions. In contrast to anionic compounds, cationic ones in GW did not affect both photocatalytic and non-photocatalytic performances at all.

4 Conclusions

Combining the photocatalyst Pt/TiO_2 and the non-photocatalyst $SnPd/Al_2O_3$ in water produced the effective photocatalytic reaction system for photocatalytic purification of groundwater polluted with NO_3^-, though pretreatment of the groundwater to remove the organic compounds from it was necessary because they poisoned both Pt/TiO_2 and $SnPd/Al_2O_3$. Anionic compounds including SO_4^{2-} and SiO_3^{2-} also lowered the photocatalytic performance of the Pt/TiO_2-$SnPd/Al_2O_3$ system in the groundwater, while there was no influence of cationic compounds on the system.

Keywords: hierarchical, zeolite, nanozeolite, Fe-silicalite-1, heterogeneous, Fenton system, advanced, oxidation, processes, (AOPs)

Design of zeolite materials containing transition metal compounds is of great importance for the development of catalysts for green liquid phase oxidation [1]. Zeolite matrices stabilizes active iron-containing species in the highly dispersed state and protects them against the deactivation [2]. Iron-containing zeolites are effective catalysts both for partial and total oxidation of organic compounds by nontoxic reagents (O_2, H_2O_2) under mild conditions [3]. Total oxidation by means of heterogeneous Fenton-like systems including Fe-zeolite/H_2O_2 is a topical process for water decontamination [4].

The key problem of zeolite catalysts is intracrystalline diffusion constraints resulting in low utilization of zeolite active surface especially in adsorption and catalytic processes involving large molecules [5]. The effective approach for enhancing zeolite surface accessibility is to produce hierarchically porous zeolites, having besides micropores an additional system of meso- and macropores [6].

The present study describes the synthesis of hierarchically porous Fe-silicalite materials with desired texture. Catalytic performance of hierarchically porous Fe-silicalites was studied in total peroxide oxidation of different organic molecules – phenol, EDTA, lignin and clarithromycin lactobionate, belonging to the group of macrolide antibiotics.

1 Results and discussion

To create hierarchically porous Fe-silicalites with desired texture, two main approaches were applied: template synthesis [7] and patterning Fe-silicalite nanocrystals [8]. Template approach was to fill arrays composed of closely packed monodisperse polymer microspheres with Fe-silicalite precursor followed by the hydrothermal synthesis and the calcination of obtained composites, resulting in the formation of 3D ordered macroporous Fe-silicalite materials (Fig. 1a).

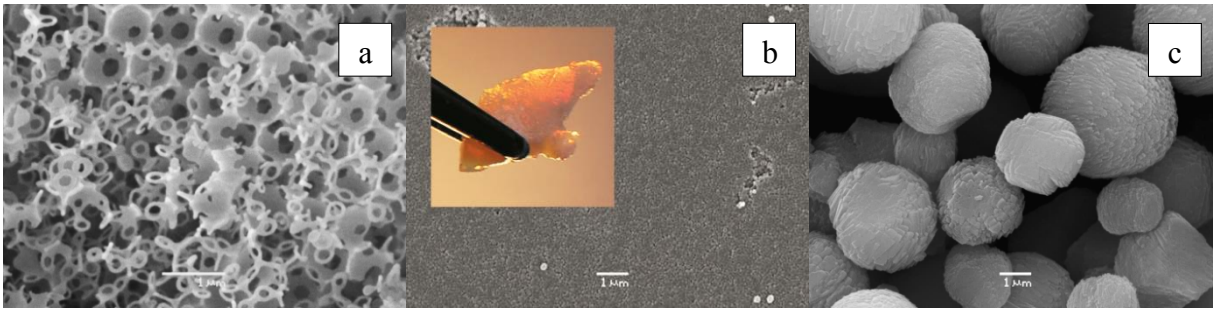

Fig. 1. SEM images of 3D macroporous Fe-silicalite material (a), pellets built of Fe-silicalite nanocrystals (b) and Fe-silicalite microbeads (c). The inset shows a photograph of Fe–silicalite pellets.

The assembling of Fe-silicalite nanocrystals into random and close packing was carried out *via* drying or centrifugation of nanozeolite suspensions, respectively. Fig. 1b shows SEM image and a photograph of Fe-silicalite pellets consisting of closely packed nanobeads. Fe-silicalite pellets built of closely packed nanobeads show good mechanical stability in benzene and water. Large FeZSM-5 microbeads with the average size of 5 μm have been also designed for comparing structural features of nanozeolite materials (Fig. 1c).

The synthesized samples were characterized by a number of methods: laser diffraction analysis, X-ray diffraction, scanning and transmission electron microscopy, energy-dispersive X-ray spectroscopy, argon and nitrogen adsorption measurements, inductively coupled plasma optical emission spectrometry, UV visible diffuse reflectance spectroscopy and temperature-programmed desorption of ammonia.

All hierarchical Fe-silicalites exhibited high crystallinity, high BET surface area (369-550 m^2/g), external surface area (84-277 m^2/g) and total pore volume (0.50-0.75 cm^3/g). Calcined Fe-silicalite-1 materials contained highly dispersed ferric clusters no more than 3 nm in size according to TEM, UV-visible DR spectroscopy and EDS mapping.

Hierarchically porous Fe-silicalites were tested in total liquid phase catalytic oxidation of different organic molecules, including phenol, the natural polymer – lignin, macrolide antibiotic – clarithromycin lactobionate and metal ion complexing agent – EDTA by H_2O_2 at low temperatures (298-323 K) compared with Fe-silicalite microspheres and homogeneous Fenton reagent. The use of heterogeneous Fenton system Fe-silicalite/H_2O_2 allowed increasing the efficiency of hydrogen peroxide utilization for phenol oxidation compared with the homogeneous Fenton system due to the adsorption of phenol on the zeolite surface. Performances of hierarchical Fe-silicalites in oxidation of large organic molecules by hydrogen peroxide were significantly improved *vs.* the reference Fe-silicalite microbeads, resulted from increasing catalytic sites accessibility. Heterogeneous Fenton system based on Fe-silicalites is promising for post-treatment of sewage and liquid nuclear wastes by the destruction of radionuclide–organic acid complexes with the following radionuclides sedimentation. Another direction of heterogeneous Fenton-system practical use is preparation of biomedical samples, containg macromolecules such as DNA and proteins, for radiocarbon analyses by accelerating mass spectrometer.

Keywords: hydrogen, carbon, dioxide, methanation, ruthenium on alumina, catalyst, activation, stability

1 Introduction

CO_2 hydrogenation with renewable hydrogen is an interesting option as a CO_2 Capture and Storage technology (CCS) allowing to reduce the emissions of greenhouse gases and at the same time to produce useful compounds, i.e. hydrocarbons, alcohols, formic acid.

Methanation reaction was widely studied in last decades and applied in industry to convert COx (mainly CO) present in hydrogen prior to ammonia synthesis. Thus the developed catalysts are mainly optimised for CO and not for CO_2 conversion. To date, commercial catalysts optimized for methanation feeds primarily composed of carbon dioxide are apparently lacking. A number of studies are currently undertaken to characterize CO_2 hydrogenation processes and to develop and optimize catalysts [1,2]. Ni/Al_2O_3 are confirmed to be very active in CO_2 methanation [3,4], the coproduction of CO depends on catalyst loading and pretreatment. The aim of the present study was to investigate activation, catalytic activity and stability of Ni/Al_2O_3 and Ru/Al_2O_3 commercial catalysts.

2 Experimental/methodology

Ni/Al_2O_3 and Ru/Al_2O_3 were purchased from ACTA (Pisa, Italy) and were characterised with XRD, IR, UV-vis, H_2-TPR, FE-SEM before and after reaction.

Catalytic experiments were carried out in a fixed-bed tubular silica glass flow reactor, operating isothermally, loaded with 700 mg of silica glass particles (60-70 mesh sieved) and variable amounts of catalyst. Gaseous mixtures of CO_2 and H_2 (with excess H_2) diluted with nitrogen were fed, 75 ml_{NTP}/min. Temperature was varied step by step in-between 523 K and 773 K and then descending back to 523 K. GHSV was varied in between 15000 and 55000 h^{-1}. Experiments have been performed without any pretreatment ("as received sample") or after a prereduction.

Moreover a series of experiment was done in order to determine the kinetic orders of reactant partial pressures and the possible use of the best catalyst in intermittent conditions.

Products analysis was performed on line using a Nicolet 6700 FT-IR instrument with previous calibration using gas mixtures with known concentrations, in order to have quantitative results. Produced water was partially condensed before the IR cell.

3 Results and discussion

With both catalysts the thermodynamic equilibrium was approached at 723K and 773 K while at lower temperature, where methanation reaction is largely favoured the best catalyst result to be Ru-based one in the descending temperature experiment, where the catalyst appears

to be definitively activated. A simple pre-reduction of this catalysts did not improve low temperature conversion, but the activation was observed on stream. In figure 1 the obtained results at 648 K are reported for the two catalysts under investigation. It is possible to observe that ruthenium takes approximately 100 minutes to reach the steady state value, while Nickel takes only few minutes; even though Ru based catalyst demonstrate better performance after activation procedure without coproducing CO as by-product that was instead present with nickel.

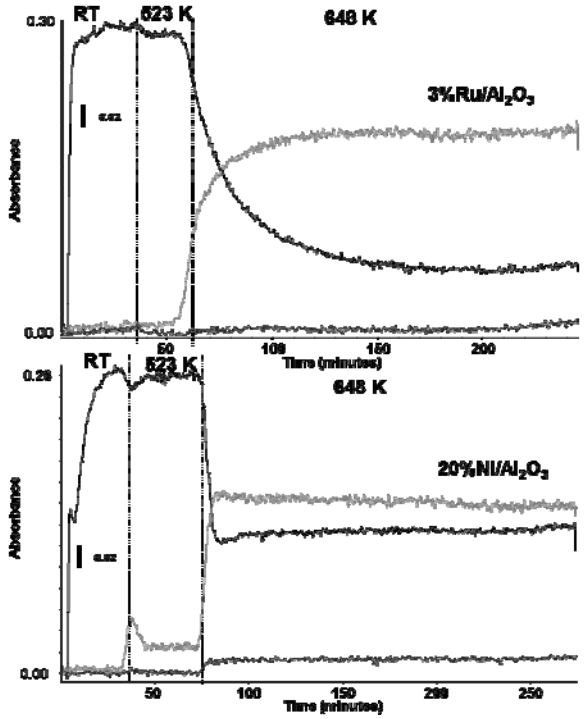

Fig. 1. CO_2, CO and CH_4 absorbances in function of time at RT, at 523 K and 648 K for 3%Ru/Al_2O_3 catalyst (top) and 20%Ni/Al_2O_3 catalyst (bottom) in the following conditions: 6%CO_2, 30% H_2, 64% N_2, 75 Nml/min with a GHSV= 55000 h^{-1}.

4 Conclusions

Both investigated catalysts results to be active for CO_2 methanation in the reported conditions arriving at the displacement of thermodynamic equilibrium at 773 K. Ruthenium based catalysts results to be more active and at 648 K completely selective to methane without any coproduction of CO that was instead evidenced on Ni-based catalyst. 3% Ru/Al_2O_3 is an excellent catalyst for CO_2 methanation, arriving at 96% methane yield with no CO coproduction at 573 K at 30000 h^{-1} GHSV in excess hydrogen. Kinetic orders of reactant partial pressure were successfully determined for both catalysts. To provide optimal activity, Ru/Al_2O_3 catalyst must be conditioned on stream, simple reduction in hydrogen not giving rise to a fully active catalyst. This behaviour suggests that activation implies not only reduction but also other chemical conversion. Ru/Al_2O_3 catalyst was not deactivated after nine cycles thus may be adopted in intermittent condition operations.

Keywords: carbon, capture, utilization, CO_2 hydrogenation, Fischer-Tropsch, iron catalysts, potassium

1 Introduction

The one-pot catalytic hydrogenation of CO_2 to liquid hydrocarbons is a very attractive process to convert a primary green-house-molecule into added value products. A Fischer-Tropsch like chemistry would be desirable, but only a few information is available in the open literature on the reactivity of CO_2 at high temperature and pressure in the presence of H_2 and of catalysts based on VIII group metals [1-3]. The hydrogenation of CO_2 containing streams over Co-based catalyst has been recently studied by some of us [1]. It has been shown that in absence of co-fed CO, CO_2 is easily hydrogenated to methane and light hydrocarbons, while, in presence of CO, CO_2 behaves as inert specie. On the contrary, we have shown that heavy hydrocarbons can be produced on Fe-based catalysts even starting from CO_2 containing feed-gases [2].

Potassium is well known to improve the long-chain hydrocarbons in CO hydrogenation on Fe-based catalysts. Lee et al. [3] reported a positive effect of potassium also in CO_2 hydrogenation, but they examined catalysts containing K loading as low as 3 at.%. Such loadings are appropriate for converting CO/H_2 mixtures, but no information are available for CO_2 rich feed-gases. In this work, the performances of Fe-based catalysts with different K-loadings were comparatively investigated in presence of $H_2/CO_2/N_2$, $H_2/CO/N_2$ and $H_2/CO/CO_2$ mixtures. A particular attention was devoted to the quantification of paraffins and olefins in the products, because their relative content can give informative indications on the nature of the catalytic surface and on the nature of the ad-species.

2 Experimental/methodology

Following the procedure reported in [4], 100Fe/10Zn catalysts (atomic ratio) were prepared by co-precipitation of ferric and zinc nitrates. The obtained precursor was promoted with Cu and K by adopted the incipient wetness impregnation techniques with copper nitrate and potassium carbonate aqueous solutions. Samples with K/Fe atomic ratios of 0.02, 0.04 and 0.1, named with sample tags "Fe2K" (100Fe/10Zn/1Cu/2K), "Fe4K" (100Fe/10Zn/1Cu/4K) and "Fe10K" (100Fe/10Zn/1Cu/10K) were prepared, characterized and tested.

Activity tests were carried out in a lab-scale fixed-bed reactor operating 24/7. Before starting the activity tests, the catalysts were activated at 270°C for 1h, feeding syngas (H_2/CO = 2). Then, the catalysts were tested for few hundreds hours at the following process conditions: 220°C, 30 barg, 6000 $Ncm^3/h/g_{cat}$, H_2/CO_x inlet molar ratio = 1-3.

3 Results and discussion

As shown in Table 1, for K/Fe atomic ratios between 0.02 and 0.10, potassium has only a slight effect on the CO_2 hydrogenation rate. Also, potassium has minor effect on the selectivity to CO, which shows a weak local minimum for the sample Fe4K, in correspondence to which a local maximum in the CO_2 conversion is observed. On the contrary, as shown in Fig. 1,

potassium shows a strong effect on the distribution of the hydrocarbon products. Upon increasing the K-loading, the chain growth probability (α) grows (from 0.56 to 0.64), as well as the fraction of unsaturated species in the products (from 53.6% to 88.6%).

Table 1. CO, CO_2 and H_2 conversions and CO selectivity during CO_2 and CO/CO_2 hydrogenations.

Sample Tag	Fe2K		Fe4K		Fe10K	
Conditions	$H_2/CO_2/N_2$	$H_2/CO/CO_2$	$H_2/CO_2/N_2$	$H_2/CO/CO_2$	$H_2/CO_2/N_2$	$H_2/CO/CO_2$
χ_{CO} [%]	-	10.3	-	11.2	-	12.7
χ_{CO2} [%]	8.9	2.4	9.3	2.6	7.1	2.5
χ_{H2} [%]	16.1	24.9	19.9	30.3	18.4	33.0
sCO [%]	19.5	-	17.3	-	23.7	-

These results can be explained by attributing to potassium a role in stabilizing/promoting the formation the carbides species on the catalyst surface. Upon increasing the K-loading, more carbides and less metal/oxide sites are available: as a consequence, the chain growth process is more effective, and the fraction of olefins undergoing secondary hydrogenations decreases. In addition to this effect, the presence of higher K-contents weakens H_2 chemisorption, thus making the catalyst less hydrogenating.

On the contrary, in the case of the hydrogenation of CO/CO_2 mixtures, K slightly promotes the CO conversion, while both the CO_2 conversion and the product distribution are substantially unaffected. In this case, indeed, the H* concentration on the surface is intrinsically low because of the strong CO adsorption and carbides are stabilized by the presence of high concentrations of CO in the gas phase. Similar effects were also observed during pure CO hydrogenation tests.

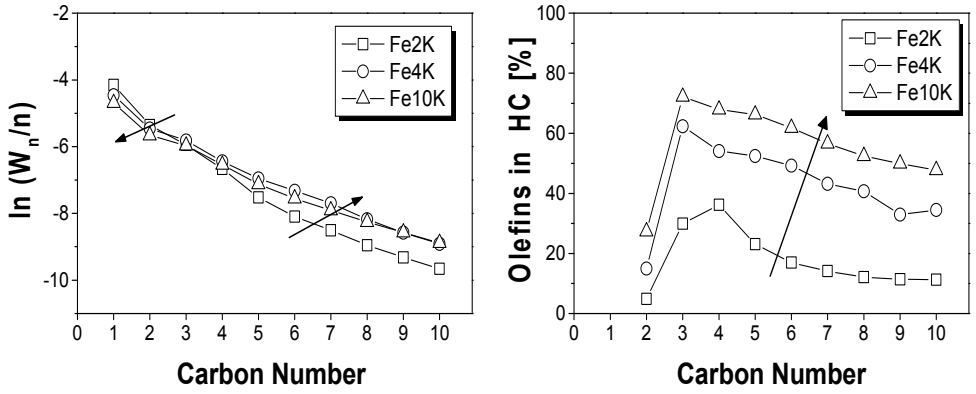

Fig. 1. ASF distribution (left) and fraction of olefins in the products (right) during CO_2 hydrogenation on iron catalysts with different K-loadings (220°C, 30 barg, $H_2/CO_2 = 3$, GHSV = 6000 $Ncm^3/h/g_{cat}$).

4 Conclusions

The presence of potassium dramatically changes the product distribution during CO_2 hydrogenation on Fe-based catalysts. High K-loadings promote the chain growth process and inhibit the secondary reactions of primary olefins. Observed results can be explained in terms of K-effects (i) on the nature of the surface species, (ii) in inhibiting the double-bond shift, and (iii) as electron donor, able to modify the relative adsorption strengths of H_2, CO and CO_2.

Conversion of CO and H_2 to Liquid Hydrocarbons via Dimethyl Ether on Zeolit Catalysts

Ionin I., Bukina Z., Kolesnichenko N.*, Khadzhiev S.

Topchiev Institute of Petrochemical Synthesis RAS (TIPS RAS), Moscow, Russia

- nvk@ips.ac.ru

Keywords: dimethyl ether, liquid hydrocarbons, modified zeolites

1 Introduction

Russia takes a special place with regard to the natural gas stocks (NG) and volumes of its extraction. Chemical processing of natural gas offers the prospects of a step-by-step transition from raw materials export to the export of products of deeper processing that will provide powerful start to the development of domestic innovative economy. The synthesis of hydrocarbons via intermediate conversion of methane in synthesis gas (syngas) is more attractive. The syngas can be converted into hydrocarbons via methanol and/or dimethyl ether (DME) on zeolites (Fig. 1). Zeolites have structure and space-regular cannel system and cavities with severely defined diameters and represent ideal matrix for stabilization of catalytically active sites. High termic and chemical stability of zeolites allow obtaining functional materials which can efficiently work under unfavorable conditions such as higher temperature and corrosive medium.

2 Experimental/methodology

The dates, obtaining in the field of creation of new processes of liquid hydrocarbons production with use zeolite catalysts (ZSM-5 with $SiO_2/Al_2O_3 \geq 30$) generalized in the present work. Catalysts were modified by metals II and VIII groups of periodic system [1,2]. Experiments of catalytic transformation DME to gasoline (DTG) were carried out in the fix bed reactor flow-circulation type at pressure range 5-10 MPa and temperature 340-370 °C, weight velocity for DME ≥2 h-1.

n- Results and discussion

The liquid hydrocarbons are the major products of DME conversion on catalyst modified by metals VIII group of periodic system at pressure 5-10 MPa. Composition of liquid products represents a wide range of hydrocarbons from C_4 to C_{12} (table 1). With comparison Mobil process the liquid hydrocarbons contain small quantity of aromatics.

Depending on the process conditions can be obtained as high-octane gasoline (octane number ≥90, benzene is not present, the durene ≤1 wt.%), and the mixture of hydrocarbons with a low aromatic content (in wt.%: iso-paraffins ≥69, aromatic hydrocarbons ≤7,5, including durene <1), which is essentially analogous to a light synthetic oil, which can be used as a product of processing of associated petroleum gas (APG) for injection into the pipeline. Selectivity is more than 75%.

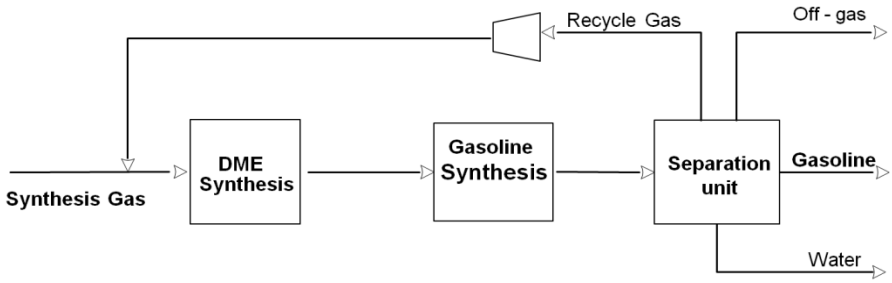

Fig. 1. Conversion of CO and H_2 via dimethyl ether to liquid hydrocarbons

For this process the composition of the catalyst was optimized with further modification of the zeolite matrix by lanthanum. Modification of the zeolite with a high content of lanthanum cations was carried out in an autoclave at a temperature of 220°C and pressure of water vapor (2Mpa). Under these conditions, ion exchange in zeolites undergo in the whole volume of zeolite crystals [3,4].

A study of stable run of catalyst showes, that catalyst activity after 100 hours does not change. Run time of DTG catalyst more than 700 hours.

Table 1. Composition of gasoline produced by Mobil and TIPS RAS

Composition, wt.%	Mobil	TIPS RAS	
		type I	type II
i- paraffin's	51	60	73
n- paraffin's		7	6
naphthenes	7	8	11
aromatics	38	25	≤ 8

4 Conclusions

TIPS RAS has developed the technology of highly selective preparation of the gasoline range hydrocarbons from CO and H_2 via oxygenates (DME and methanol) which is an analog process to the one of TIGAS by Haldor Topsoe company, which uses synthesis gas with the ratio of $H_2/CO = 1$. Advantage of the method developed in TIPS RAS is ability to use the synthesis gas of practically any composition with achievement of high conversion of synthesis gas for pass, thereby reducing the flow of the recycle gas, thus reducing capital costs.

The benefits of this technology can also be attributed to flexibility in orientation to the final product with respect to the characteristics and needs of a particular oil field in certain processed products based on their consumption on the premises and transport possibilities.

Performing Industrial Scale Steam Reforming of CO_2-Rich Gas

Mortensen P.M.*, Dybkjær I.

Haldor Topsoe A/S, Kgs. Lyngby, Denmark

* pmor@topsoe.dk

Keywords: carbon formation, CO_2-reforming, dry reforming, industrial scale

1 Introduction

Synthesis gas production is one of the largest industries in the world with its development stemming back from 1930 [1]. Important bulk chemicals as hydrogen, ammonia, and methanol are produced on the basis of this. Reforming of methane with mixtures of steam and carbon dioxide (in the following referred to as CO_2-reforming) or with carbon dioxide alone ("dry methane reforming", DMR) is receiving much attention as it in theory offers a way of using CO_2, which in many industries is considered as a waste product and environmentally is considered as a polluting greenhouse gas. CO_2-reforming also offers a direct route to production of synthesis gas with a relatively low H_2/CO ratio (in the order of 1 or lower), which is suitable for production of CO rich gas required for, e.g., higher alcohol synthesis or acetic acid [2].

One of the primary tasks in the development of CO_2-reforming or DMR is to find operating conditions in combination with a suitable catalyst to avoid carbon formation. Nickel, cobalt, and noble metal catalysts have been tested as catalyst for CO_2-reforming, with nickel being the most investigated system, as this is the conventional choice in steam methane reforming (SMR) and a relatively cheap catalyst in comparison to noble metals [2].

Haldor Topsoe A/S has many years of experience in reforming. The first startup of a steam reformer designed by Haldor Topsoe A/S dates back to 1956. In the current work, our experience within the field of CO_2-reforming and DMR is summarized, giving the scientific background for the development and explaining how this has been bridged to industrial scale plants [3].

2 CO_2-reforming: from laboratory development to industrial scale

CO_2-reforming and DMR are closely related to steam methane reforming (SMR), and reaction mechanism and kinetics are comparable in the two reactions [3]. This implies that much of the knowledge developed in the field of SMR can be applied on CO_2-reforming as well. Thus, catalysts for CO_2-reforming can be found from already developed SMR catalysts. The primary challenge of CO_2-reforming is carbon formation, as the low H/C ratio of the feed implies that a high potential for carbon formation exists. The primary focus in the development of CO_2-reforming and DMR has therefore also been on the development of catalysts resistant to carbon formation.

A typical industrial scale reforming process will operate at around 30 barg. A mixture of CH_4, CO_2, and H_2O will be fed to a tubular-like reactor at a temperature of ca. 400°C and then heated to an exit temperature of ca. 900°C in order to achieve sufficient conversion of the endothermic reforming reactions. A general tool in designing a SMR, DMR, or CO_2-reforming process, is evaluating the thermodynamics and in this way develop the limits for carbon formation. This will be dependent on operating conditions, but also the catalyst. The limits for carbon formation can be illustrated in a Tøttrup diagram as shown in Figure 1. This shows the severity of operation for a specific gas composition evaluated on the basis of the O/C and H/C ratios of the gas (or the inlet H_2O/CH_4 and CO_2/CH_4 ratios).

Nickel based catalysts, as the general choice for reforming, is prone to carbon formation, which gives some restrictions on the application of this type of catalyst. Industrial scale references of CO_2 reforming with nickel catalysts are illustrated in Figure 1 as the green points.

High fractions of CO_2 have been processed, but this has been accompanied by a high fraction of H_2O in the feed as well as to decrease the severity for carbon formation.

As alternative to the traditional nickel catalyst, the SPARG (Sulphur PAssivated ReforminG) process has been used to perform CO_2 reforming at much more severe conditions with high content of CO_2 and low co-feed of water (see orange points in Figure 1). In this concept, a small co-feed of sulphur is used to partly passivate a nickel catalyst which markedly reduces the potential for carbon formation.

The last process demonstrated in industrial scale is use of a noble metal catalyst. This lowers the affinity for carbon formation significantly compared to Ni and therefore makes reforming possible on much more severe conditions, illustrated by the blue points in Figure 1.

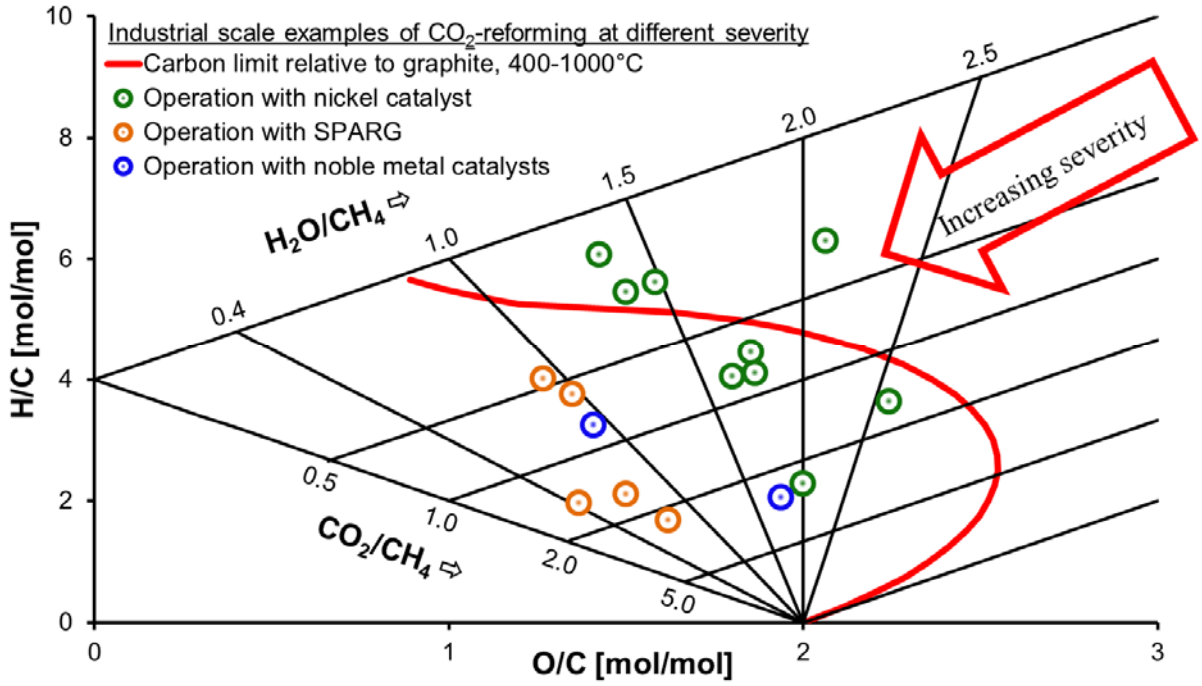

Fig. 1. Tøttrup diagram illustrating the carbon limit with respect to graphitic carbon relative to the O/C and H/C ratio of the gas at 400-1000°C and 25 bar. The O/C and H/C ratio can be translated to inlet conditions of H_2O/CH_4 and CO_2/CH_4 as also shown. Points represent industrial scale references. Green: Nickel catalyst references, Orange: SPARG references, Blue: Noble metal catalyst references.

3 Conclusions

Much work has been done to understand the limits for carbon formation during reforming. These limits are especially challenged when performing CO_2-reforming or DMR. A nickel based catalyst is the industrially preferred catalyst and this has been successfully used for CO_2 reforming as long as a sufficient co-feed of H_2O is present to balance the severity of the gas. Pushing the boundaries further has been done by using the SPARG process approach or noble metal catalysts. This is a clear example of how laboratory work performed to understand the reactions has been bridged to industrial scale.

Methanol Synthesis from Steel Mill Gases

Bukhtiyarova M.[1*], Schlögl R.[1,2]

1 - MPI for Chemical Energy Conversion, Mülheim a.d. Ruhr, Germany
2 - Fritz Haber Institute of MPG, Berlin, Germany

* Marina.Bukhtiyarova@cec.mpg.de

Keywords: methanol synthesis, benzene, catalyst, stability

1 Introduction

The green-house effect is caused by the release of carbon dioxide into the atmosphere from different power and chemical plants [2]. Conversion of CO_2 to methanol by catalytic hydrogenation is recognized as one of the most promising processes to stabilize the atmospheric CO_2 level because of a potentially large demand for methanol as both a fuel and a basic chemical. The methanol synthesis is the way to store electrocatalytically produced hydrogen using fluctuatingly appearing renewable energy [1].

The emitted gases from steel mill can be used for methanol synthesis. As main components the gases contain CO, CO_2, H_2 and N_2 which are gas feed mixture for methanol synthesis. However, the steel mill gases are contaminated by different impurities: N- and S-compounds, polycyclic aromatic hydrocarbons, BTEXs and metals. To understand which impurities should be removed from gas mixture it is necessary to measure their influence on catalytic performance. There is practically no information about influence of BTEX and PAHs in literature. At the first set of experiment we studied the catalytic properties using the gas feed containing benzene as impurity.

2 Catalytic test

Methanol synthesis is performed over a Clariant industrial catalyst. The setup is equipped with liquid storage vessel to collect methanol-water mixture. The temperature of vessel was kept at 5°C to condense the liquid products. The concentration of methanol is measured by gas chromatography-mass spectrometry.

The methanol synthesis is carried out using different gas compositions such as synthesis gas (H_2/CO/CO_2), H_2:CO_2 = 3:1, H_2/CO_2/(500 ppm C_6H_6 in N_2), . This is done to understand how feed gas mixture influence on catalytic behaviour of the industrial catalyst. Catalyst testing is performed at the temperature range of 190 – 260°C and pressure of 15 – 30 bars.

3 Results and discussion

There is discussion about the origin of the carbon atom in methanol in literature: carbon monoxide or carbon dioxide. The early works report that the main source of carbon in methanol molecule is carbon monoxide [3]. However, later on researchers found by different experiments (isotopic labelling of CO_2 [4] or varying the concentration of CO and CO_2 in the feed [5]) that the origin of the carbon atom is CO_2 when the methanol synthesis is performed over Zn-containing catalyst.

The first set of measurement was carried out with H_2/CO_2 = 3:1 molar ratio at different temperatures, pressure of 30 bar and space velocity of 4800 h^{-1}. It was shown that CO_2 conversion and methanol yield increase with temperature since the reaction rate is higher at higher temperature. However, selectivity to methanol decreases (Fig.1), that can be explained by two competitive reactions: methanol synthesis ($CO_2 + 3H_2 = CH_3OH + H_2O$, ΔH = -49,7 kJ/mol) and reverse water gas shift reaction ($CO_2 + H_2 = CO + H_2O$, ΔH = 41,2 kJ/mol). These

two reactions have different thermal effects, high temperature results in higher contribution of reverse water gas shift reaction and production higher CO amount.

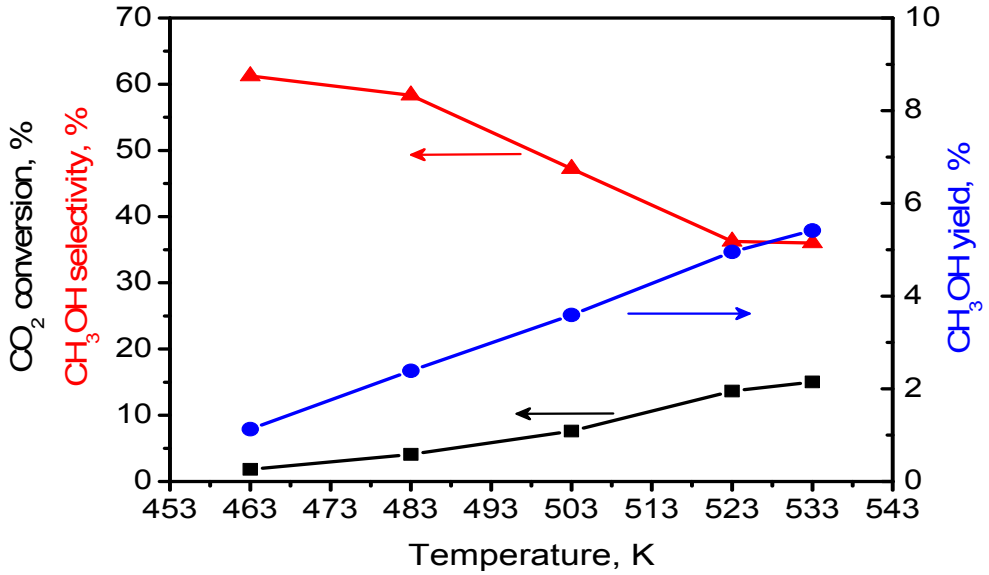

Figure 1. Catalytic performance of industrial catalyst at 30 bars and 4800 h^{-1}

The stability test with benzene in the feed gas was done at 250°C, 15 bars and 4800 h^{-1} for 250 hours. The methanol rate of ~0.27 – 0.30 kg/(kg_{cat}*h) practically does not change during the experiment, that confirms stability of the catalyst at the chosen reaction conditions. The TEM images showed the formation of carbon layer on the copper particles. It is worth to note that toluene also was detected as by-product of reaction. It can be caused by reaction of benzene with carbon-containing molecule following by toluene formation. The methanol synthesis with benzene impurities is done at temperature range of 190 – 260°C to understand which reaction conditions can be critical for using gas containing aromatic compounds.

4 Conclusions

The methanol synthesis performance depends on reaction conditions such as gas feed, temperature, space velocity and pressure. The low temperature and high pressure are preferable for high methanol selectivity and methanol yield. The presence of benzene impurities in the gas mixture does not change catalytic activity with time-on-stream; the catalyst is stable under the reaction conditions.

Molybdenum-Based Catalysts for the Biogas Dry Reforming

Gaillard M., Virginie M.*, Khodakov A.

UCCS - Unité de Catalyse et de Chimie du solide - UMR 8181, Villeneuve d'Ascq, France

* Mirella.Virginie@univ-lille1.fr

Keywords: biogas dry reforming, sulfur, molybdenum, promoters, stability

1 Introduction

In the worldwide current energy situation, it is crucial to develop new pathways for renewable energy production. In Europe, methanisation is an alternate way widely implemented because it produces biogas from organic waste digestion. This gas contains CH_4 and CO_2 and the major advantage for the utilization of biogas is the consumption of the two main greenhouse gases for the production of syngas (H_2, CO), which could be industrially attractive for the Fischer-Tropsch process, eventually setting up a promising waste-to-liquids fuel substitute.The major technological challenge for CO_2 reforming of biogas is to develop catalysts, which can tolerate contaminants such as hydrogen sulphide, present as impurity in the above-mentioned biogas.

The nature of the work herein introduced lies in the development and optimization of catalysts enabling the dry reforming of methane (DRM), paying particular attention to the stability of the studied systems in the presence of sulphur. Some attempts have aimed at developing DRM catalysts in order to improve their performance in terms of cocking suppression. To the best of our knowledge, few researchers have reported sulphur resistant catalysts for CO_2 reforming of biogas [1].

In this context, it is of great interest to design a catalyst with the potential to maintain its activity in the presence of sulphur and/or in a sulphided state.It is widely known that molybdenum (Mo) based catalysts exhibit sulphur tolerance, whereas Ni based catalysts are very sensitive to carbon deposition and S-poisoning [2]. This Ni sensitivity leads to an increasing need for Mo-based catalysts in industry.

The goal of this study was to investigate the effects of the sulphidation on the catalytic performance of Mo-based catalysts. Metallic promoters were used to enhance the catalyst thermal stability and help suppressing carbon deposition. The catalysts were characterized by BET, TPR, XRD, Raman spectroscopy and XPS. An attempt was made to elucidate the relation between the catalysts structure and catalytic activity.

2 Experimental/methodology

A set of Mo supported on γ-Al_2O_3 catalysts, promoted with Ni, Ce, Mg, Pb and W has been synthesized (promoter/Mo ratio = 1/10) by an incipient wetness co-impregnation method. The catalysts were calcined at 600°C for 4h.

The catalytic tests of methane dry reforming (DRM) were performed on the catalysts previously reduced overnight under a H_2 flow.The quartz fixed bed reactor (i.d. 1 cm) wasfed with a CH_4:CO_2:N_2=1:1:1.6 mixture with a total flow of 90ml/min (GHSV = 6800 h^{-1}), at a temperature range of 650°C-800°C. To study the influence of sulphur, the Mo catalysts werepreviously exposed to a H_2S/H_2 flow, and then tested in the DRM conditions.

3 Results and discussion

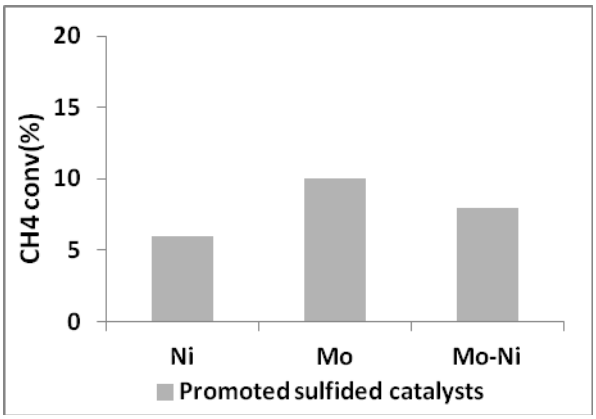

Fig. 1. Methane conversion on nickel and molybdenum sulphite catalysts at 750°C in the presence of sulphur

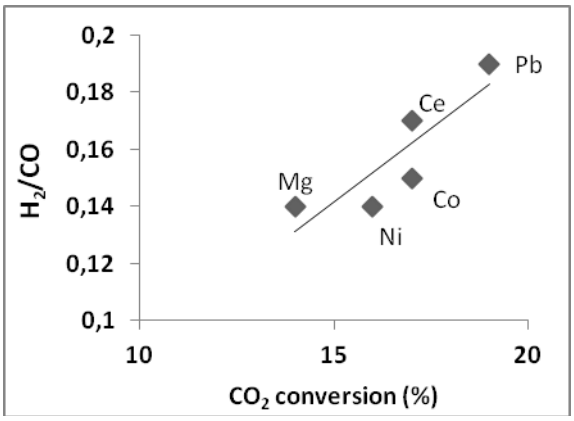

Fig. 2. Influence of the promoter on the RWGS reaction (750°C)

The synthesized then sulphurized catalysts have been tested in DRM in the presence of sulphur (>1%).The results obtained at 750°C, for the Ni reference catalyst, the Mo catalysts alone or promoted with Ni are shown in fig. 1. The sulphided Mo catalyst exhibits twice activity of the Ni catalyst.The Ni, as a promoter of Mo catalyst, does not contribute to increase the catalyst activity. Additionally, TGA was performed on this catalysts and no trace of carbon deposit has been found. Hence, the Mo catalyst presents the benefit of being stable and active without and with presence of sulphur, while the Ni catalyst activity drops drastically.

The fig. 2 displays the H_2/CO ratio obtained in DRM as a function of the CO_2 conversion. The promoters impact on the Reverse Water Gas Shift (RWGS) reaction rate. The Ni favours the hydrogenation reaction and the smallest side reaction ratio is being obtained with Pb promotion, leading to an increase in H_2/CO ratio with the increase in CO_2 conversion.

Moreover, the electronegativity difference between the used promoters and Mo can control the interaction set in the catalyst and therefore the conversions. Yet the catalytic performance is also affected by the Mo dispersion and catalyst reducibility.

4 Conclusions

The Mo catalysts have shown some very promising features for the DRM in the presence of sulphur. They also exhibited higher stability to carbon deposition. The reaction rate and H_2/CO in syngas can be further optimized by efficient use of promoters.Our characterisation results are indicative of strong interaction between the molybdenum and promoters, occurring during catalysts preparation, activation and reaction. .

Keywords: CO_2 hydrogenation, dimethyl ether, Cu-ZnO-ZrO_2 catalysts, zeolites

1 Introduction

In the last years CO_2 hydrogenation into alternative clean fuels, like dimethyl ether (DME), has attracted great interest. DME is characterized by a good profile of combustion (i.e., near-zero smoke, low NOx emissions, …) and a full compatibility with existing infrastructures (transportation and storage facilities as for LPG) or end-users (no modification of the engine required) [1]. Differently from the conventional process in which the DME synthesis by dehydration of methanol (MeOH) represents the second step, the one step production of DME by CO_2 hydrogenation could help to overcome the thermodynamic restriction existing for methanol synthesis, enhancing so the CO_2 conversion [2-4].

In this work the optimization of multifunctional systems, based on the combination of CuZnZr methanol catalysts and HZSM-5 zeolites of different acidity [5,6], is studied. Factors affecting activity, selectivity and productivity of multi-site CuZnZr-zeolite catalysts are discussed. The feasibility of the direct hydrogenation of CO2 to DME, by an integrated catalytic process, is also addressed.

2 Experimental

Three methanol CuZnZr catalysts at different composition were prepared by gel-oxalate coprecipitation method [4] (see Table 1). Their activity was evaluated in the CO_2-to-methanol hydrogenation reaction at 3.0 MPa in the T_R range 180-240°C, using a fixed bed reactor.

Four home-made HZSM-5 zeolites, characterized by different acidity, were prepared by tuning the Si/Al ratio (see Table 2). Catalytic behavior and stability in the presence of water (side-product of reaction) were investigated at atmospheric pressure in the MeOH-to-DME dehydration reaction.

CuZnZr catalysts and HZSM-5 zeolites were combined in different ways: conventional physical mixing or coprecipitation of the methanol precursors in a solution containing zeolite particles finely dispersed. These multifunctional catalysts were tested under the same conditions adopted for methanol synthesis.

3 Results and discussion

Preliminary tests were carried out in CO_2-to-MeOH hydrogenation reaction to find out the best CuZnZr composition suitable to maximize the methanol yield. At 3.0 MPa and 240°C (Tab. 1), all the catalysts exhibited a good activity-selectivity pattern with a similar methanol yield (7-8%). However, a thorough normalization of such data in terms of copper loading pointed out a superior surface functionality of the IT-OX/1 catalyst in CO_2 activation (877 $mol_{CO2}/m^2/h$).

With regard to the catalytic data in the MeOH dehydration reaction, the zeolite with a Si/Al_{bulk} of 38 (UNI-25) showed the best compromise between activity and resistance to the

deactivation of acid sites by water presence (Tab. 2).

At last, a comparison of the performance of multifunctional systems prepared by simple mixing evidenced that there is no need for a great number of acid sites (like in UNIT-25/1-PM) to run the direct CO_2-to-DME hydrogenation reaction with high productivity: a metal-oxide/acid site ratio of 9:1 was enough (see Tab. 3). Furthermore, the generation of a hybrid system by coprecipitation accounts for a superior productivity of DME (*STY*, 0.250 $kg_{DME}/kg_{cat}/h$), as the result of a long-range "homogeneity", both in terms of morphology and sites distribution, due to a better contact among metal-oxide and acid sites.

Table 1. Physico-chemical properties and performances of the CuO–ZnO–ZrO_2 methanol catalysts (T_R, 240°C; P_R, 3.0 MPA, GHSV, 10,000 *N*L kg_{cat}^{-1} h^{-1}; $CO_2/H_2/N_2$, 9/3/1).

		[m^2 g^{-1}]	[%]	no water	water 15 vol.%	[%]
UNI-15	27	360	602	60.5	55.1	-8.8
UNI-25	38	365	515	51.1	54.0	+5.5
UNI-50	68	316	354	42.2	40.8	-3.3
UNI-100	127	382	147	22.2	22.3	+0.8

Table 3. Catalytic multifunctional systems CuZnZr-HZSM5 used in direct CO_2-to DME hydrogenation reaction. (Experimental: T_R, 240°C; P_R, 3.0 MPA, GHSV, 10,000 *N*L kg_{cat}^{-1} h^{-1}; $CO_2/H_2/N_2$, 9/3/1).

Catalyst	Preparation method	MeOH cat/zeolite [wt/wt]	X_{CO2} [%]	*STY* (kg_{DME} kg_{cat}^{-1} h^{-1})
UNIT-25/1-PM	physical mixing	1:1	12.8	0.201
UNIT-25/9-PM	physical mixing	9:1	16.4	0.247
UNIT-25/9-OX	coprecipitation	9:1	16.9	0.250

4 Conclusions

Multifunctional CuZnZr-HZSM5 systems resulted to be effective to produce DME by CO_2 hydrogenation in one step. With respect to the conventional physical mixing between methanol catalyst and zeolite, the incorporation of metal-oxide and acid sites in a single system can enhance the CO_2 conversion, also allowing a higher rate of MeOH formation/dehydration on neighbour surface sites.

New Fiberglass Based Pt Catalyst for VOC and CVOC Removal

Kovalyov E.V.[1], Suknev A.P.[1], Gulyaeva Yu.K.[1], Zaikovskii V.I.[1,2], Kaichev V.V.[1,2], Bal'zhinimaev B.S.[1*]

Keywords: deep, oxidation, VOC, platinum, fiberglass, clusters, SSITKA

1 Introduction

Catalytic abatement of volatile organic compounds (VOCs) is an efficient and environmentally good way to treat these harmful emissions. The catalysts for this process contain a variety of different noble metals, metal oxides and mixtures of those to fulfill the high abatement requirements such as high purification degree, the absence of toxic byproducts (CO, chlorine, phosgene, dioxins) and poison resistance. In spite of a high content of noble metal, Pt/Al_2O_3 is the most active and widely used catalyst. Catalytic performance is known to be determined by the size of Pt nanoparticles. However, the dispersed metal particles tend to beaggregated at high temperatures, thus reducing the catalytic activity. So, the development of active and stable catalyst with a low content of noble metal is a real challenge.

Here, we present the new data on the fiberglass (FG) based Pt catalysts, their preparation and characterization by means of XPS, HRTEM/STEM, UV-Vis DRS, etc., as well as on their high performance in VOC and CVOC (chlorinated VOC) abatement.

2 Experimental/methodology

Commercial leached fiberglass textile modified with 10% Zr was used for catalyst preparation. Platinum was confined in the bulk of glass via ion exchange of protons with a Pt(II) tetramine complex solution. The highly dispersed metal clusters were stabilized in the upper layers of glass fibers by redox treatments at elevated temperatures. Meanwhile, the ratio of metal species located on the external fiber surface to the bulk one was controlled by the heating rate of platinum complexes decomposition, so that in the best catalysts Pt was confined mostly in the bulk. The Pt/FG catalyst where metal is deposited on the external surface of the fiber was prepared using the anionic platinum precursor (H_2PtCl_6). The prepared catalysts were tested in deep oxidation of hydrocarbons (methane, propane, butane, ethylbenzene, etc.) and oxidative destruction of different chlorinated hydrocarbons, including dioxins. The kinetic studies on deep propane oxidation were performed in a flow reactor at wide range of reaction conditions. The SSITKA study using $^{18}O_2$ was carried out in deep oxidation of propane.

3 Results and discussion

Optimization of parameters of the ion exchange process and further redox treatments allowed us to confine a very small 1-1.5 *nm* Pt clusters (Fig. 1A) in the bulk of glass at a depth of 10-20 *nm*. Nevertheless, the reaction rate is not limited by diffusion of the reactants at such a depth. It was shown clearly that the highly dispersed Pt clusters are responsible for activity because the contribution of surface particles to the observed reaction rate at the same platinum content is negligible. Although the Pt content (0.01-0.02% wt.) is 30-60 times lower, the fiberglass catalysts reveal a higher activity in deep oxidation of C_1-C_4 paraffins than traditional/commercial ones. Similar data were obtained in deep oxidation of aromatic

hydrocarbons (Fig. 1B). Basing on the kinetic data for deep oxidation of propane as well as on the dispersion of Pt nanoparticles, we calculated turnover frequencies (TOFs) for fiberglass catalysts and compared with those for Pt supported on alumina and silica. It appeared that TOF of 0.01%Pt/FG is 5-10 times higher in comparison with conventional catalysts. This catalyst revealed high performance in CVOC abatement and did not produce more harmful compounds

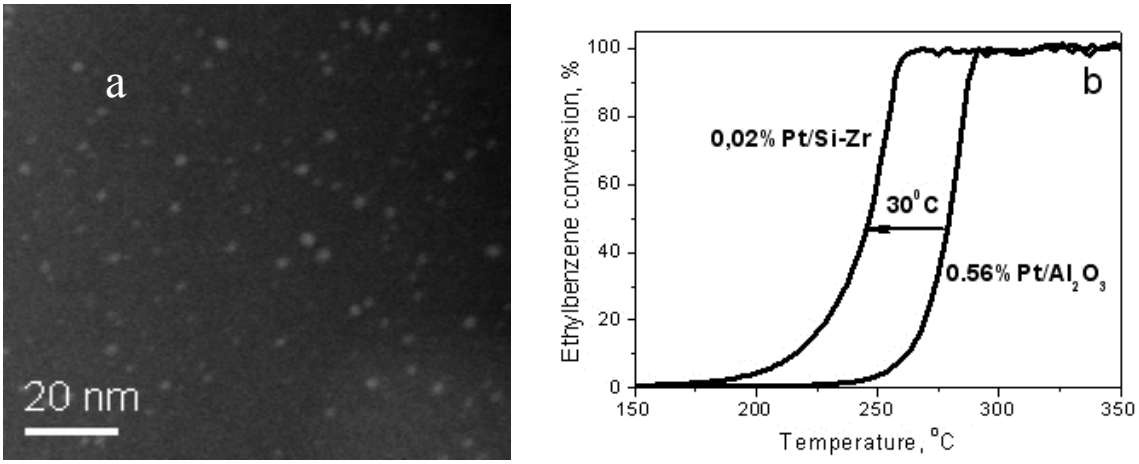

Fig.1.(a) STEM-HAADF image of the 0.01%Pt/FG catalyst; (**b**) deep oxidation of ethylbenzene on the 0.02%Pt/FG-Zr catalyst compared with commercial one. Feed gas: 1.2% C_8H_{10} + 16% O_2 + He, GHSV = 4000 h^{-1}.

like phosgene and dioxines. Moreover, the Pt/FG catalyst demonstrated high efficiency in the destruction of 1,2,3,4-TeCDD (95%), so that the residual concentration did not exceed 0.4 ppb.

To elucidate the reasons of so high specific activity of the 0.01%Pt/FG sample, the SSITKA study with labeled molecular oxygen was performed. The 0.12%Pt/FG catalyst where platinum was located only on the surface of the fiber was used as a reference one because the activity of a similar sample with 0.01%Pt was negligible. Surprisingly, unlike 0.12%Pt/FG, in the case of 0.01%Pt/FG sample the stepwise replacement of $^{16}O_2$ by $^{18}O_2$ in the feed gas did not lead to the formation of mixed $^{16}O^{18}O$ oxygen, while in the reaction product CO_2 the equilibrium distribution between different oxygen isotopic fractions took place. This means that the molecular oxygen species are active in deep oxidation of propane on highly dispersed Pt species located in fiberglass bulk.

High performance of fiberglass based catalysts was successfully demonstrated in the VOC removal from synthetic rubber plant (JSC Nizhnekamskneftekhim, Russia) when the catalyst showed a purification efficiency of 99.9% for more than 4 years of its operation.

4 Conclusions

The highly dispersed 1 *nm* Pt species were stabilized in the bulk of Zr-silicate glass at a depth of 10-20 *nm*. These small Pt clusters showed high performance in both VOC and CVOC abatement. In spite of a very low noble metal content (0.01-0.02%), the Pt/FG catalysts showed a higher activity in comparison with conventional ones containing 30-60 times more platinum. The TOF was 5-10 times higher as compared with the alumina-, or silica-supported Pt catalysts. The SSITKA study showed that molecular oxygen species are active in deep oxidation of hydrocarbons. The high performance of the fiberglass catalyst was successfully confirmed at industrial level.

Keywords: diesel, emission control, monolithic catalyst, noble metal, manganese, synergetic effect

1 Introduction

The TWC catalysts for catalytic converter of diesel engines usually contain noble metals – Pt and Pd, which have high catalytic activity in CO and hydrocarbon oxidation. In the last decade there has been a trend of progressive alteration of the preferred loadings of Pt or Pd, depending mostly on dynamics of market-value of these metals. The catalytic systems with a low noble metal (Pt, Pd, Rh) content and their combination with transition metal oxides are shown to be attractive option for TWC perfecting, especially for close-coupled converters operated at high temperatures [1,2]. There is a great number of data on non-additive increase of catalytic activity of noble metals combination with transition metal oxides in the oxidation of carbon monoxide and hydrocarbons [2-7].

We early demonstrated synergetic effect of Pt and manganese oxides which allows decreasing the Pt loading to 0.7-1.05 g/L in the catalytic system for diesel engine exhaust treatment [7], but such Pt loading is enough high. Here, we are reporting our systematic study of the effect of Pd addition into Pt-MnO_x-Al_2O_3 monolithic catalysts on their catalytic activity and stability in hydrocarbon and CO oxidation. We are discussing also Redox properties, particles size and morphology, and interaction of nanoscale Pt/Pd particles with Mn-modified alumina in order to explain a positive effect of Pd on catalytic behaviour of Pt-Mn-alumina catalyst.

2 Experimental

The PdPt/MnO_x-Al_2O_3 catalysts have been prepared by wetness impregnation of cordierite monolithic substrate (400 cpsi) preliminarily washcoated by MnO_x-Al_2O_3 with solutions of Pt and Pd precursors, and subsequent treatment at 600°C. The catalyst preparation approach emphasized variation of a Pd precursor (H_2PdCl_4, $Pd(CH_3COO)_2$, $Pd(NO_3)_2$ and $Pd(NH_3)_4(NO_3)_2$), total Pd-Pt loading (0-0.70 g/L or 0-0.11 wt.%) and Pd/Pt ratio.

Catalytic activity of the initial and aged samples was tested in DIESEL test runs with a mixture of propane/propene (100/200 ppm), CO (1900 ppm), NO (300 ppm), O_2 (14.6 vol.%), CO_2 (2.5 vol%), H_2O (3.9 vol%), and N_2 (balance) at 67000 h^{-1}, in two heating/cooling cycle. The catalyst aging was carried out at 750°C in flow of dry or wet air.

Redox properties of the initial and aged Pt-MnO_x/Al_2O_3 and PdPt-MnO_x/Al_2O_3 catalysts were studied by TPR-H_2, size and nanostructure of active particles – by HRTEM and CO-chemosorption, the interaction of Pt/Pd with MnO_x and Al_2O_3 – by the chemical differentiating dissolution.

3 Results and discussion

In the DIESEL test the activity of washcoated Pt-MnOx-Al_2O_3 monoliths with Pt loading 0.17 g/L greatly increases by addition of Pd. The catalytic activity of the PdPt-MnOx-Al_2O_3 increases with Pd loading, which is characterized by a decrease of the temperature of 50%

conversion of HC and CO (Fig.). The light-off temperature for the PtPd-MnO_x-Al_2O_3 monolith with total noble metal loading 0.52g/l is lower when the atomic Pt/Pd ratio is higher. The sample containing 0.17gPt/L – 0.35gPd/L prepared using $Pt(NH_3)_2(NO_2)_2$ and $Pd(NO_3)_2$ is more active in the reaction of HC and CO oxidation than the samples prepared using H_2PtCl_6 and H_2PdCl_4.

Important to note that the bimetallic PdPt-Mn-Al_2O_3 catalysts are characterized by synergetic effect in catalytic activity. For example, catalytic activity of Pd(0.35)Pt(0.17)-Mn-Al_2O_3 is higher than the sum of the activities of 0.17 g/L of Pt and 0.35 g/L of Pd catalysts. At the same loading of noble metals the bimetallic PdPt-MnO_x-Al_2O_3 catalysts are more thermostable than the monometallic Pt-MnO_x-Al_2O_3 and Pd-MnO_x-Al_2O_3 monoliths.

The catalytic activity in light hydrocarbon oxidation is shown to correlate with RedOx properties of PdPt-MnO_x/Al_2O_3 catalysts and Pt-Pd particles size. The non-additive increase of catalytic activity of bimetallic catalyst is suggested to connect with a formation of nanoscale PdO-PtO_x particles on surface of Mn_3O_4 and a modification of alumina structure by Mn^{3+} and Pt(Pd)-cations.

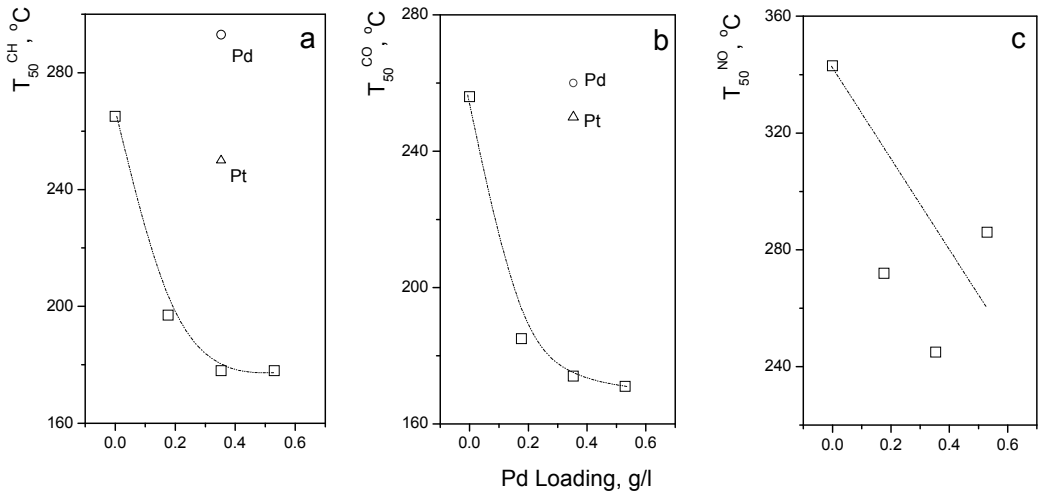

Figure. Temperature of 50% conversion of CH (T_{50CH}, °C) and CO (T_{50CO}, °C) and NO conversion at 400°C (X_{NO}, %) for monolithic catalysts prepared using $Pt(NH_3)_2(NO_2)_2$ (0.17 g/L) and $Pd(NO_3)_2$ vs Pd loading. The catalysts have been aged at 750°C in dry air.

4 Conclusions

Advantages of the synergetic effects of Pt, Pd and manganese oxides observed in the light hydrocarbon oxidation resulted in the development of the new diesel exhaust catalyst with a Pt loading as low as 0.17 g/L instead of traditional amount of 1.0-1.2g/L at the Pd loading of 0.35 g/L. The PtPd-MnO_x-Al_2O_3 catalyst has high activity in low temperature oxidation of light hydrocarbons and high thermal stability.

Keywords: propane oxidation, size effect, selectivity, selective oxidation

1 Introduction

Precious metal supported catalysts are widely used as catalytic converters of automotive engines exhaust. The efficiency of catalytic converter is strongly depends on the activity, stability and selectivity of supported metal in CH_x and CO oxidation reactions. The reaction conditions, such as the temperature and concentrations of exhaust components, also can change the catalyst behavior. Identification of factors changing the catalytic properties of the active component can help one to create the most efficient catalytic converter, which would provide total hydrocarbons and carbon monoxide oxidation at various exhaust composition and temperature.

The aim of this work was to reveal the correlations between the palladium particles dispersion in $Pd/\gamma\text{-}Al_2O_3$ catalysts and its activity, stability and selectivity towards propane oxidation at different temperatures and C_3H_8:O_2 ratios

2 Experimental/methodology

Three $Pd/\gamma\text{-}Al_2O_3$ catalysts with different palladium particles sizes (2, 5 and 11 nm, next denoted as Pd2, Pd5 and Pd11, respectively) were prepared via wet impregnation and subsequent calcination of support ($\gamma\text{-}Al_2O_3$, Sasol, S_{BET}=215 m^2/g). $Pd(NO_3)_2$ aqueous solution was used as the precursor. Catalyst samples than were tested in propane oxidation reaction at different temperatures (350, 400, 450 °C) and C_3H_8:O_2 ratios (1:1, 1:5, 1:15) in continuous stirred-tank flow reactor. TOF values were used as the measure of catalytic activity. Palladium dispersion was determined by XRD, TEM and CO chemisorption methods, whereas Pd charge state and the catalyst surface composition were determined by XPS technique.

3 Results and discussion

It was shown that TOF values increased with palladium particles size in total propane oxidation reaction. Moreover, the difference between the activities of high and low dispersed catalysts increases with temperature (see Fig. 1). It was also shown that at higher temperatures the increase of C_3H_8:O_2 ratio lead to the change of reaction path from total oxidation to steam conversion of propane. The selectivity towards CO formation in the steam conversion reaction decreased with palladium particles dispersion.

XPS in-situ studies revealed that Pd^{2+}/Pd^0 ratios increase with particles size. Thus, it is believed that the Pd/Al_2O_3 catalyst activity, stability and selectivity in propane oxidation reaction strongly depends on the relative concentrations of Pd^{2+} and Pd^0, which, in turn, can be controlled by the catalyst preparation technique, reaction temperature and CH_x:O_2 ratio in inlet gaseous mixture.

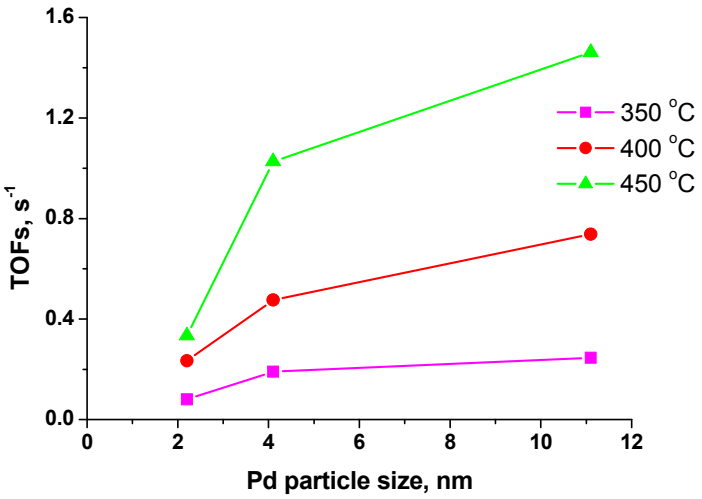

Fig. 1. Size effect for Pd/Al_2O_3 catalysts in total propane oxidation (C_3H_8:O_2=1:15) reaction at different temperatures

4 Conclusions

A series of Pd/Al_2O_3 catalysts with different palladium particles size were studied in propane oxidation reaction with varying the C_3H_8:O_2 ratios and the temperature of inlet gaseous mixture. It was shown that in propane-rich mixtures the change of reaction path from total oxidation to steam conversion occurred. Negative size effect was revealed for total propane oxidation reaction. Catalytic properties of supported palladium are strongly depend on Pd^{2+} and Pd^0 relative concentrations, which in turn can be the function of reaction temperature and CH_x:O_2 ratio in the inlet gaseous mixture.

Methane Oxidation over Palladium: on the Mechanism in Rich Methane-Oxygen Mixtures at High Temperatures

Stotz H.[1], Maier L.[2], Deutschmann O.[1,2*]

1 - Institute for Chemical Technology and Polymer Chemistry, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

2 - Institute for Catalysis Research and Technology, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Keywords: methane oxidation, palladium, detailed kinetics, *in-situ* sampling, catalytic partial oxidation

1 Introduction

Palladium-based catalysts are widely used in emission control systems for gas-engines to avoid methane slip. Methane oxidation can proceed over oxidized and reduced palladium, making it difficult to separate both the kinetic processes occurring on the active phases.

As first steps towards a detailed kinetic scheme of the methane oxidation over palladium this work focus on the development of the surface reaction kinetics for the catalytic partial and total oxidation under conditions where reduced palladium is the only active phase present. We present a surface reaction mechanism evaluated by comparison of simulated species profiles in a catalyst channel with experimentally obtained axially resolved species concentration profiles by in-situ sampling within a commercial Pd/Al_2O_3 coated cordierite honeycomb monolith.

2 Kinetic Model and Numerical Simulation

Numerical simulations of the steady-state species concentrations profiles in a catalyst channel were performed using DETCHEM^{CHANNEL} [1]. Axial wall-temperature profiles of the center channel from in-situ measurements were provided for the calculation. The model assumes cylindrical symmetry and solves the two-dimensional steady-state flow field using the boundary-layer approximation. Chemical source terms in the washcoat are calculated via the effectiveness factor model in order to account for internal pore transport limitations. Detailed heterogeneous reaction kinetics were developed using the mean-field approximation, including 6 gas-phase species (CH_4, O_2, CO, CO_2, H_2, H_2O) and 11 surface intermediates (CH_4*, CH_3*, CH_2*, CH*, C*, O*, OH*, CO*, CO_2*, H*, H_2O*). Kinetic parameters of 20 reversible elementary steps were derived from transition-state theory and semi-empirical methods for a Pd(111) surface in the limit of zero coverage. Selected steps were corrected for coverage dependent activation energies. The newly formulated surface reaction kinetics obeys thermodynamic consistency.

Since the reaction mechanism is based on elementary molecular steps, it presents all the global processes in the CH_4/O_2 mixture over palladium catalyst, including (i) partial oxidation and/or (ii) steam reforming of methane to syngas; (iii) methane combustion; (iv) water-gas-shift reaction; (v) surface carbon formation. The mechanism includes a pyrolytic and an oxygen-assisted path to activate methane on the Pd surface. Although atomic adsorbed oxygen O* is the key species of the mechanism, it does not consider a bulk-phase oxidation of Pd.

3 Experiments

Experimental profiles for different carbon-to-oxygen ratios between 0.9 and 1.0 were measured using in-situ sampling technique within a Pd/Al_2O_3 coated monolithic honeycomb catalyst. The gas composition at various axial positions inside a center channel of the monolith was analyzed using FT-IR, MS, and GC/MS, respectively [2].

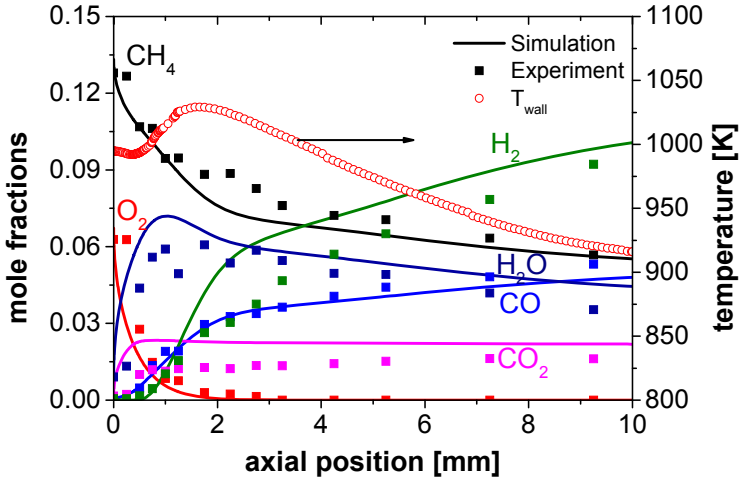

Fig. 1 Comparison of simulated and experimental species [2]and wall-temperature profiles within the catalytic section at 4 slpm and a measured catalyst inlet C/O-ratio of 0.94.

4 Results and Discussion

Figure 1 shows measured wall-temperature and species concentration profiles compared with the simulated profiles. Methane first undergoes total oxidation within a small 0.5 mm zone, right at the entrance of the catalyst, the partial oxidation products, H_2 and CO, are not observed. At the end of the total oxidation zone at 0.5 mm, most of the oxygen is converted. Further downstream (0.5-3.3 mm) an extended oxy-reforming zone is found, where CH_4 is consumed by combined total and partial oxidation as well as steam reforming. After consumption of all oxygen at axial positions > 3.3 mm, steam reforming of CH_4 is the preferred conversion path, leading to a prolonged consumption of CH_4 and a simultaneous decrease in H_2O concentrations. This observation is supported by the fact that CO and H_2 show a further increase in concentration, while the CO_2 signal remains constant.

5 Conclusion

The indirect formation of synthesis gas is the preferred route for partial oxidation of methane. The developed multi-step surface reaction kinetics on reduced palladium, predicts all features of the experimental spatially-resolved species profiles. Additional experiments are recommended to clarify the oxidation state of Pd in operando, in particular in the entrance zone of the catalyst.

Keywords: catalytic methane oxidation, hierarchical ZSM-5, palladium

1 Introduction

Catalytic methane oxidation is applied in exhaust gas treatment to reduce unburnt methane emissions in stationary combustion processes as well as in natural gas vehicles to mitigate the severe greenhouse effect of methane [1]. Pd is the precious metal of choice for methane oxidation. Several supports for Pd-based catalysts are reported to provide higher activity than the commonly used Al_2O_3, e.g. CeO_2, SnO_2, ZrO_2 or zeolites [2,3,4]. The latter material is advantageous because of many adjustable parameters (lattice type, Si/Al ratio, acidity, pore size and shape), which allow to tailor the support for the requirements of catalyzed reaction. However, Pd/zeolite catalysts suffer from rapid deactivation under reaction conditions, especially in the presence of steam. It is considered that poor performance of Pd-based catalysts is due to extensive sintering of Pd nanoparticles and formation of inactive $Pd(OH)_2$ species [5].

In this work a novel approach is proposed with the aim to inhibit sintering of Pd particles dispersed on zeolite support. Small Pd clusters are stabilized within constricted mesopores of ZSM-5 obtained by desilication with NaOH in the presence of tetrapropylammonium bromide.

2 Experimental/methodology

Commercial Na-ZSM-5 (Zeochem PZ-2/40, Si/Al=20) was used as a starting material. A series of desilicated supports was obtained by leaching the parent zeolite with a solution containing 0.2M NaOH and 0.2M TPABr at 65°C for 10, 30, 60 and 300 min. The corresponding samples were denoted as D0 (parent), D10, D30, D60 and D300. The parent zeolite and the leached samples were then ion-exchanged with a $Pd(NH_3)_4(NO_3)_2$ solution at room temperature for 24h to obtain 1 wt.% Pd loading. After drying at 120°C for 24h, the samples were calcined in air at 500°C for 2h and then pressed, crushed and sieved to obtain 150-200μm fraction.

Catalytic activity was evaluated in a quartz glass plug-flow reactor (ID = 6 mm) with a feed of 1 vol.% CH_4 and 4 vol.% O_2 (bal. N_2) at GHSV=30,000 h^{-1} and with a heating ramp of 10°C/min. To simulate wet conditions 5 vol.% of water vapour was added to the flow.

The outlet gas flow composition was analyzed by mass-spectrometry. Structural properties were evaluated by nitrogen physisorption, X-Ray diffraction and electron microscopy.

3 Results and discussion

Table 1. BET surface area and total pore volume of parent and desilicated ZSM-5 from N_2 adsorption

Sample	S_{BET}, m^2	V_{total}, cm^3/g
D0	539	0.393
D10	504	0.432
D30	492	0.480
D60	497	0.474

D300	469	0.490

Table 1 shows that the total pore volume increased with leaching time. Figure 1 illustrates that the catalytic activity of all samples was very similar under dry conditions. A slight decrease of the light-off temperature was observed for the samples leached for 30 and 60 min. The addition of 5 vol.% water vapour in the stream increased the light-off temperature of the D0 sample by 100°C, whereas for the leached samples the shift is only 50-60°C, with the lowest temperatures achieved by the D30 catalyst.

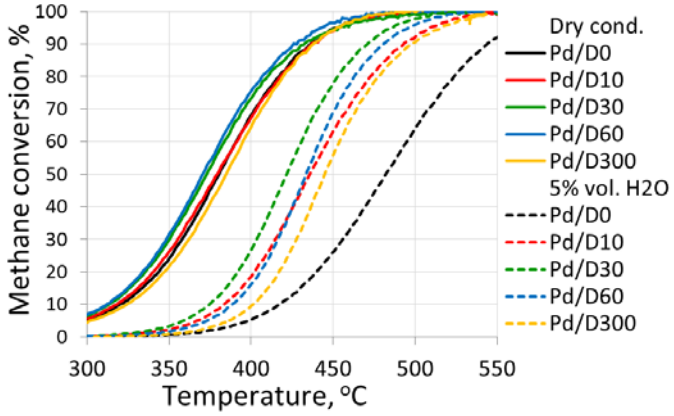

Fig. 1. Methane conversion curves in dry and humid conditions for D0-D300 samples

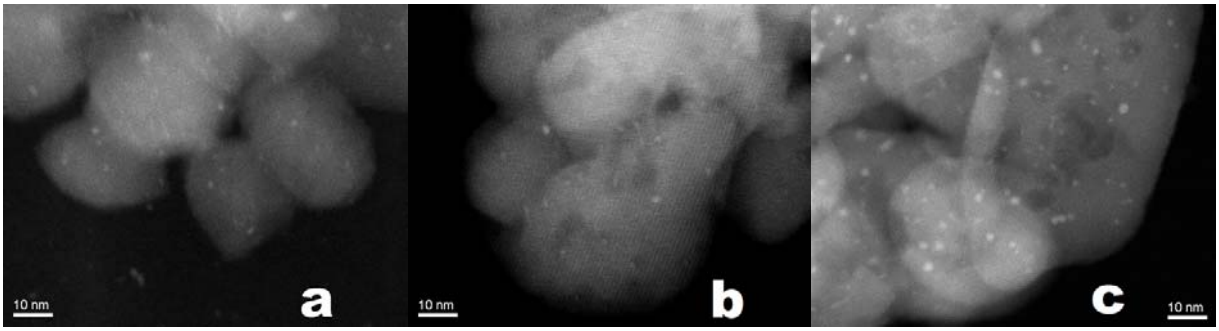

Fig. 2. STEM images of calcined samples (a) Pd/D0, (b) Pd/D30 and (c) Pd/D300.

STEM images (Fig. 2) of calcined D0, D30 and D300 catalysts reveal constricted mesopores in samples D30 and D300 (dark areas in the ZSM-5 crystallite). Some Pd nanoparticles in D30 and D300 samples were located within these constricted mesopores. Increased activity in the presence of water vapour could be explained through these isolated from each other Pd nanoparticles.

4 Conclusions

Palladium nanoparticles stabilized on desilicated ZSM-5 support with constrained mesopores showed promising results in methane combustion in the presence of water vapour.

Keywords: GPF, nano-cell catalyst, gadolinia-doped ceria, gasoline direct injection, soot

1 Introduction

Future changes in Europe regulation (Euro 6c in 2017) concerning particle matter (PM) abatement will probably lead to the implementation of filter devices in direct injection gasoline (GDI) engines. Catalyzed-Gasoline Particulate Filter (cGPF) can be combined with conventional three way converter (TWC) to meet pollutants standards. Recently, electro-promoted nano-dispersed catalysts for vehicles exhaust after-treatment is getting growing attention [1] since they can combine electrochemical promotion of catalysis [2] and high metallic active site availability. Nano-cell catalysts are composed of nano-electrodes (two different natures of metallic nanoparticles) supported on a mixed ionic-electronic conductor (MIEC). This study reports the preparation and catalytic performances of MIEC based-cGPFs for GDI exhaust treatment. Catalysts were composed of Pd and Rh nanoparticles dispersed on gadolinia-doped ceria (CGO), a mixed oxygen-electronic conductor. These materials have been washcoated in SiC mini-GPFs equipped or not with a filtration membrane. Catalytic activity measurements have been performed independently in lean and rich feed conditions for different catalyst loadings and locations inside mini-cGPFs. Finally, the impact of PM on catalytic performances has been explored.

2 Experimental/methodology

Pd and Rh nanoparticles were dispersed on CGO ($Ce_{0.8}Gd_{0.2}O_2$, Nextech, 34 m²/g) using incipient wetness method. The Pd/Rh ratio was 5 for an overall PGM loading of 1.3 wt%. Powdered catalysts were washcoated into SiC mini-GPFs (1x2 inch) either in the walls porosity or on the surface of a SiC filtration membrane deposited by CTI on the surface of the inlet channels (Table 1). Catalytic tests were carried out in a pilot plant scale which simulates the exhaust line of a GDI engine. Particulate Matter (PM) was generated using a mini Combustion Aerosol Standard (mini-CAST). The total flow rate was 20 Nl/min using N_2 as carrier gas. Tests were carried out under two different conditions: rich (O_2 /CO/CO_2 /NO/C_3H_6/C_3H_8/H_2O: 4000 ppmv/ 1.4 vol.%/ 14 vol.%/ 740 ppmv/ 1125 ppmv/ 375 ppmv/1%) and lean (O_2 /CO/CO_2 /NO/C_3H_6/C_3H_8/H_2O : 1 vol.%/ 6000 ppmv/ 14 vol.%/ 740 ppmv/ 1125 ppmv/ 375 ppmv/1%). Mini cGPFs were placed downstream a mini commercial three-way converter (1x0.8 inch) to mimic a real GDI exhaust after-treatment. Exhausts were sampled with an on-line IR analyzer, a microGas Chromatograph and a chemiluminescence analyzer. Soot particle number and size distribution were measured using an Engine Exhaust Particulate Sizer.

Table 1. Characteristic of the tested GPFs

cGPF	Catalyst loading in porous walls / g/L	SiC Filtration Membrane	Catalyst loading onto the membrane/g/L
Config 0	86	No	-
Config 1	-	Yes	12
Config 2	80	Yes	12
Config 3	80	Yes	12 (only CGO)
Config 4	80	Yes	-

3 Results and discussion

Figure 1 displays catalytic results (NO reduction and CO oxidation) together with the filtering efficiency in lean operating conditions. Differences between samples are only significant at high conversions since the commercial mini-TWC placed upstream cGPFs is very active. The maximum CO conversion was reached in a short temperature interval (250-280 ºC). All the samples showed high performances for NOx conversion, especially those equipped with a catalytic layer on the filtration membrane such as Config 2. This can be attributed to a higher availability of catalytic sites. The filtration membrane has a strong impact on the filtering efficiency (Fig. 1C). Furthermore, in a lesser extent, the presence of catalyst in the porosity of the membrane also improves the soot filtration. On the other hand, the higher the catalyst loading, the higher the pressure drop.

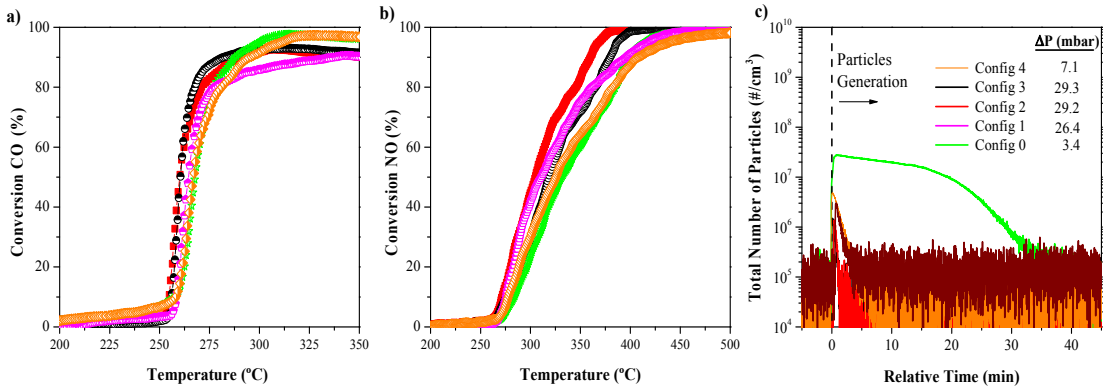

Fig. 1. Catalytic results of the different c-GPFs: a) CO conversion, b) NO conversion and c) Particles number

4 Conclusions

Washcoated MIEC-based catalysts inside mini-GPFs have been tested for GDI exhaust aftertreatment using a bench scale plant. The presence of a membrane in GPFs modifies both, their catalytic and filtering performance. The impact of the membrane, the catalyst loading and location as well as the presence of soot particles on the catalytic properties will be discussed.

Keywords: glycerol, bio-fuels, biomass usage, surface chemistry, renewable energies, model catalysts

1 Introduction

Employing renewable sources from vegetal oil to produce chemicals and energy appears to be one of the most important technological approaches to solve the need for replacement of oil. In this way, the new concept of bio-refineries to produce energy and derivatives from biomass comes into the picture. When obtaining biodiesel from biomass conversion, about 10 % of the reaction by-product is glycerol [1]. Thus, it is accepted that glycerol will play a very important role in bio-refineries future and it is, therefore, mandatory to search for new processes to upgrade this by-product into more valuable chemicals.

Glycerol is a highly functionalized compound which could be used as a starting material for a great variety of chemical products of industrial interest [2]. One of the interesting upgrades for glycerol is to produce propylene glycol by dehydration followed by hydrogenation [3]. In another aspect, glycerol can be selectively oxidized, in acid or basic conditions, to different products of interest depending if the targeted hydroxyl is in primary or secondary position [4, 5]. Furthermore, glycerol can be reacted with metal catalysts to obtain H_2 and CO (reforming reactions) [6]. Another interesting upgrade is to obtain dihydroxyacetone or acrolein using reducible metal oxides as catalysts which present a variety of acid-base sites [7].

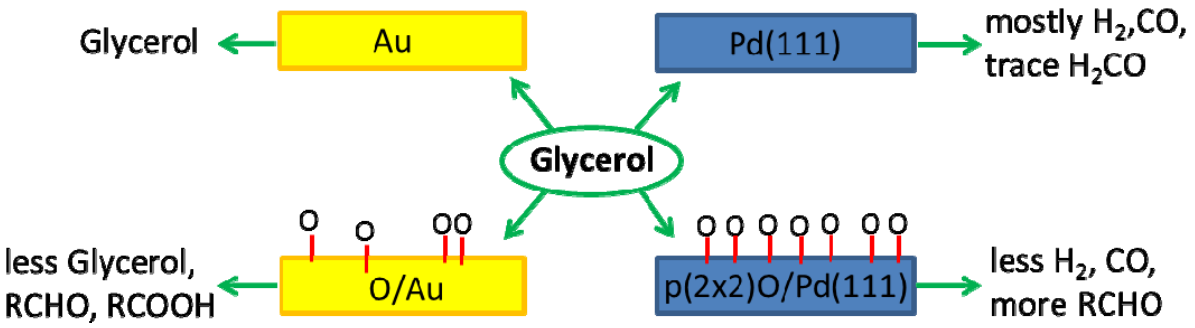
2 Experimental

All experiments were performed in an ultra-high vacuum chamber with capabilities for infrared absorption and x-ray photoemission spectroscopies (IRAS and XPS), temperature programmed desorption (TPD) and low energy electron diffraction (LEED). The model catalysts used were either metal single crystals (Pd(111) and Au(111)) and their corresponding chemisorbed oxygen structures or oxides or cerium oxide (CeO_2(111)) films grown on top of a Ru(0001) single crystal. Using this battery of surface science techniques we studied the adsorption and further decomposition of the polyol and are able to distinguish adsorbed intermediates in-situ.

2 Results and discussion

When the polyalcohol is adsorbed on the metallic Pd surface it primarily decomposes into H_2 and CO, with traces amount of formaldehyde and methane. On the other hand, on the Au(111) surface, it interacts very weakly showing no decomposition. Preliminary results regarding influence on the chemistry observed in the presence of chemisorbed oxygen or surface oxide thin films show that the interaction with both surfaces can be tuned towards different products (Pd) or boost up its reactivity on the coinage metal (Au). These later results are of interest to understand the mechanistic processes of selective catalytic oxidation of glycerol. Results from IR spectroscopy upon adsorption of the molecule onto the surface at low temperatures, show its adsorption geometry and the cleavage of specific intra/intermolecular

hydrogen bonds are key parameters dictating the decomposition pathways observed for the polyalcohol at higher temperatures.



Scheme 1. Different reactivity of glycerol molecules depending on metal substrate and the presence of oxygen species.

Some preliminary results of the interaction of glycerol with cerium oxide films will be shown and compared with the single crystal metals. CeO_2 is a very versatile reducible oxide with high oxygen storage capabilities, thus being a good candidate for selective oxidation or oxidative dehydration reactions. In the past years, several studies have shown that its role as a catalyst, especially in the presence of oxygen vacancies, is of great importance.

4 Conclusions

The adsorption and reactivity of glycerol with metal single crystals and metal oxide model catalysts have shown that this polyalcohol promptly reacts on Pd surfaces producing mostly CO and H_2, thus presenting promising results for using this metal for reforming reactions. The presence of oxygen on Pd opens up other decomposition pathways where more aldehyde is observed. For the case of Au surface, the interaction is very weak on the clean surface, but it can be boosted up with chemisorbed oxygen, and formation of carboxylates as intermediates towards total combustion were observed. The present results show the importance of studying adsorption and reactivity of polyalcohols as model compounds from biomass conversion catalysis at the atomistic level. Great understanding can be reached from these surface science studies which can be then applied for the development of new catalytic materials.

Keywords: CO_2 conversion, imidazolium, ionic liquid cyclic, carbonates, silica, microreactors

1 Introduction

Research involving carbon dioxide conversion attracts the interest of the scientific community since carbon dioxide is a non-toxic, renewable and easily available source of carbon. Its reaction with epoxides to produce high added value products like carbonates and polycarbonates is one of the most important topics in green chemistry [1]. To carry out this transformation, is necessary a catalyst able to activate either the carbon dioxide molecule, either the epoxide or both species [2]. In the last years, ionic liquids have demonstrated a good catalytic activity in the CO_2 transformation under both homogeneous [3] and heterogeneous conditions [4, 5, 6]. There are different strategies for the heterogeneization of ionic liquids involved in the transformation of carbon dioxide including adsorption and grafting of the ionic liquid moiety onto a solid support [4], [7].

Herein, we present a novel heterogeneization strategy in which a double alkyl chain imidazolium ionic liquid has been polymerized as liposome-like structure and used as template for the synthesis of mesoporous silica [8]. The organic-inorganic hybrid silica microreactors, synthesized in one-pot procedure, present porous shell and accessible imidazolium core. The novel catalysts displayed excellent performances in the synthesis of cyclic carbonates via chemical fixation of carbon dioxide into various epoxides [8].

2 Experimental/methodology

The N,N'-bis(10-undecenyl)-2-methylimidazolium ionic liquid was synthetized starting from 2-methylimidazolium and 11-bromo-1-undecene in toluene, as previously reported [9]. The silica microreactors were synthetized via the sol-gel method [10, 11], and using the double alkyl chain imidazolium ionic liquid (Figure 1) as structure directing agent. The final material, appeared as a hollow silica sphere with a porous inorganic shell and active imidazolium core, was characterized by TEM, ^{29}Si-MAS-NMR spectroscopy, elemental analysis and N_2 adsorption. The catalytic tests were carried out in a batch reactor with individual temperature control and mechanical stirring, designed to operate at high pressures.

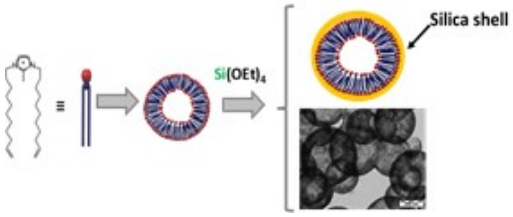

Fig.1. Synthesis of the silica microreactors and TEM image of the as-prepared materials.

3 Results and discussion

The novel imidazolium based silica microreactors were synthesized following a straightforward one-pot procedure and used as catalysts for the synthesis of cyclic carbonates. The operation pressures of CO_2 ranged between 50 and 90 bar and other parameters like temperature, presence of solvent and relative epoxide to catalyst ratio were also tested.

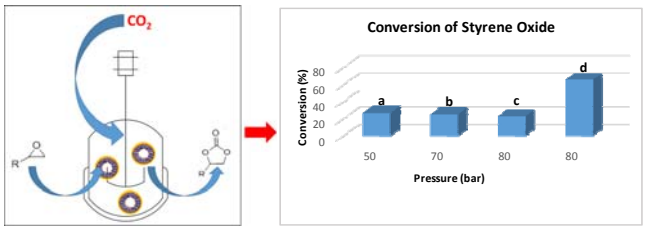

Fig.2. Reaction scheme (left) and tests performed within the silica microreactors (right); tests *a*, *b* and *c* were performed in the presence of solvent (DCM) at 50, 70 and 80 bar, respectively; test *d* was performed without solvent at 80 bar.

The materials showed good performance for the reaction of CO_2 with different epoxides; for the transformation of styrene oxide into styrene carbonate the best conversion (53 %, figure 1 right, test d) was obtained in the absence of solvent. Under the selected conditions the turnover number (TON =300) was one of the higher reported in the literature [7]. The excellent catalytic activity was justified by the presence of a confined space within the microreactors with the consequent increases of local concentration of the regents. Moreover, these materials were used in consecutive catalytic cycles with no substantial decrease of the catalytic performances.

4 Conclusions

An imidazolium ionic liquid bearing two undecenyl chains was polymerized leading to a liposome-like structure. This polymeric matrix acted as template for the preparation of porous silica architecture. The solid behaves as an organic/inorganic hybrid microreactor with enhanced catalytic activity for the synthesis of cyclic carbonates starting from carbon dioxide and epoxides. The good performances were confirmed by the high TON and selectivity obtained. Moreover, the catalytic activity was maintained in multiple catalytic cycles although a small decrease in the carbonate yield was observed after the first run.

Keywords: natural monoterpene alcohol, amination, gold nanoparticles, one-pot

1 Introduction

Complicated amines are important chemicals *per se* or as intermediates for fine organic synthesis. In particular complicated terpene amines, synthesized from renewable raw materials, were recently shown to exhibit specific physiological properties and can be used as intermediates of potential drugs for neurological diseases [1]. A perspective approach to control synthesis of complicated amines is the one-pot alcohol amination over heterogeneous catalysts, consisting of three consecutive steps: dehydrogenation of alcohol to aldehyde, which interacts with an amine to form imine and finally hydrogen transfer to produce the secondary amine. The one-pot multistep reaction holds a high potential for increasing the efficiency for chemical synthesis of medicinally and biologically important compounds. At the same time, the complexity of this process is reflected by a large number of parameters which can influence each step. Thus, the purpose of the current work is to study general regularities of one-pot alcohol amination in the presence of gold-containing catalysts and to obtain systematic knowledge about the key parameters determining the catalyst performance including the investigation of the support nature and the catalyst redox activation effect. Myrtenol, which represents a natural terpene alcohol with a primary OH-group and C=C double bond, and aniline were selected as model substrates (Fig. 1).

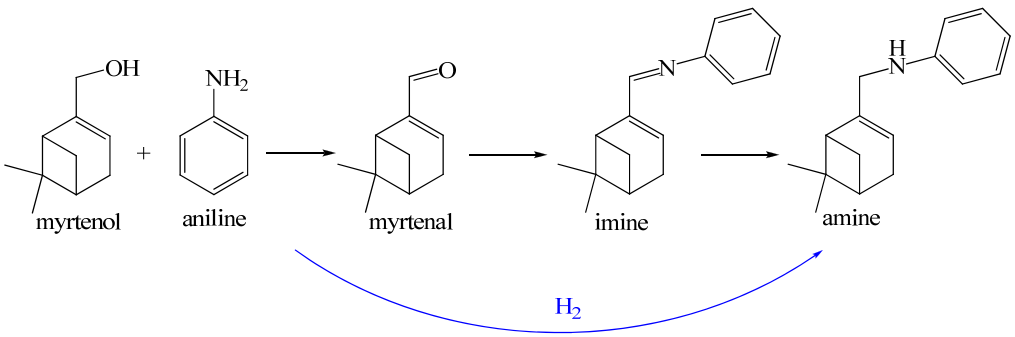

Fig. 1. General reaction network of one-pot myrtenol amination with aniline over gold catalysts.

2 Experimental

Liquid-phase myrtenol amination was carried out in a stainless steel reactor, equipped with an electromagnetic stirrer (1100 ppm) and a sampling system. In a typical experiment, a mixture of myrtenol (1 mmol), aniline (1 mmol) and Au catalysts (92 mg) in toluene (10 ml) was intensively stirred at 413-453 K under N_2 atmosphere. The reaction components were analyzed

by GC using a SLB-5ms column, GC-MS as well as ^{1}H- and ^{13}C-NMR. A series of gold catalysts including Au and AuPd samples over different metal oxides (ZrO_2, MgO, Al_2O_3, CeO_2, La_2O_3) were prepared by deposition-precipitation method using urea as a precipitating agent, pre-treated under oxidizing or reducing atmospheres and characterized by TEM, XPS and TPR/TPO-MS.

3 Results and discussion

To study the effect of the catalyst support and redox thermal pre-treatment a series of nanosized gold catalysts over ZrO_2, Al_2O_3, CeO_2 and La_2O_3 pre-treated under oxidizing or reducing atmosphere were tested. First, the catalytic performance in each step was found to be strongly dependent on acid-base properties of the support requiring a certain balance between different sites for efficient alcohol amination [2]. Among the catalysts tested in the reaction zirconia-supported gold catalyst with both acidic and basic surface sites afforded optimum consecutive myrtenol transformations resulting in the myrtenol total conversion and selectivity to the target amine of about 53%. The basic sites on metal oxides surface were suggested to be required for the initial alcohol activation, while the availability of protonic groups was important for the target amine formation. At the same time it was found that the catalytic activity and selectivity can be also regulated by the catalyst redox pre-treatment. Differences in activity and selectivity between pre-reduced and pre-oxidized catalysts were demonstrated to be related to an extent of ammonia removal from the catalyst surface rather than to the electronic state of gold species depending on the type of catalysts redox pretreatment. The amount of ammonia species remained on the catalyst surface influenced surface acidity determining catalytic behavior in different amination steps.

A special attention was given to kinetic investigations with a further development of the kinetic model. The reaction kinetics was modelled based on the mechanistic considerations with the catalyst deactivation step introduced into the mechanism [3]. The kinetic model was compared with experimental data through numerical data fitting showing a good correspondence (degree of explanation equal to 95%), which confirms its applicability. In fact, the developed model is a very generic one and can be used for a number of other hydrogen borrowing reactions.

4 Conclusions

One-pot myrtenol amination was studied in the presence of nanosized gold catalysts supported on different metal oxides with equimolar amounts of the substrates in the temperature range 413-453 K under nitrogen pressure. It was shown that catalytic activity and product distribution in one-pot alcohol amination can be regulated by the metal oxide support properties, namely acidity and basicity, interactions of Au with other metals and conditions of catalyst pre-treatment. A mechanistic model for hydrogen borrowing reaction taking into account catalyst deactivation was developed from the proposed reaction mechanism resulting in a kinetic model, which was able to describe experimental data with sufficient accuracy.

Keywords: dehydrogenation, CO_2, TAP, reactor, propane

1 Introduction

The oxidative dehydrogenation (ODH) of alkanes to alkenes by molecular oxygen is a relatively new and a promising technology. The presence of O_2 may however, lead to process flammability, production of carbon oxides and over-oxidation, resulting in poor process selectivity. This can be overcome by using a safer, milder and readily available oxidant: CO_2.[1] As the issue of CO_2 emissions has become one of the main subjects in environmental chemistry, this reaction seems to serve also a great example for CO_2 utilization.[2] The route of this reaction may follow Mars van Krevelen mechanism, where CO_2 will dissociate on the surface of catalyst, facilitating further dehydrogenation. Catalysts with high oxygen storage capacity (OSC) and ability to dissociate CO_2 in low temperatures would be ideal for this process. One of the active metal oxides, which possess these properties, is CeO_2. Addition of ZrO_2 to CeO2, however, increase OSC and additional presence of another metal oxide-Al_2O_3 has a positive influence on the surface area and catalyst thermal stability.[3] Here, we report the oxidative dehydrogenation of propane (ODP) with the use of CO_2 and Pd/ Ce-Zr-Al-O_x based catalyst. The use of temporary analysis programme (TAP) reactor for CO_2 dissociation over Pd/Ce-Zr-Al-O_x catalyst was also investigated.

2 Experimental/methodology

Catalysts were prepared by physical grinding method to give support composition Ce: Zr: Al: 1:1:2. Further Pd was wet impregnated onto calcined support following the protocol: to the aqueous solutions of Pd precursor, requisite amount of support was added under vigorous stirring at room temperature. The solution was agitated in this way until it formed a paste, which was dried at 120°C for 12h and further calcined. Catalytic measurements were performed using a fixed bed laboratory micro reactor at atmospheric pressure, keeping GHSV at 6385 h^{-1} and total flow rate of 15 mL min^{-1}. Reaction mixture consisted of He, CO_2 and C_3H_8, keeping He on the level of 26% volume and using different ratio between CO_2 and C_3H_8. The reactants and products were analysed by a Varian 3800 online gas chromatograph using Porapak Q and Molsieve columns with TCD and FID detector.

3 Results and discussion

Pd supported catalyst were highly active for the oxidative dehydrogenation of propane. Studies with different CO_2: C_3H_8 ratio over 5%Pd/Ce $_{0.25}$Zr $_{0.25}$Al $_{0.5}$O $_{1.75}$ catalyst showed that changing the ratio between CO_2: C_3H_8 lead to increase in CO_2 and C_3H_8 conversion This may be attributed to the fact, that CO_2 is changing the equilibrium in the reverse water-gas shift reaction, as well as faster CO_2 dissociation over Pd supported catalyst. When investigating the metal loading on Ce-Zr-Al-O_x support for activity in ODP reaction, it was found that catalyst with 7% Pd loading increased the conversion of propane to more than 35% during 0.5 h reaction, as it is shown in **Figure 1**.

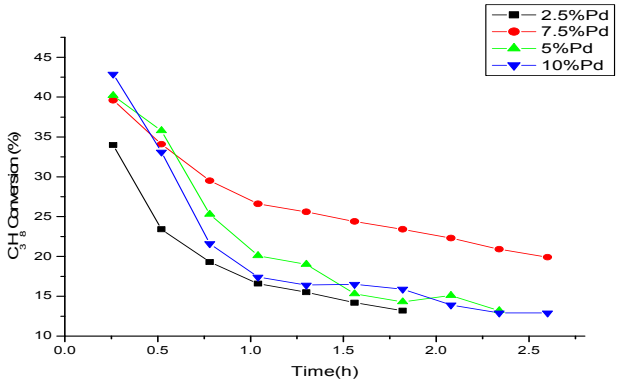

Fig. 1. Conversion of C_3H_8 in ODP with $Ce_{0.25}Zr_{0.25}Al_{0.5}O_{1.75}$: different Pd loading

Studies involving TAP measurements over $5\%Pd/Ce_{0.25}Zr_{0.25}Al_{0.5}O_{1.75}$ clearly showed CO production from CO_2 at temperature higher than 300°C. These findings indicate that CO_2 dissociate on the surface of the catalyst yielding highly oxidative O species, maintaining Ce in a highly oxidized state, therefore helping to facilitate the dehydrogenation process.[4]

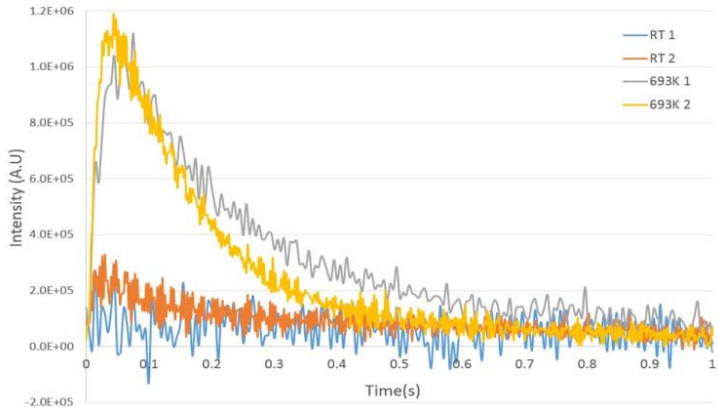

Fig. 2. TAP reactor analysis: Mass 28 at RT and 420°C pulsing CO_2

The most active catalyst has been fully characterized using several techniques, e.g.: TEM, EXAFS and TPRDO. Also DRIFT analysis with CO_2 and CO will be presented.

4 Conclusions

Pd based catalysts have been found very active for propane dehydrogenation process with the use of CO_2. The role of CO_2 in reverse water gas shift reaction as well as in oxidative dehydrogenation via Mars van Krevelen mechanism will be fully presented.

Keywords: glycerol hydrodeoxygenation, methanol reforming, Cu-catalyst, reaction, pathways

1 Introduction

Glycerol (GLY), being a by-product of various biomass conversion processes is a high available, low-cost and renewable feedstock for the production of chemicals which are at present produced using oil derivatives. Catalytic hydrodeoxygenation (HDO) of glycerol to 1,2-propanediol (1,2-PDO) is a process of commercial and environmental significance. However, the need of external H_2 supply may render the process unprofitable. This work presents an innovative method according to which, glycerol is subjected to HDO conditions and selectively converts to 1,2-PDO under inert atmosphere. Aqueous methanol (MeOH) reforming generates H_2 required for GLY HDO in a tandem reaction cycle under identical conditions [1,2]. A $Cu_{0.6}Zn_{0.3}Al_{0.1}$ catalyst, was proved to be the most efficient material for the above reaction cycle [3]. In this study, efforts are directed towards optimizing the performance of the promising catalyst by tuning the operating conditions and testing its stability. In addition, emphasis was placed on the elucidation of the reaction pathways.

2 Experimental/methodology

The $Cu_{0.6}Zn_{0.3}Al_{0.1}$ catalyst was prepared using the oxalate gel co-precipitation method [3]. The standard catalytic tests were conducted in an autoclave 100ml reactor (Parr Instruments) at 250°C and 3.5MPa initial N_2 for 1h employing a reactant mixture 82v/v% H_2O, 9v/v% MeOH and 9v/v% GLY. The stability of the catalyst was tested for five reaction cycles. The effect of operating conditions was investigated by varying the parameters at ranges of C_{MeOH}: 4.5-36v/v%, T:200-250°C, P:1.0-3.5 MPa N_2, 1.0-8.0MPa H_2, w_{cat}:0.1-1.4g. The method of intermediate addition to the reactant mixture was applied so as to elucidate the reaction pathways. Small amounts of hydroxyacetone (HA) and glyceraldehyde (GLA) were separately added in the aqueous feed solution of GLY and MeOH and the reaction rates were calculated. In addition, experiments using intermediate (HA) and final (1,2-PDO) products as reactants were also performed.

3 Results and discussion

Under the optimum operating conditions (t=1h, T=250°C, P_{N2}=1.8MPa, 36v/v% C_{MeOH} +9v/v% C_{GLY}), GLY was almost fully converted (96.4%), while 1,2-PDO was the major product formed with 77.0% selectivity and a site time yield equal to 14.1h^{-1}. Higher C_{MeOH} resulted in increased H_2 formation rates and as a consequence a significant increase in 1,2-PDO selectivity was obtained. It was found that temperature increment positively affects the activity, but its combination with longer reaction times disfavors 1,2-PDO selectivity, due to consecutive HDO of 1,2-PDO to 1-propanol. When H_2 is externally supplied, increment of P_{H2} favored both activity and 1,2-PDO selectivity. The latter is due to increased H_2 solubility in liquid phase. On the other hand, when H_2 is in-situ formed, variation of P_{N2} did not have a significant effect on catalyst performance. In this case, H_2 is generated nearby the catalytic active sites and readily consumed by absorbed glycerol. This provides the ability of operating at lower system

pressures. Upon catalyst reuse, an activity loss of 33.0% was observed, due to Cu agglomeration. However, the performance was stabilized after the 3rd run, because of Cu redispersion, as evidenced by the measurement of the active Cu area. Worthy to note that TOF did not vary, revealing the structural integrity of the nature of the active sites.

For GLY HDO three different mechanisms were considered: a) dehydration-hydrogenation (HA route), b) dehydrogenation-dehydration-hydrogenation (GLA route) and c) direct GLY hydrogenolysis [3]. **Table 1** shows the reactant consumption and product formation rates for each test. In both tests with intermediate addition, HA and GLA added were fully converted and 1,2-PDO was the main product formed. The latter excludes a direct mechanism. HA addition in the feed negatively affects methanol APR rate and consequently H_2 availability. This was not observed when GLA was added, while in both cases glycerol rate was unaffected. It could be inferred that HA and MeOH compete for the same catalytic active sites. On the other hand, there is no competitive adsorption between reactants and GLA, as GLA reaction rate is much faster than MeOH and GLY rates. 1,2-PDO formation rate decrease upon intermediate addition (by 60% and 30% with HA and GLA addition, respectively). Decreased 1,2-PDO rate in the case of HA is a result of low H_2 availability (low MeOH APR rate), while the addition of GLA seems to have an inhibition effect on GLY HDO to 1,2-PDO. Taking the aforementioned into account as well as the identification of HA in all tests, it can be inferred that GLY HDO under the present reaction conditions primarily proceeds via the dehydration-hydrogenation mechanism. However, contribution of the GLA route to 1,2-PDO formation cannot be excluded. When 1,2-PDO and methanol were used as reactants, 1,2-PDO presented low reactivity pointing out that it is a rather stable component and 1-propanol was the main product formed via sequential HDO of the target diol. Hydrogenation of HA intermediate to 1,2-PDO is a reversible equilibrium-limited reaction, however under our experimental conditions 1,2-PDO dehydrogenation is not favoured.

Table 1. Reaction rates

Feed (mmol)	Consumption rate · 10^{-3} [mol/g_{cat}·hr]				Formation rate · 10^{-3} [mol/g_{cat}·hr]	
	MeOH	**GLY**	**1,2-PDO**	**HA**	**1,2-PDO**	**HA**
MeOH (66.8)+GLY(36.9)	3.42	21.74	-	-	14.17	3.34
MeOH (66.8)+GLY(36.9)+HA(3.9)	1.77	16.92	-	-	5.68	-
MeOH (66.8)+GLY(36.9)+GLA(3.9)	3.79	21.28	-	-	10.06	2.98
MeOH (66.8)+1,2-PDO(36.9)	1.29	-	5.81	-	-	2.01
MeOH (66.8)+HA(3.9)	1.26	-	-	2.67	0.9	-

4 Conclusions

The present innovative method validates the potentiality of glycerol HDO to 1,2-PDO under inert atmosphere. High 1,2-PDO yield (74.3%) was achieved over the $Cu_{0.6}Zn_{0.3}Al_{0.1}$ catalyst and under the optimum operating conditions. Finally, the elucidation of reaction pathways showed that GLY HDO primarily proceeds via the dehydration-hydrogenation mechanism.

Keywords: hydrogen production, formic acid decomposition, K-doping, Au Catalysts

1 Introduction

Formic acid (FA) is a non-toxic by-product of biomass cellulose hydrolysis used for production of levulinic acid. Catalytic FA decomposition has a great potential to produce hydrogen for fuel cells. Furthermore, FA can be used as a hydrogen donor in catalytic hydrogenation reactions.

Gold has an ability to perform highly selective and efficient catalysis at low temperature to achieve targets of green chemistry. Au can catalyze all kinds of reactions considered as the domain of Pt and Pd catalysts. Thus, Ojeda and Iglesia showed that well dispersed Au supported on Al_2O_3 gave higher turnover frequencies (TOFs) in FA decomposition than those for supported Pt [1]. Doping with alkali metals have been reported to increase considerably the catalytic performance of a Pd/C catalyst in FA decomposition [2]. In this paper, we report for the first time that doping of a Au/Al_2O_3 catalyst with potassium carbonate improves the catalytic activity by a factor of 4.5 and leads to about 100% selectivity to H_2 at low temperatures (<360 K).

2 Experimental/methodology

All catalysts were prepared by deposition-precipitation technique to get 3 wt.% of Au [3]. Potassium carbonate was deposited by impregnation on the most active catalyst. The catalysts were characterized by TEM, EXAFS and XPS. Vapour-phase FA (1.9 vol.%) decomposition reaction was carried out in a fixed bed quartz reactor. Activity tests were performed at atmospheric pressure with 23.5 mg of catalyst reduced in a 1 vol.% H_2/Ar mixture for 1 h at 573 K and cooled in He to the reaction temperature. A total flow rate equal to 51 cm^3 min^{-1} was used in all experiments. In the first step, a number of calcined Au catalysts supported on a different metals oxide and pre-treated in oxygen at 623 K were tested. In the second step, the catalytic properties of the pre-calcined Au sample with the highest activity and selectivity (Au/Al_2O_{3calc}) was compared to those for noncalcined sample (Au/Al_2O_3) doped with 3 and 6 wt.% of K.

3 Results and discussion

Figure 1a) compares the temperature for 50% conversion and selectivity for pre-calcined Au catalysts on different supports in FA decomposition. The activity trend for Au on the supports was the following: $MgO \leq CeO_2 << ZrO_2 \sim La_2O_3 < Al_2O_3$. The Au/Al_2O_{3calc} catalyst showed the highest activity and selectivity for H_2 production. It is important that the mean Au particle sizes were close for all catalysts (2.4-3.0 nm). The XPS analysis indicated the presence of mainly metallic state (93.4% Au^0) in the Au/Al_2O_{3calc} catalyst. Figure 1b) demonstrates the activity of the Au/Al_2O_{3calc} catalyst as compared to the noncalcined Au/Al_2O_3 sample with smaller mean Au particle size of 1.9 nm (after the reaction). At 373 K, the noncalcined Au/Al_2O_3 catalyst was

3 times more active than the Au/Al_2O_{3calc} catalyst. The obtained results can be explained by the presence of atomically dispersed Au species or clusters with a few atoms, which could be active sites of the reaction in accordance with the data of refs.[1,4]. Among the used supports alumina may provide better stabilization of such sites. Calcination might cause sintering of Au which decreases the amount of the Au active sites.

To further improve the catalytic properties the noncalcined Au/Al_2O_3 catalyst was doped with K carbonate. The $3K\text{-}Au/Al_2O_3$ sample was 4.5 times more active than the undoped Au/Al_2O_3 catalyst in spite of the activation energies increased considerably with doping from 53-54 to 94 kJ mol^{-1}.The selectivity to hydrogen was about 100% for all K-doped Au/Al_2O_3 catalysts. Additionally, the catalyst doped with 3 wt.% of K was also the most stable in the reaction for at least 25 h in this series of the catalysts. As the behaviour of the Au catalysts after doping with K carbonate is similar to that of the Pd/C catalyst discussed earlier [3], we use the same explanation of the K doping effect. At the used conditions, FA is condensed in the pores of the catalyst and transforms K carbonate to K formate, thus increasing considerably the concentration of formate ions in the solution. These ions become active intermediates of the reaction decomposing on the Au active sites with the formation of only H_2 and CO_2.

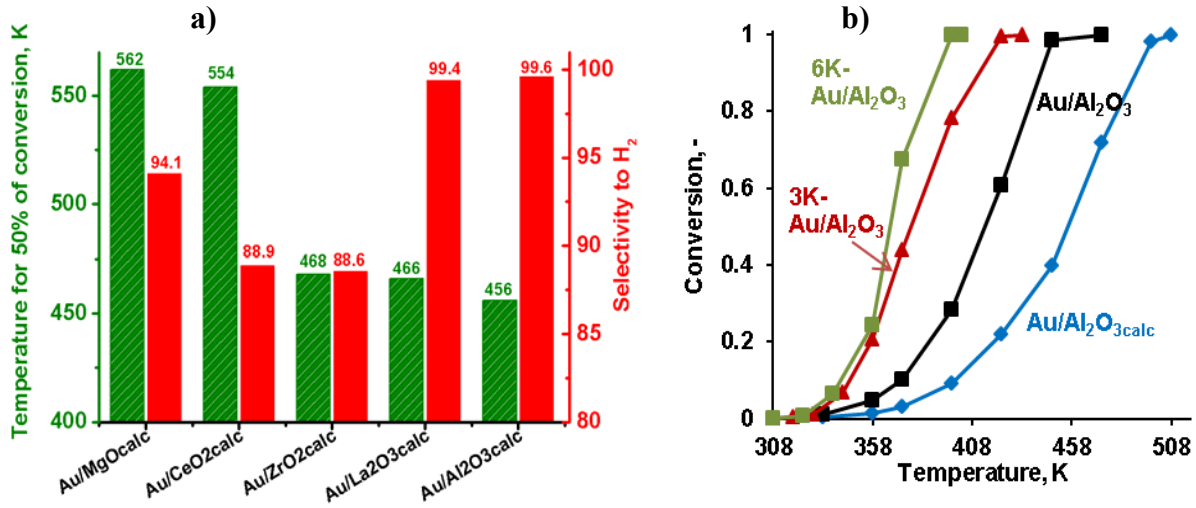

Fig. 1. a) Temperature for 50% of conversion and H_2 selectivity for calcined 3 wt.% Au catalysts on different metal oxides and b) temperature dependence of conversion in the decomposition of FA over pre-calcined and doped with K and undoped noncalcined 3 wt.% Au/Al_2O_3 catalysts.

4 Conclusions

We showed that alumina is the best support to stabilize active Au species for FA decomposition. The 3 wt.% Au/Al_2O_3 catalyst with 3 wt.% of K is an effective and stable catalyst in FA decomposition reaction at relatively low temperature (<360 K). It provides CO free hydrogen production from FA decomposition. The K-doping effect could be explained by the presence of K^+ ions in FA condensed in the catalyst's pores, which stabilize formate ions in the solution providing a different mechanism of FA conversion through these ions as compared to the undoped catalyst.

Keywords: products, alcohols, rapeseed oil, catalysts, structure, hydrocarbon fuel, catalytic activity

1 Introduction

Ethanol, 2-methylpropanol-1, 3-methylbutanol-1, mixture of fermentation organic products, glycerol and rapeseed oil are known to give rise bio-fuel components under hydro-deoxygenation conditions. In this paper, new catalysts based on alumina and zeolite supports containing nanosized bimetallic active components of I, II, VI, VIII groups have been tested in the reactions. Selective conversions of bio-substrates into alkanes, olefins, aromatics and naphthenic hydrocarbons components of gasoline and diesel fractions were observed.

2 Experimental/methodology

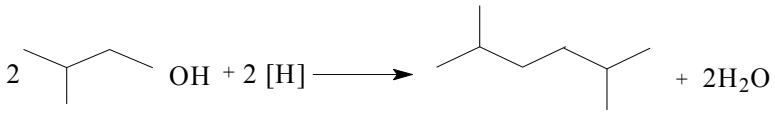
Industrial and laboratory elaborated catalyst samples were used in catalytic experiments. Both gaseous and liquid organic products in aqueous and organic phases were identified by GC-MS technique. The catalysts were tested in a PID Eng & Tech microcatalytic fixed-bed flow reactor unit, equipped with relevant instrumentation and control devices, under 350 °C, 5 atm of Ar, and substrates space velocity in the range of 0.6 h^{-1}. The local structure and charge state of active components were studied by XAS, XPS, XRD and TEM EDX. Relationships between structure of active components and catalytic activity of catalysts are discussed.

3 Results and discussion

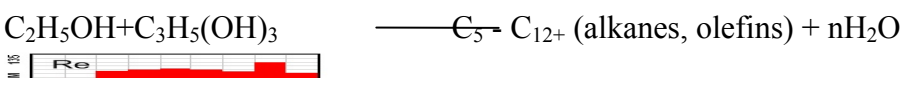
Ethanol conversion to fraction of alkanes C_5-C_{10+}[1] at 300-350^{0}C in inert atmosphere was found to be catalyzed with industrial Pt/Al_2O_3 catalyst after special pre-activation:

$$mC_nH_{2n+1}OH + H_2 \rightarrow C_{mn}H_{2mn+2} + mH_2O,$$
were $n \geq 1$; $m \geq 2$

2-methylpropanol-1 and 3-methylbutanol-1 were converted into 2,5-dimethylhexane and 2,7-dimethyloctane, respectively:



Cross-condensation of ethanol with acetone, bio alcohols, and glycerol in the presence of Pt/Al_2O_3 и [W(Ta)-Re]-catalytic systems leading toward the formation of new hydrocarbon with



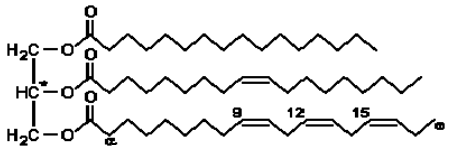
enlarged and branched carbon skeleton was observed[1]:

Ethanol/bio-alcohol transformation is multivariate reaction and mainly depends on feed-stock composition, reagent structure, and catalyst composition:

1. in the presence of modified platinum-contained catalyst reaction involves oligomerization of ethylene as intermediate;
2. aldol condensation is the main stage of hydrocarbons forming in the presence of W(Ta)-Re/Al_2O_3 and Pd-Zn/ Al_2O_3 catalysts;
3. alkane-aromatic hydrocarbons forming according to well-known "hydrocarbon pool" mechanism[2] in the presence of Pd-Zn/ZSM-5 catalyst.

Hydrogen consumed in product forming reactions originated from in-situ in reaction zone via parallel reaction dehydrogenation and aromatization of initial alcohol.

In the presence of original $Pt\text{-}Sn/Al_2O_3$ catalyst at 400-420^{0}C and 30 am H_2 rapeseed oil was unexpectedly found to yield dominantly narrow alkane-olefins C3, C18 and H_2O[3]:



$\longrightarrow C_3 + C_{18} + H_2O$

The selectivity of direct deoxygenation reaches up to 99%. The acid rest of the starting reagent converts quantitatively into C3 and C18 hydrocarbons (~ 92%). The total yield of C1 and C2 hydrocarbons as well as carbon oxides does not exceed 0,5-0,7 % that provides minimization of the carbon loss in the process of rapeseed oil deoxigenation.

Conversion of products fermentation and rapeseed oil into alkane-aromatic components of gasoline and kerosene without loading of molecular hydrogen was found. Hydrogen consumed for rapeseed oil hydrogenative deoxygenation was formed in the reaction zone via coupled reaction carrying out of ethanol aromatization.

Structure and evolution of the catalyst active sites were studied using TP-desorption of molecules-probes, XAFS, XPS, X-Ray and TEM HR.

Keywords: Standard SCR, NO oxidation, Fe zeolites, Mössbauer spectroscopy, active sites

1 Introduction

Fe zeolites have attracted major interest in catalysis because of their potential for a variety of reactions important for NOx abatement and for oxidations with N_2O and with H_2O_2. The identification of their active sites has been complicated by the abundance of different site structures formed by Fe species in zeolites. Apart from isolated Fe oxo cations located at three cation sites, oligomeric Fe oxo structures have been postulated. There can be irregular Fe oxo clusters of different sizes as revealed by EPR spectroscopy [1] and detected near the crystal boundaries by STEM [2], and well-crystalline particles on the external surfaces. In earlier papers, the role of binuclear Fe oxo clusters was emphasized [3]. They were considered as a majority species, e.g. derived from EXAFS measurements [4]. Meanwhile such sites have been lumped into the category "oligomers" because evidence offered for them has been considered inconclusive.

Work on Fe-containing catalysts may benefit from Mössbauer spectroscopy which differentiates Fe sites according both to oxidation state and coordination. However, due to the competition between thermal and spin coupling energies in very small clusters, measurements at very low temperatures, including examination of external field influence, are mandatory when the iron speciation in Fe zeolites is explored. We present here a study on active sites for standard SCR (sSCR) and NO oxidation, where catalytic rate data have been combined with state-of-the-art Moessbauer measurements on isotopically enriched samples.

2 Experimental

Fe-ZSM-5 (Si/Al ≈ 14, ≤ 0.7 wt-% Fe) was prepared via Solid-State Ion Exchange. In some cases, cation sites were partially blocked by inert cations (Na, Ca) prior to introduction of Fe. Activities were measured in flow regime with 1000 ppm NH_3, 1000 ppm NO, 2 % O_2 in He for sSCR, and 1000 ppm NO, 2 % O_2 in He for NO oxidation, both at a GHSV of 750,000 h^{-1}. For Moessbauer spectroscopy, samples were used for the corresponding reaction at 673 K for 45 min, cooled to room temperature in He and filled into capillaries. Mössbauer spectra have been measured at temperatures down to 5K and external fields up to 5 T in a setup equipped with a superconducting magnet. Analysis with a combination of Lorentzian doublets and sextets and paramagnetic subspectra has been made with a spin-Hamiltonian formalism as described in [5].

3 Results and Discussion

The catalytic behavior of the isotopically enriched samples is in agreement with that of conventional samples reported recently [6]. Specifically, Fe-ZSM-5 calcined at 873 K after preparation is drastically activated for NO oxidation by contacting the catalyst with sSCR feed at the same temperature (Fig. 1a). From experiments with variation of the Fe content, it will be

demonstrated that the active site of NO oxidation is a minority of the Fe present even at <0.7 wt-% Fe. In sSCR, the iron introduced into a ZSM-5 with 50 % of exchange sites blocked by Na is most active, while it is least active in the zeolite with 25 % of exchange sited blocked by Ca (Fig. 1b). Experiments with variation of the Fe content show the existence of two different active sites, where the one with the larger intrinsic activity is populated at the higher Fe contents, most likely a clustered species.

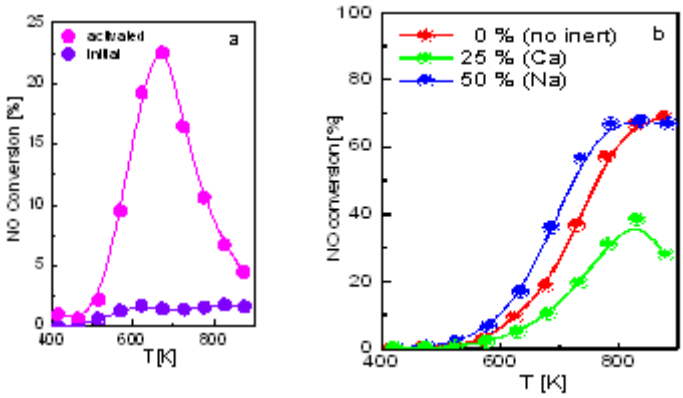

Fig. 1. NO conversions in NO oxidation (a) and sSCR (b); exchange capacity blocked: a - 25 % (by Ca), b – see legend. Activation by contact with sSCR feed at the same temperature (a). Fe contents - 0.39 … 0.43 wt-%.

Fig. 2 shows typical Moessbauer spectra, where the sample with the highest sSCR activity has been selected as an example. The spectra have been analyzed by five components. K1 arises from Fe(III)oxide nanoparticles, K2 indicates high-spin Fe(II) ions. K4 and K5 are attributed to isolated paramagnetic Fe(III) oxo ions appearing in EPR at g' ≈ 4. (K4) and g'≈ 6 and 2 (K5). K2 arises from two species because its intensity varies with the field: some of its intensity at low field appears in K1 at high field, where the shape of the residual signal indicates a diamagnetic structure. While the former may indicate very small Fe oxo aggregates (oligomers), the latter should arise from paired Fe oxo structures with an even number of Fe(III) ions, most likely from bridged Fe(III)-O-Fe(III) dimers. To our best knowledge, this is the first hard proof for an existence of this structure, which is, however, a minority site (ca. 20 % of Fe in Fig. 2). Measurements at higher temperatures (e.g. 77K) do not resolve signals K2, K4, and K5 and underestimate K2.

The comparison of Mössbauer spectra before and after activation for NO oxidation shows that clusters are destroyed and the intensity of signal K5 increases significantly, however, without direct correlation between activity and signal intensity. Possible reasons for this will be discussed. Regarding sSCR, high activities have been observed with samples offering large intensities of the K2 state. The chances to identify of the clustered site for sSCR in more detail will be discussed.

Fig. 2. Mössbauer spectra of Fe-ZSM-5 catalyst (sample "50 % (Na)" in Fig. 1b). T = 5 K, at low and high magnetic fields.

4 Conclusions

Moessbauer spectrosopy at low temperatures, comparing spectra at low and high fields, is a powerful tool for the identification of active sites in Fe zeolites. The method was successfully employed to identify active sites of NO oxidation and standard SCR in Fe-ZSM-5 or narrow down candidates for them.

Keywords: selective catalytic Rreduction, zeolites, Cu-CHA, mechanism, density, functional theory, spectroscopy

1 Introduction

The current technology of choice to reduce NOx emissions from power plants and exhausts from diesel-driven vehicles is based on the selective catalytic reduction of nitrogen oxides by ammonia (NH_3-SCR). The best known catalysts for this reaction are V_2O_5 supported on TiO_2, and Cu- or Fe- exchanged zeolites. In NH_3-SCR, NO is reduced by ammonia to N_2 and H_2O, according to the equation $4\ NO + 4\ NH_3 + O_2 \rightarrow 4\ N_2 + 6\ H_2O$. Despite the fact that this reaction has been known for many years, the precise mechanism and the rate determining step of this reaction are still under discussion. Since adding NO_2 to the reactant gas mixture enhances the rate of the SCR reaction, it has been argued that the activation of NO by O_2 is the rate determining step of the SCR reaction[1–4]. This conclusion is questioned, based on an observation that the rate of NO oxidation over a Cu-zeolite is much slower than the SCR reaction, which suggests that the activation of NO to NO_2 cannot be part of the SCR reaction.[5] Based on a new reaction scheme for the SCR reaction, the contradiction about NO activation by O_2 being the rate determining step can be resolved.

2 Experimental/methodology

A reaction scheme for the SCR reaction is constructed, in which only stable molecules are adsorbed and desorbed from the catalyst, and which describes the overall stoichiometry of the NH_3-SCR reaction correctly. By example of a Cu-CHA catalyst, the stability of the intermediates appearing in the reaction scheme and the transition state energies of relevant reaction steps have been verified by density functional theory (DFT). These calculations were performed using a real space grid-based projector augmented wave method (GPAW-package),[6] and the BEEF-vdW functional to account for Van der Waals interactions.[7]

3 Results and discussion

From the reaction scheme, it can be determined that the rate determining step for NH3-SCR over a Cu-CHA catalyst is the activation of NO by O_2 on a Cu^+ site. The two possibilities that follow from the reaction scheme are 1) the formation of a nitrate from O2 and NO adsorbed on a Cu-ion in the zeolite or 2) the formation of a nitrite by reaction with a nitrate and NO.[8,9] Figure 1 shows the calculated activation barriers for these steps. The calculated activation barrier for the formation of the nitrate is about 1.0 eV; that of the transformation to nitrite is

about 0.7 eV, indicating that the formation of the nitrate intermediate is the rate determining step.

To reconcile the activation of NO by O_2 as the rate determining step in NH_3-SCR with a low activity for NO oxidation to NO_2 in the absence of NH_3, it is realized that the rate of this reaction is the result of a catalytic cycle that is different from that of the NH3-SCR reaction. The NO activation in the SCR reaction is not a complete catalytic cycle, since the Cu^+ is oxidized to a Cu^{2+}. Since no NH_3 is present in the oxidation of NO to NO_2, the reduction of the Cu site to complete the catalytic cycle must be different from the corresponding reduction in the SCR cycle. If this reduction is much slower, compared to SCR, then this step becomes rate determining in the NO oxidation to NO_2.

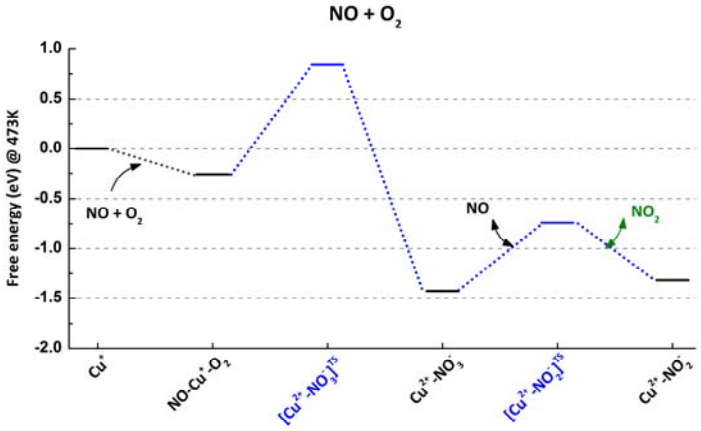

Figure 1. Calculated energies and activation barriers for NO activation by O_2 in NH_3 –SCR over a Cu-CHA catalyst

4 Conclusions

We have shown, based on a new reaction scheme for NH_3-SCR, that the rate determining step of the NH_3-SCR reaction is the activation of NO by oxygen to a nitrate species, and that this is not in contradiction to a very low rate for NO oxidation to NO_2 in the absence of ammonia. The reaction scheme further provides new insights in the role of several reaction intermediates, resulting in a deeper understanding of the NH_3-SCR reaction.

1 Introductio

Metal exchanged zeolites are excellent materials for the abatement of NO_x emissions from lean burn engines and are largely employed as wash-coated monolith for the NH_3-SCR technology. A demand for excellent performance of SCR systems is essential to comply with the current NO_x emission limits, as the exhaust gas temperature decreases for improvements in the combustion process. Due to their very good low temperature activity, Cu zeolites are the preferred catalysts; however, different zeolite structures could, in principle, result in different catalytic behaviour and selectivity towards undesired products, such as ammonium nitrate or N_2O [1]. The aim of this study is the elucidation of the structure-activity relations for three different Cu exchanged zeolites, namely a Cu-BETA, a Cu-SSZ-13 and a Cu-SAPO-34.

Steady state experiments were aimed at the comparison of the catalyst in terms of performance and selectivity towards by-products, whereas transient runs and in-situ DRIFT experiments were dedicated to the mechanistic investigation of SCR reactions and byproduct formation mechanisms.

2 Experimental/methodology

Three Cu zeolite catalysts, characterized by different zeolite structures (BETA, SSZ-13 and SAPO-34) but by the same Cu loading (2 % w/w) have been tested in the form of powders, in order to rule out any role of mass transfer phenomena. Steady state data have been collected varying NO_X feed concentration, temperature and gas flow under typical NH_3-SCR conditions (NO_2/NO_X = 0-1, T = 150-550 °C, 266'250/937'500 Ncc/h*$g_{a.p.}$, He used as carrier gas). Transient experiments included NH_3 and NO_2 adsorption + TPD, NO TPSR after nitrates adsorption, NO_2 adsorption after NH_3 adsorption. Transient experiments results were also analyzed by in-situ spectroscopic techniques, in order to collect information regarding surface species formation and stability.

3 Results and discussion

Results of NH_3 adsorption/desorption experiments revealed comparable NH_3 storage capacities for the three catalysts, with only small differences depending on the catalyst structure: the Cu-BETA had the lowest NH_3 storage capacity, the Cu-CHA the highest. Interestingly, the behaviour in the TPD was found different for the three catalysts: in particular, the Cu-BETA and the Cu-SAPO catalysts showed only one NH_3 desorption peak at 330/340 °C whereas the Cu-CHA showed two desorption peaks, at 300 and at 430 °C; this is in accordance with various literature reports on similar catalysts [2, 3].

In addition, Figure 1A shows results obtained during a TPD performed after NO_2 adsorption: the Cu-BETA showed lower nitrates storage capacity and nitrates stability with peaks at 250 and 370 °C; on the other hand, small pore zeolites (Cu-CHA and Cu-SAPO) exhibited similarly higher nitrates stability, with desorption peaks at 330 and 400 °C. As regards

NH_3 oxidation activity, the Cu-BETA showed the lowest activity while the Cu-CHA had the best performance. Related to the SCR activity, namely in the cases of Standard SCR (NO_X conversion reported in Figure 1B) , NO_2 SCR and Fast SCR activity, the Cu-SAPO-34 was the worst catalyst. However, as reported in Figure 1B, the same Cu-zeolite, tested after an ageing process carried out for 2 hours at 750°C, exhibited enhanced Standard SCR performance. A general improvement of SCR activity of the aged Cu-SAPO compared to the fresh sample was evident also for NH_3 oxidation, NO_2 SCR and Fast SCR. Such an improvement can be ascribed to an improved Cu dispersion.

Lower nitrates stability on Cu-BETA possibly explains higher $deNO_x$ activity observed in presence of NO_2, confirmed by greater nitrates reducibility by NO in NO TPSR experiments. On the other hand, this catalyst showed also greater NH_4NO_3 formation and greater N_2O selectivity on Cu-BETA when NO_2 is present, in particular under NO_2 SCR conditions as noticeable by inspection of Figure 1C. In particular, as regards N_2O selectivity, the Cu-SAPO showed the lowest selectivity towards this undesired product.

The systematic in-situ DRIFT study aimed at clarifying the mechanisms of SCR reactions and N_2O formation, confirmed different stability of nitrites/nitrates species, in line with the experimental evidence collected during steady state and transient runs experiments.

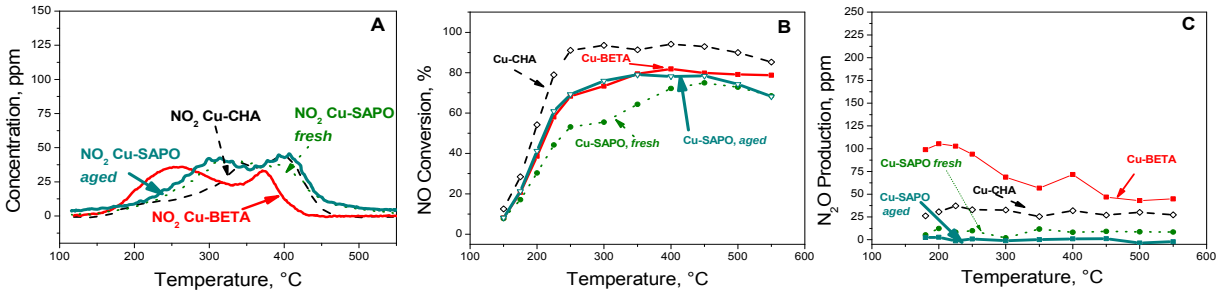

Fig. 1. Comparison of Cu-BETA, Cu-CHA, Cu-SAPO fresh and Cu-SAPO aged: A) TPD results after NO_2 adsorption at 120°C; B) NO_X Conversion in Standard SCR; C) N_2O production in NO_2 SCR.

4 Conclusions

Comparison of the activity of Cu-BETA, Cu-SAPO and Cu-CHA catalysts characterized by the same Cu loading suggests an important role of the zeolite structure in determining not only the $deNO_X$ activity, but also the product distribution (NH_4NO_3 formation and selectivity towards N_2O). In particular, from the results obtained by in-situ DRIFTS and transient runs experiments, zeolite structure and Cu distribution seem to strongly affect the formation of nitrites/nitrates surface species, which play a key role in the mechanism of SCR reactions.

Keywords: selective catalytic reduction (SCR), NOx removing, NH_3-SCR, Fe-zeolite

1 Introduction

Environmental protection standards with respect to air pollutants such as nitrogen oxides (NO_x) are becoming increasingly stringent [1]. Selective catalytic reduction of NO_x by NH_3 (NH_3-SCR) is one the most efficient technologies used for removing NO_x, where the vanadia catalyst is the first commercialized catalytic system. However, several problems still remain, e.g. toxicity of vanadia, formation of N_2O at high temperatures and instability when these catalysts are applied for diesel vehicles [2,3]. Therefore, there are continuous efforts in developing new catalysts. Fe-loaded zeolites received much attention due to its high activity, thermal stability and sulfur and water resistance than the vanadia catalyst, under SCR reaction conditions [4,5]. It is well recognized that the activity of Fe-loaded zeolites for SCR depended strongly on the preparation method [4,5]. The aim of the present work was to investigate the influence of the preparation method and the support used (ZSM-5, Beta and LTL) on the SCR-NH_3 activity of the different Fe-loaded zeolites catalysts.

2 Experimental/methodology

ZSM-5, Beta and LTL supports were hydrothermally synthesized, as described in detail elsewhere [6]. The active phase (Fe) was introduced by impregnation (IMP) and in-situ hydrothermal (HT) methods and, these catalysts after aged were characterized by N_2 adsorption, ICP, RMN, XRD, XPS and TEM. Catalytic tests were carried out using 25 mg of catalyst and a reactant mixture containing [NO] ≈ [NH_3] ≈ 1000 ppm, [O_2] ≈ 8 vol.%, [H_2O] ≈ 3 vol.% and He as carrier gas (GHSV = 142.000 h^{-1}). Temperature was increased by a ramp of 2°C min^{-1} up to 500°C. After this treatment, all catalysts were tested during the cooling ramp.

3 Results and discussion

XRD spectra of the zeolites and the Fe-loaded zeolites catalysts are quite similar, which means that the crystalline nature of the zeolites was not modified after the Fe incorporation. No peaks could be assigned to the presence of metallic iron or iron oxide, evidencing high Fe dispersion. XPS results showed that, Fe cations were presented mainly as Fe^{3+} ions (Fe_2O_3, 711 eV), along with a small amount of Fe^{2+} (FeO, 709 eV) in the case of the hydrothermal catalysts, whereas the impregnated catalysts presented the formation of aggregated Fe^{3+} ions (Fe_3O_4, 710.76 eV). Moreover, for a given preparation method, the Fe particles size follows this trend Fe/ZSM-5 > Fe/Beta > Fe/LTL. This could be attributed to the zeolite structure, where the iron solution is expected to enter more easily into the Beta or LTL than on the ZSM-5 porosity [5], Table 1, favoring the higher dispersion.

The preparation method used affects the SCR activity of Fe-loaded zeolites catalysts. The hydrothermal catalysts presented higher activity and N_2 selectivity than the impregnated one. This could be a consequence of the partial pores blockage of the zeolite, with the impregnated

catalysts, then some of the active Fe sites could not participate in the reaction and also, the Fe_3O_4 oxides formation due to the Fe particles agglomeration [5,7]. Moreover, the N_2O formation was lower for the hydrothermal catalysts than for the impregnation ones, which could be also attributed to the absence or lower amount of Fe_3O_4 oxides presented in these catalysts [8]. Moreover, for a given preparation method (hydrothermally synthesis) and same Fe amount (1%wt. Fe) the NH_3-SCR activity at low temperature follows this trend Fe/LTL ≈ Fe/Beta > Fe/ZSM-5. However, the N_2-selectivity of Fe/LTL decreases dramatically at higher temperatures, Fig. 1. This indicates that the framework structure and/or pore geometry are crucial for determining the SCR activity [5,9].

Table 1. Physicochemical properties of hydrothermal catalysts.

Catalysts	Si/Al $_{RMN}$	Fe loading (wt.%)$_{ICP}$	BET surface area (m^2g^{-1})	Total pore volume (cm^3g^{-1})	Average pore size (nm)
HT-Fe/ZSM-5	27,3	1	376	0.14	5.1
HT-Fe/Beta	8,4	1	670	0.29	9
HT-Fe/LTL	2,9	1	401	0.31	8.6

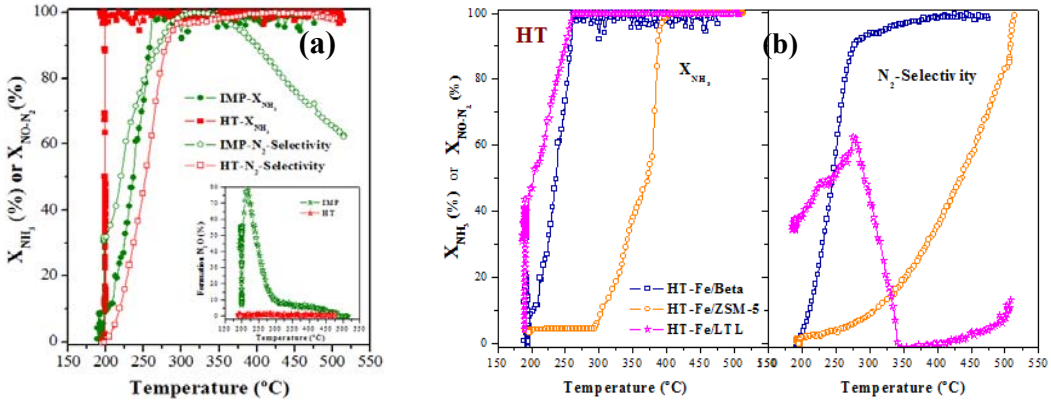

Fig. 1. (a) Comparison impregnated and hydrothermal **Fe-Beta** catalysts activity and **(b)** NH_3-SCR activity of **Fe-loaded zeolites** catalysts hydrothermally synthesized.

4 Conclusions

The particular NH_3-SCR behavior of the catalysts depends on the preparation method and the zeolite nature. Thus, the hydrothermally synthesis allowed a more active catalyst, maintaining the selectivity to N_2 with low N_2O formation and, the framework structure and/or pore geometry was crucial for determining the SCR activity.

Keywords: SCR, DeNOx, ammonia, vanadium, diesel exhaust gas

1 Introduction

Reduction of NO_x by NH_3 is recognized as the most efficient technology for practical application for both stationary and mobile sources. However commercial V_2O_5–WO_3/TiO_2 or V_2O_5–MoO_3/TiO_2 can suffer from vanadium toxicity due to the presence of V_2O_5. By contrast, cerium orthovanadate material ($CeVO_4$) has interesting properties related to the stabilization of Ce^{3+} and V^{5+} cations in tetragonal zircon-type structure. This compound is also active in oxidation reaction thanks to its reducibility. In the present study we investigated the catalytic behaviour of $CeVO_4$ in the Selective Catalytic Reduction of NO_x by ammonia. Particular attention was focused on the impact of synthesis procedure and thermal ageing treatments on the catalytic activity in standard SCR, fast SCR and NO_2 SCR conditions.

2 Experimental/methodology

$CeVO_4$ was prepared according to Xie's method [1] using Na_3VO_4 and $Ce(NO_3)_3{,}6H_2O$ precursors. The precursors were dissolved in water at different pH adjusted by dropwise addition of NaOH solution. Then, the mixture was treated in hydrothermal conditions at 180°C for 24h. The solid thus obtained was washed in water and ethanol. BET, SEM, Raman spectroscopy, XRD and XPS analyses were achieved before and after thermal ageing treatment. NO, NO_2, NH_3, N_2 and N_2O concentrations were measured during temperature-programmed reactions in a fixed bed reactor at GHSV=150,000 $mL.g^{-1}.h^{-1}$ from 200°C to 550°C under standard, fast and NO_2 conditions. Realistic gas mixture consisted of 400 ppm NO_x+400 ppm NH_3+8 vol.% O_2+10 vol.% CO_2 +10 vol.% H_2O in Helium with NO/NO_x ratio equal to 0.9, 0.5 and 0.3 for standard, fast and NO_2 SCR respectively. The thermal ageing treatment consisted of ageing the catalyst in 10 vol.% H_2O in air between 500°C to 850°C.

3 Results and discussion

XRD patterns evidenced the formation of the tetragonal zircon-type structure for $CeVO_4$ and also the presence of bulk CeO_2 impurity in small extent when the final pH of the solution was higher than 2. Subsequent, thermal ageing at 500°C, 600°C and 850°C led to a progressive sintering and a correlative decrease of the specific surface area from 46 m^2/g to 0.5 m^2/g. It should be noticed that the characterization by Raman spectroscopy and XRD confirmed the absence of V_2O_5 segregation independently the synthesis or thermal ageing procedure.

The catalytic performances were evaluated in presence of steam, CO_2 and an excess of O_2 on aged samples at different temperature. $CeVO_4$ synthesized at final pH=3.3 and further aged at 500°C in 10 vol.% H_2O/air exhibited interesting NO_x conversion with a complete selectivity to

N_2 formation in the wide range of temperature whatever the NO/NO_x ratio. In Fast SCR conditions, the conversion of NO_x to N_2 remains stable around 90-95% between 200°C and 400°C at 150,000h^{-1}. In standard conditions with NO/NO_x=0.9, the NO conversion progressively increased from 34% at 200°C to 79% at 450°C. NO_x conversion also progressively increased until 99% at 450°C for NO_2 SCR.

Table 1. Specific surface area and crystalline size of $CeVO_4$ (pH=3.3) according to the ageing temperature

	After drying at 80°C	Ageing temperature 500°C	600°C	850°C
BET surface area (m^2/g)	46	17.7	5.8	0.5
$CeVO_4$ crystalline size (nm)*	27	46	85	96

* estimated from XRD using Scherrer method

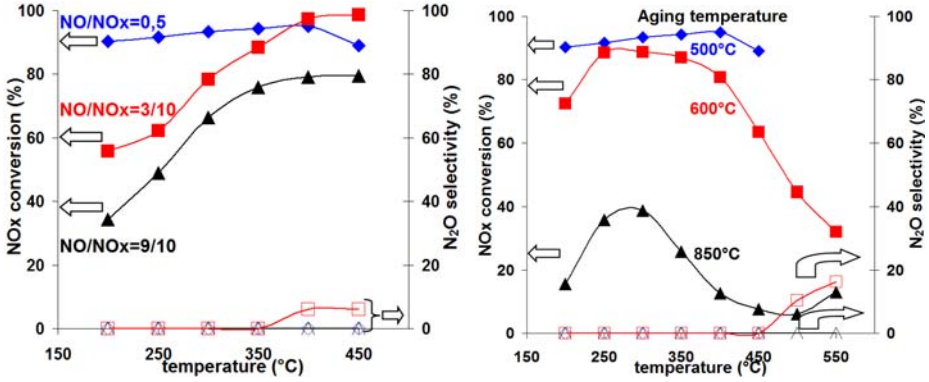

Fig. 1. Comparison of NO_x conversion and N_2O selectivity of $CeVO_4$ (pH=3.3) in standard, fast and NO_2 SCR after thermal ageing at 500°C (A) and in fast SCR after thermal ageing under 10%H_2O/air at 500°C, 600°C and 850°C (B)

The NO_x conversion in fast SCR conditions was slightly decreased between 250 and 350°C after ageing at 600°C whereas ammonia oxidation led to NO and N_2O above 500°C. Clearly, the sintering of active phase strongly influences the catalytic performances at high temperature. The final thermal ageing at 850°C which was accompanied by very low specific surface area also led to a significant decrease of NO_x conversion at the expense of NH_3 oxidation above 500°C. The conversion reached 39% at 300°C which is quite high if we take into account its low specific surface area. This point suggested that the stabilization of specific surface area for $CeVO_4$ is a key point for further application of $CeVO_4$ in mobile sources. Subsequent incorporation was found to improve the catalytic performances limiting the impact of deactivation. XPS analysis and adsorption of probe molecules provided important information related to the resistance to deactivation of acidic and redox functions.

4 Conclusions

This study reports the first application of CeVO4 in deNOx catalysis for stationary and mobile sources. The CeVO4 catalyst is promising for stationary sources applications. The catalyst exhibited NOx conversion to N2 around 93% at 150,000 mL.g-1.h-1 between 200 and 400°C after thermal ageing at 500°C in 10%H2O/air. In the case of mobile sources, the stabilization of specific surface area will be discussed.

Keywords: ammonium, formate, gold catalysis, effect of base, formic acid, decomposition, SCR

1 Introduction

Urea has been one of the most widely used ammonia storage compounds for selective catalytic reduction (SCR) of NO_x in automobiles. However, the observable problems with urea solution initiated research efforts to replace this compound with alternative ammonia precursors, such as concentrated guanidinium formate, ammonium formate (AmFo) and methanamide solutions, that are more thermally stable, freeze at lower temperature, have higher ammonia storage capacity, and decompose more selectively [1,2]. AmFo is experimentally the simplest choice to study the activity and behaviour of catalysts for the decomposition of the aforementioned precursors under realistic conditions [3]. We have recently identified Au/TiO_2 as a uniquely selective catalyst to convert AmFo into CO_2 without oxidizing the co-evolved ammonia even under highly oxidizing conditions prevalent in the exhaust gases [4]. Since, AmFo thermolyzes into ammonia and formic acid in the gas-phase, it is important to understand the effect of ammonia on formic acid decomposition as a step towards catalyst optimization. A promotional effect of ammonia was observed on the decomposition rate which also entailed an enhanced selectivity for CO_2 formation [5]. Such a promotional effect of the basic gas-phase reactant was also realized as a catalytic effect by introducing a base metal oxide (La_2O_3) into the catalyst. Additionally, by corollary, it is shown that acid-modification (WO_3) of the catalysts results in suppressed activity.

2 Experimental

The catalysts were prepared by incipient wetness impregnation of $HAuCl_4$ on commercial anatase, 10 wt% La_2O_3-TiO_2 and 10 wt% WO_3-TiO_2 (Cristal Global). The gold composition was fixed at 0.5 wt%. The catalysts were washcoated on cordierite monoliths and tested on a laboratory-scale reactor setup in a feed containing 650 ppm AmFo or formic acid, 0-7800 ppm ammonia, 10 vol% O_2, 5 vol% H_2O and balance N_2 at 750 $L \cdot h^{-1}$ in order to realize very high GHSVs in the range 50,000 h^{-1} to 300,000 h^{-1}. Full experimental details are given elsewhere [4,5].

3 Results and discussion

A systematic investigation of the effect of ammonia on formic acid decomposition revealed a highly beneficial influence on the reaction rate and the CO_2 yield in the temperature range 160–300 °C (Fig. 1a). Ammonia oxidation did not occur at any of the studied temperatures and space velocities which is remarkable considering the high concentrations of O_2 (10%) and H_2O (5%) in the feed. Analogously, it was found that La_2O_3-modification results in significant promotion, while modification by WO_3 causes an opposite effect leading to suppressed activities

(Fig. 1b). At 300 °C, using the lowest contact time, formic acid decomposition rate increased 3.5-fold over Au/La_2O_3-TiO_2 and decreased 0.7-fold over Au/WO_3-TiO_2. Under the same conditions, CO_2/CO ratio underwent an increase by a factor of 10 in the case of Au/La_2O_3-TiO_2 compared to the unmodified Au/TiO_2, while WO_3-modification halved the CO_2/CO ratio. Determination of kinetic orders with respect to formic acid strongly suggested surface-poisoning of all the catalysts, with Au/La_2O_3-TiO_2 exhibiting the most negative order. CO_2 adsorption on the three catalytic systems analyzed using FTIR spectroscopy confirmed the high basicity of Au/La_2O_3-TiO_2 in the form of high CO_2-uptake. The presence of La_2O_3 favored the formation of smaller gold particles as indicated by HAADF-STEM analysis. Thermal aging of Au/La_2O_3-TiO_2, leading to gold particle growth to the gold size range of Au/TiO_2, did not alter the base-induced trends in activity and CO_2 selectivity. The activity tests of the modified supports in the absence of gold confirmed the crucial role of gold for the realization of such a base-induced promotional effect.

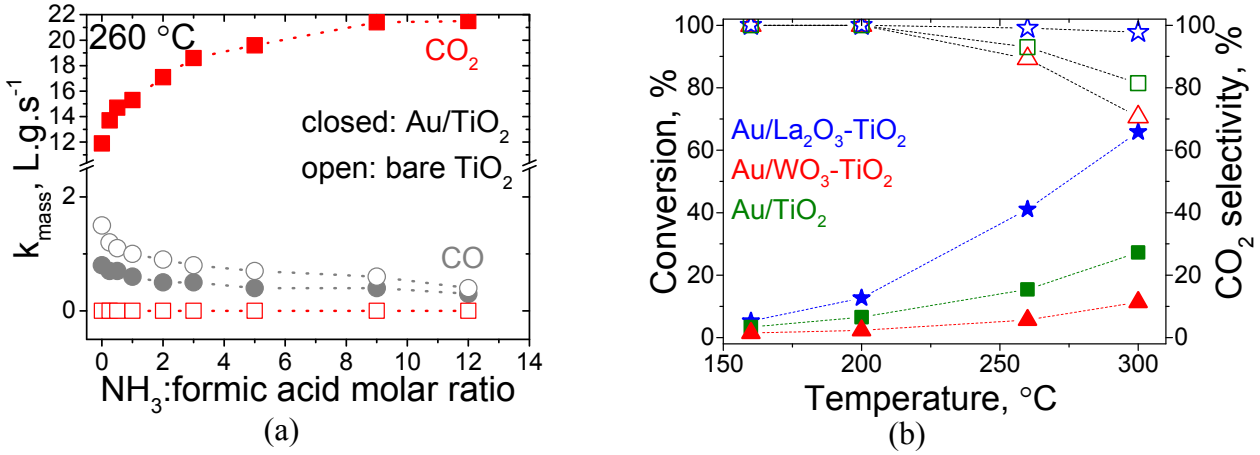

Fig. 1. (a) Effect of ammonia on rate constants for CO_2 and CO production from formic acid decomposition at 260 °C, (b) effect of La_2O_3- and WO_3-modification on formic acid decomposition (closed symbols: conversion, open symbols: CO_2 selectivity).

4 Conclusions

Fast decomposition of the formate part of alternative ammonia precursor compounds presents two advantages: (1) the cationic part is destabilized and (2) formic acid is no longer available to form side products like methanamide or HCN [3]. Au/TiO_2 apart from being a highly active and selective catalyst for AmFo decomposition also showed an enhanced decomposition activity in the presence of excess gas-phase ammonia. As a rational step towards further catalyst optimization, the observed promotional effect of the basic gas-phase reactant was transformed into a catalytic effect by support-modification with a basic additive.

Keywords: NSR/LNT, $Al_2O_3/ZrO_2/TiO_2$, Pt, DeNOx, FTIR, TPD

1 Introduction

Some of the major challenges of NO_x Storage Reduction (NSR) or Lean NOx Trap (LNT) catalysts are associated with sulfur poisoning and thermal/structural stability [1-6]. On the other hand, improvement of sulfur tolerance of an NSR/LNT system need to be accomplished without comprising the NO_x storage capacity. TiO_2 which has a moderately high surface acidity is known as a promising oxide support/promoter against sulfur poisoning, providing much lower temperature for sulfur elimination, but leading to a relatively limited NOx storage capacity [7]. In the current contribution, we focus on the surface chemistry of $Al_2O_3/ZrO_2/TiO_2$-based NSR/LNT catalysts. In particular, we elucidate the NO_x and SO_x adsorption and thermal regeneration performances under reducing conditions at the molecular level by means of in-situ FTIR and TPD techniques. Moreover, NO_x uptake capacities aforementioned materials are quantitatively investigated in the presence and absence of sulfur poisoning via flow mode performance analysis tests.

2 Experimental/methodology

Detailed description of synthesis of ZrO_2/TiO_2 (ZT) binary and $Al_2O_3/ZrO_2/TiO_2$ (AZT) ternary oxide systems via co-precipitation technique has been explained in detail in one of our former reports [3]. The synthesis of the support materials is followed by BaO and Pt addition via incipient wetness impregnation method, forming catalytic materials in the form of $Pt/Al_2O_3/ZrO_2/TiO_2$, $Pt/BaO/Al_2O_3/ZrO_2/TiO_2$, and $Pt/BaO/Al_2O_3$ (Pt/Ba/Al). Structural properties of the synthesized catalysts were investigated via XPS, ex-situ Raman spectroscopy, TEM, EDX, XRD and BET while their NOx uptake and release behavior was investigated by employing the flow mode catalytic performance experiments as well as in-situ FTIR and TPD measurements.

3 Results and Discussion

As illustrated in Figure 1, sulfur regeneration capability of $Al_2O_3/ZrO_2/TiO_2$–supported materials are noticeably higher in the presence of a reducing agent (i.e. $H_2(g)$). While complete SO_x regeneration is achieved around 773 K on Pt/AZT, this temperature (c.a. 973 K) is much higher for Pt/Ba/Al. However, NO_x sorption ability of Pt/AZT without the basic oxide storage domains (i.e. BaO and K_2O) is too low to be considered for LNT applications at the relevant operational temperatures (e.g. 573 K) due to the high surface acidity/low basicity of this surface. Therefore, Pt/AZT material are enriched and modified by incorporation of a basic storage domain, namely BaO. While addition of 8wt % BaO has a minor influence on sulfur regeneration temperature, 20wt % BaO loading drastically change the materials characteristics as shown in the in-situ FTIR results. These findings are also supported by the TPD data as

illustrated in Figure 2. SO_x uptake capacities of investigated BaO-containing catalysts can be ranked in a decreasing order as Pt/20Ba/Al > Pt/20Ba/AZT > Pt/8Ba/AZT. Finally, all materials were tested in quantitative flow reactor measurements performed under realistic catalytic conditions (data not shown) and Pt/8BaO/AZT catalyst revealed a superior NSC at 573 K upon sulfur poisoning and subsequent regeneration, surpassing the catalytic performances of all of the currently investigated materials including the conventional Pt/20BaO/Al benchmark catalyst [8].

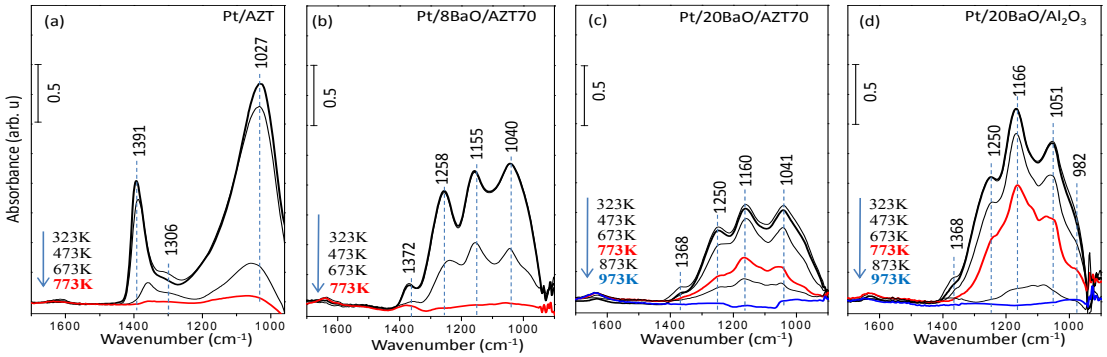

Figure 1. FTIR spectra related to SO_x release properties of sulfur-poisoned (a) Pt/AZT, (b) Pt/8Ba/AZT, (c) Pt/20Ba/AZT and (d) Pt/20Ba/Al in the presence of H_2(g).

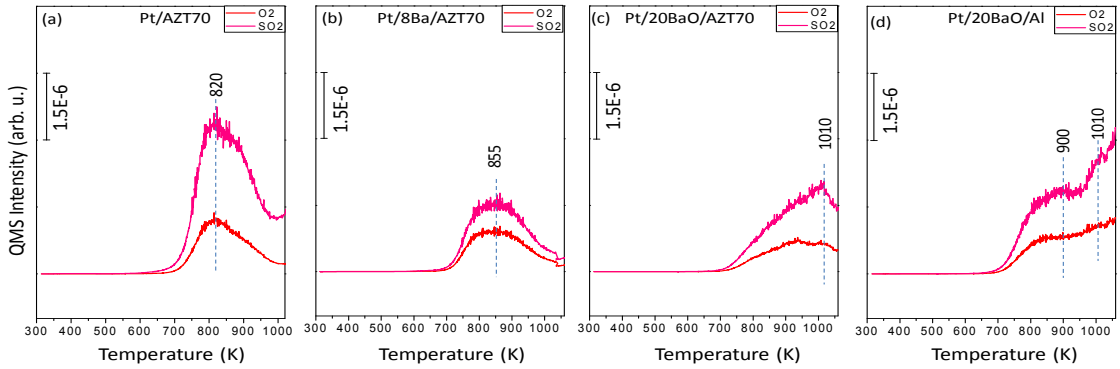

Figure 2. TPD profiles related to SO_x desorption from sulfur-poisoned (a) Pt/AZT, (b) Pt/8Ba/AZT, (c) Pt/20Ba/AZT and (d) Pt/20Ba/Al surfaces.

4 Conclusions

It is a great challenge to synthesize catalytic materials revealing superior sulfur tolerance and high NO_x uptake capacity. In this study, we provide fundamental insights regarding the molecular-level understanding of the adsorption characteristics of acidic adsorbates such as NO_x and SO_x on a novel ternary oxide catalytic support material, whose surface properties can be fine-tuned to optimize NSR/LNT performance.

Opportunities for Ceria-based Catalysts versus Platinum Catalysts in Diesel Soot Combustion

Giménez-Mañogil J., García-García A.*

MCMA Group, Dept. of Inorganic Chemistry, Faculty of Sciences, University of Alicante, Alicante, Spain

* a.garcia@ua.es

Keywords: ceria-zirconia, copper, platinum catalyst, soot combustion, NO_2 production

1 Introduction

Noble metal-based catalysts, such as platinum, have been developed to promote the oxidation of NO to NO_2, which is more oxidant than O_2, and decrease the combustion onset temperature of soot under realistic diesel conditions. However, their high cost has led to the consideration of other lower-priced materials that can be competitive in terms of catalytic activity. These include, besides cerium-based catalysts, those using transition metals.

Copper-doped ceria (and ceria-zirconia) mixed oxides have managed to overcome activity and selectivity of undoped oxides in reactions such as soot combustion [1]. The Cu-ceria interface interactions confer a synergistic effect, which enhances the redox properties of the catalyst due to the stabilization of highly reactive copper species [2].

Even though a large number of catalytic formulations have been tested for catalytic combustion of diesel soot, a lot of work is still needed in order to advance towards a rational catalyst design. Therefore, the overall aim of this research is to conduct a systematic study of the ceria-based catalysts' activities for soot combustion, comparing to a commercial Pt/alumina catalyst in a set of experiments (under isothermal/ramp modes and under different gas atmospheres) to explore the opportunities of ceria-based catalysts versus noble metal supported catalysts for this application. The results obtained from the NO_2 and "active-oxygen"-assisted soot combustion, as well as the NO ↔ NO_2 recycling efficiencies, were discussed.

2 Experimental

The $Ce_{0.8}Zr_{0.2}O_2$ support (CZ) was prepared by the co-precipitation method, and the solid obtained after filtration was dried and calcined at 500°C for 1 hour in air. The $Ce_{0.8}Zr_{0.2}O_2$-supported catalyst with 2% Cu (Cu2/CZ) was prepared by incipient wetness impregnation with an aqueous solution of $Cu(NO_3)_2 \cdot 3H_2O$ and subsequent drying and calcination at 500°C for 1 h. This amount of Cu was chosen from a previous optimization study [3]. The commercial $1\%Pt/Al_2O_3$ was supplied by Sigma-Aldrich (Pt1/AL).

The catalysts were characterized by N_2 adsorption-desorption isotherms at -196°C, XRD, Raman spectroscopy, XPS and H_2-TPR. They were tested for NO oxidation to NO_2 in TPR conditions (from room temperature up to 700ºC at 10ºC/min), and for soot combustion (TPR and isothermal reactions at 400, 425 and 450ºC). The gas mixture used comprised 500 ppm NOx, 5% O_2 and N_2 balance (or $5\%O_2$ and N_2 balance); the gas flow was fixed at 500 ml/min (GHSV = 30,000 h^{-1}).

3 Results and Discussion

According to the whole characterization results, copper remains well-dispersed (absence of segregated phases corresponding to CuO) onto the ceria-zirconia's surface and evidences of copper incorporation into the lattice were not revealed. The procedure of incipient wetness impregnation led to a dramatic improvement of the copper entities' reducibility (with regard to bulk CuO) and a concomitant ceria reduction at low temperatures was also quantified. This

synergistic effect explains the relevant improvement in the NO oxidation capacity to NO_2 that this very low copper doping provides to the ceria zirconia support. In spite of these satisfactory results, Cu2/CZ sample is still far from the NO_2 production capacities of the platinum catalyst (47% versus 75%, expressed as maximum NO_2 production in a TPR experiment).

In spite of the very high NO_2 production capacity and excellent efficiency towards the NO ↔ NO_2 recycling activities exhibited by the platinum catalyst, the superior production and transfer of "active oxygen" towards the soot surface (even in the loose-contact mode) combined to a moderate activity for NO_2 production in a convenient temperature range lead to a more and more positive performance of the 2% Cu catalyst, thus emulating the noble-metal catalyst's behavior for the complex solid-solid-gas reaction involved in the diesel soot combustion. In this sense, Figures 1 and 2 reflect the different trends in activity obtained for the selected catalysts as a consequence of the relevance of the "active oxygen"-assisted soot combustion as the temperature becomes higher and higher.

At 400°C, Pt-catalyst is the most active one (the three experiments are conducted with the same amount of catalyst) and only if the soot combustion reaction rate is expressed in terms of price, the most efficient catalyst becomes Cu2/CZ (Figure 1). More interestingly, at 450°C, the copper-containing catalyst outperforms the catalytic response given by the noble metal-catalyst, expressed as combustion rate (Figure 2).

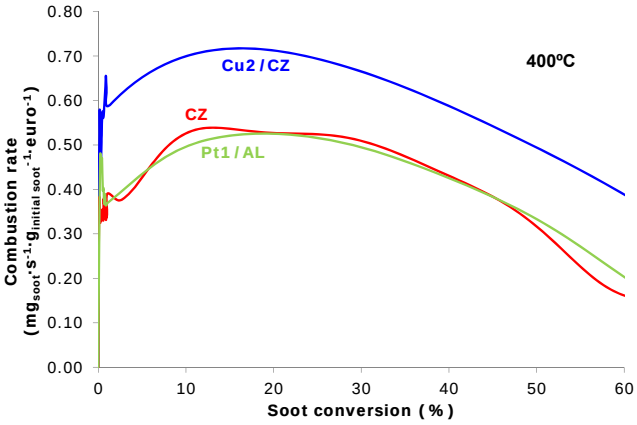

Figure 1. Soot combustion rates, expressed per euro of catalyst cost, versus soot conversion under isothermal conditions (400ºC).

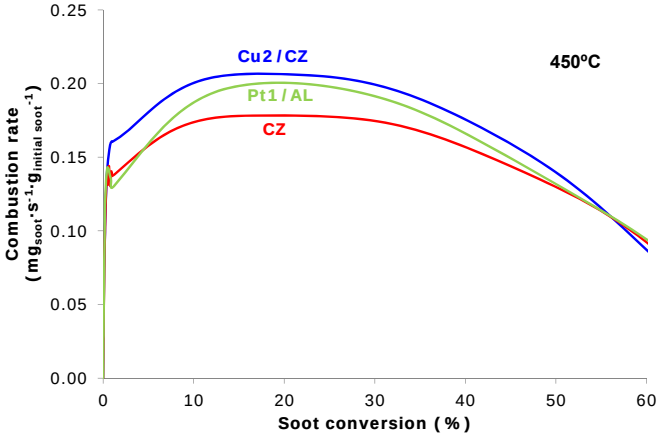

Figure 2. Soot combustion rates versus soot conversion under isothermal conditions (450ºC).

4 Conclusions

A catalyst prepared by incipient wetness impregnation of $Ce_{0.8}Zr_{0.2}O_2$ with a 2% of copper allows outperforming the catalytic performance exhibited by a commercial platinum catalyst under NOx/O_2 at 450°C, thus revealing the opportunities of ceria-based catalysts in the context of soot combustion application.

Keywords: three-way catalyst, ceria, ceria-containing oxide, oxygen storage capacity

1 Introduction

Ceria-containing oxides ($Ce_xM_{1-x}O_2$) are an intrinsic part of three-way catalysts (TWC): they increase the activity of TWC while reduce the load of precious metals and the cost of TWC. Ceria damps fluctuations of oxygen in exhaust gases, keeping its content at the catalyst surface equal to the stoichiometric ratio. These conditions provide the effective oxidation of CO and hydrocarbons to CO_2 and H_2O simultaneously with the reduction of NO_x to N_2 [1].

Dynamic oxygen storage capacity (OSC) of $Ce_xM_{1-x}O_2$, which refers to oxygen kinetically available for chemical reactions, allows one to predict the performance of TWC. OSC can be measured under cycling flow conditions when a gas with O_2 alternates a gas with CO [2]. In this method, oxygen is accumulated in the oxide lattice while the gas with O_2 passes through the sample. A release of oxygen and catalytic oxidation of CO to CO_2 proceed during the next alternative step, when the gas with CO passes through the sample. The OSC in this method is calculated from the amount of CO transformed to CO_2. $Ce_xM_{1-x}O_2$ acts as a catalyst. However, $Ce_xM_{1-x}O_2$ is almost inactive in the oxidation of CO at temperatures below 300 ^{O}C [2], which makes the OSC measurement impossible. Therefore, OSC is usually studied at sufficiently high temperatures (e.g. 400 ^{O}C).

Addition to $Ce_xM_{1-x}O_2$ of a more active catalyst allows one to decrease the temperature of the CO oxidation stage and thus to expand the boundaries of OSC research. For instance, CO oxidation on a Pt/Al_2O_3 catalyst is possible at temperatures from 150 ^{O}C [3]. Expanding the boundaries of OSC research toward lower temperatures is of great interest because it enhances the understanding of TWC properties.

2 Experimental/methodology

Mixtures comprising 56% Pt/Al_2O_3 and 44% $Ce_xM_{1-x}O_2$ were used to measure OSC. The content of Pt on Al_2O_3 was 0.8%. The mixtures were deposited on a cordierite honeycomb support from a suspension. The supported catalysts were subjected to the flow of a mixture of O_2, CO, and CO_2 in N_2. The flows of CO and CO_2 were constant and equaled 0.6 and 9.3 vol %, respectively, while the flow of oxygen was changed every 100 s from 0 to 1 vol % and backwards (Fig. 1). OSC of the samples was studied at heating of the gas flow with the constant rate (5°C/min). The temperature change within each 100-s cycle did not exceed 8 °C. During the experiment, the content of CO was measured at the outlet of the reactor.

In the presence of oxygen, CO was completely oxidized to CO_2. After switching off the O_2 supply (between t_1 and t_2 in Fig. 1), CO was oxidized with oxygen accumulated in the catalyst Pt/Al_2O_3+$Ce_xM_{1-x}O_2$. The amount of oxygen reacted with CO was calculated from the equation $CO+O = CO_2$. The oxygen capacity was determined for each cycle of changing the oxygen flow rate and then recalculated per unit mass of the ceria-containing oxide. The amount of oxygen accumulated in Pt/Al_2O_3, which was measured in separate experiments, was taken into account.

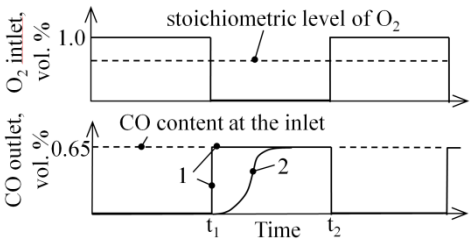

Fig. 1. Scheme of changes in CO and O_2 content within one measurement cycle. Interval t_1–t_2 corresponds to a period when CO is oxidized with lattice oxygen. Lines 1 and 2 are CO contents for a hypothetical sample with zero OSC and for $Ce_xM_{1-x}O_2$, respectively. The area between lines 1 and 2 corresponds to the amount of CO that is oxidized with lattice oxygen.

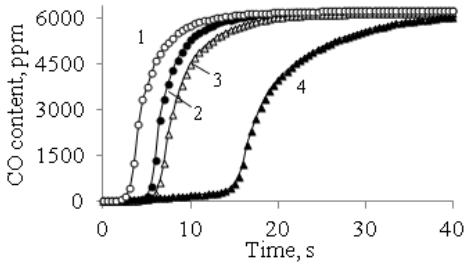
3 Results and discussion

Results of the OSC study of two oxides $Ce_xPr_{1-x}O_2$ are compared in Fig. 2, 3 with those of the two most studied oxides (CeO_2 and $Ce_{0.75}Zr_{0.25}O_2$). The original data clearly show the large differences between the capabilities of oxides in CO oxidation with the lattice oxygen (Fig. 2). There is the well-known result that the OSC of $Ce_{0.75}Zr_{0.25}O_2$ is greater than that of CeO_2 at the traditional temperature (about 400^OC). However, at low temperatures, the temperature dependence of OSC indicates that the situation changes to the contrary (Fig. 3). The same result was obtained for the other pair of oxides ($Ce_xPr_{1-x}O_2$). For example, the OSC of $Ce_{0.5}Pr_{0.5}O_2$ is two times larger at 480^OC, but three times smaller at 250^OC, than the OSC of $Ce_{0.85}Pr_{0.15}O_2$.



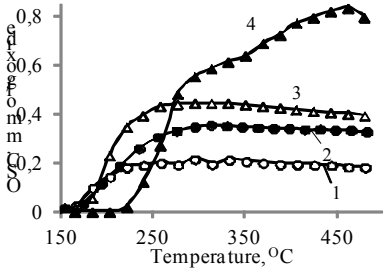


Fig. 2 (left). Change in the outlet content of CO measured at 480 ^OC between moments t_1 and t_2 (see Fig. 1). **Fig. 3 (right)** Temperature dependence of OSC. Numerals in both figures are the same: 1 – CeO_2, 2 – $Ce_{0.75}Zr_{0.25}O_2$, 3 – $Ce_{0.85}Pr_{0.15}O_2$, 4 – $Ce_{0.5}Pr_{0.5}O_2$

The larger OSC of $Ce_{0.85}Pr_{0.15}O_2$ at low temperatures explains the lower T_{50} (about 200^OC) of the catalyst $Pt/Al_2O_3+Ce_{0.85}Pr_{0.15}O_2$ compared with T_{50} (about 260^OC) of the catalyst $Pt/Al_2O_3+Ce_{0.5}Pr_{0.5}O_2$, which were obtained under conditions equivalent to the TWC test. The study represents also how the particle morphology of Ce-containing oxides correlates with OSC, with the activity of TWC, and with the content of CO, HC, and NO_x in automotive exhausts.

4 Conclusions

The suggested method allows studying the OSC of ceria-containing oxides at lower temperatures. This information is utterly essential for understanding the behavior of TWC and thus for their development.

Keywords: ceria-zirconia, mixed oxide, diesel, soot, combustion, catalyst precipitant

1 Introduction

The reduction of soot particulate emitted from diesel engines has attracted more attention due to its harm to environment and human health [1]. Currently, the most commonly used method for removing soot from engine exhaust is the use of diesel particulate filter with catalyst to oxidize soot at certain temperature or by burning oil in the filter at certain period. Clearly, filter with catalytic oxidation is favorite in application, but the issue is how to prepare effective catalysts with more favorable structure for transferring or activating oxygen species thus better catalytic oxidation activity at lower temperature. The partial substitution of Ce^{4+} ions with Zr^{4+} ions was reported to be beneficial for generating oxygen vacancies and ceria-zirconia (Ce-Zr) catalysts have been extensively applied in soot oxidation. However, the studies often focused on the effect of cerium precursor [2], cerium loading [3], calcination temperature [4], etc. Herein, we reported that active Ce-Zr catalysts can be successfully synthesized using different precipitants, and corresponding characterizations were also carried out to illustrate the structure-activity relationship.

2 Experimental/methodology

$Ce_{0.75}Zr_{0.25}O_2$ catalysts were prepared based on co-precipitation method using KOH, $NH_3.H_2O$, and their mixture as precipitant. The precipitates were dried at 120 °C and calcined at 500 °C for 5 h. The obtained catalysts were labelled as K-CZ, K-CZ and KN-CZ, respectively.

N_2 adsorption-desorption isotherms were measured volumetrically using a Micromeritics ASAP 2020 instrument. XRD characterization was carried out on an X' Pert Pro automatic powder diffractometer operated at 40 kV and 30 mA, using Cu Kα (λ=0.15406 nm) monochromatized radiation. XPS patterns were collected using a VG MiltiLab 2000 spectrometer with Mg Kα radiation and a multichannel detector.

The oxidation of soot (10 mg printex-U carbon), contacted loosely with 190 mg catalyst, was evaluated on a tubular quartz reactor, and temperature-programmed oxidation reaction (TPO) run from 25 to 700 °C at a rate of 2 °C min^{-1} in a stream 5% O_2 balanced with N_2 at a flow rate of 50 ml min^{-1}. The catalytic activity was evaluated by the values of T_{10}, T_{50}, T_{90}, represented as the temperatures at 10%, 50%, and 90% of soot conversion, respectively.

3 Results and discussion

First, XRD characterization was used to determine the effect of precipitant on particle size of the catalysts. As shown in Fig. 1a, all the CeO_2-based catalysts is characteristic of a typical crystalline fluorite structure with four sharp diffraction peaks corresponding to (111), (200), (220) and (311) plane, respectively. It is noted that these peaks arising from Zr insertion shift to high 2θ and become wider as compared to that of pure CeO_2. This suggested zirconium is partially loaded into the ceria lattice and some appears to be segregated as a separated phase.

According to Scherrer's formula, the particle size of KN-CZ (4.7 nm) is smaller than that of K-CZ, N-CZ (Table 1). It indicates that precipitant plays a vital role in particle size of catalysts.

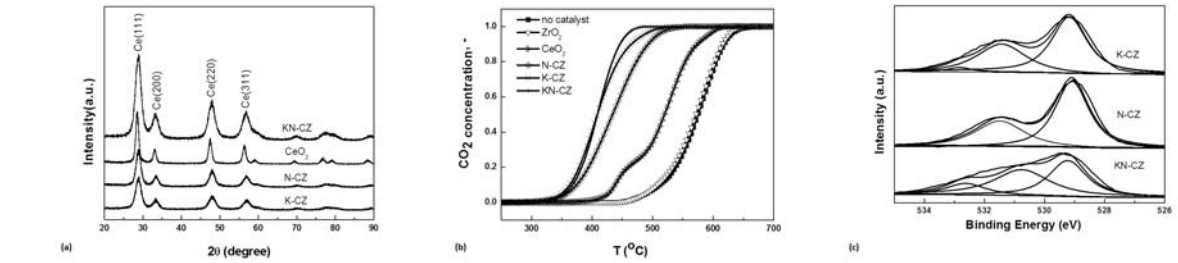

Figure 1 XRD patterns (a), TPO profiles (b), and O 1s XPS spectra of Ce-based catalysts

Then, the TPO profiles for soot oxidation over CeO_2-based catalyst were carried out for exploring the effect of particle size on catalytic performance. And the tested results (Fig. 1b and Table 1) indicates that the soot oxidation takes place around 438 ^oC (T_{10}) and the corresponding T_{90} for CeO_2 catalyst is near 574 ^oC. However, the TPO profiles for all Ce-Zr catalyst were shifted to lower temperature compared with that of CeO_2 catalyst. The order of oxidation activity is KN-CZ>K-CZ>N-CZ.

Table 1 Soot oxidation activities and physicochemical properties of various Ce-based catalysts

Catalyst	T10 (oC)	T50 (oC)	T90 (oC)	SBET (m2/g)	Dp (nm)	O2- (%)	O22- (%)	O2- (%)	Ce3+/Ce 4+
K-CZ	367	413	469	54.3	6.8	2.3	41.4	56.3	1.1
N-CZ	375	434	493	91.3	7.1	0.2	35.9	63.9	0.96
KN-CZ	367	409	446	78.5	4.7	14.0	43.6	42.3	0.89
CeO2	438	520	574	41.3	9.2	-	-	-	-
ZrO2	507	572	616	22.3	24	-	-	-	-

The precipitant can affect the particle size, and this will affect the chemical state of ceria due to interaction of Ce with Zr. Therefore, XPS characterization was performed for the Ce-based catalysts. The results showed that the KN-CZ catalyst possesses almost the lowest superficial ratio of Ce^{3+}/Ce^{4+} to that of other Ce-Zr samples, but it provides the highest quantity of absorbed oxygen species (O_2^- and O_2^{2-}) on the surface (Fig. 1c and Table 1). Therefore, it can be concluded that the Ce^{3+} and Ce^{4+} species significantly affect the capacity for activating oxygen. Combined with the activity of soot oxidation, it is concluded the quantity of adsorbed oxygen species, affected by precipitant, plays a vital role in soot oxidation.

4 Conclusions

The Ce-Zr catalysts with different oxidation activity were synthesized using precipitants. And the precipitant affects the particle size of catalyst, and modify the interaction of Ce with Zr. The suitable interaction results in increasing the quantity of absorbed oxygen species, which is closely linked with the performance for soot oxidation.

Keywords: soot oxidation, diesel particle filter, silver, yttria-stabilized zirconia, E-TEM

1. Introduction

Since Particulate Matter emissions have been regulated by US/EU standards for Diesel vehicles, Diesel Particle Filter (DPF) has become mandatory to satisfy the required levels. To assist the regeneration of the DPF, oxidation catalysts combining good activity and stability under exhaust conditions are used. Ag-supported catalysts have been already reported as active materials for soot combustion, related to the high mobility of Ag to get in contact with the soot [1]. This study investigates the soot oxidation mechanism on Ag nanoparticles supported on Yttria-Supported Zirconia (YSZ), an oxygen ionic conductor. YSZ is a thermally stable support, active for soot oxidation thanks to its bulk oxygen mobility [2]. This study aims to investigate the synergy for soot combustion between Ag nanoparticles and YSZ. Different characterizations techniques, such as temperature programmed oxidation (TPO) and reduction (TPR), isotopic $^{18}O_2$ exchange, XPS and Environmental Transmission Electron Microscopy (E-TEM) have been implemented. Various kinds of oxide supports: inert (SiO_2), non-conductive (ZrO_2), reducible (ceria-zirconia) and O^{2-} conductor (YSZ) have been used to understand the mechanism.

2. Experimental

Various Ag-supported samples were prepared by aqueous impregnation of silver nitrate (Alfa Aesar, 99.9%) over YSZ (Tosoh), ZrO_2 (Tosoh), $Ce_{0.7}Zr_{0.3}O_2$ (Solvay), SiO_2 (Sigma-Aldrich), and followed by a calcination at 700°C for 4 hours. Samples displayed Ag loadings of 1%wt. Catalysts were characterized by XRD, SEM, TEM, BET and particle size distribution by Laser diffraction.

Soot oxidation was studied using a mixture of carbon black (Printex U) and catalyst in tight and loose contact conditions. In addition, experiments were conducted in intimate carbon/catalyst contact which was achieved by propene cracking as detailed in [2]. Temperature-programmed oxidation (TPO) experiments were performed by heating the mixture under different oxygen partial pressures: 1, 5 and 10% O_2 in He at 10°C/min up to 700°C. TPR (Temperature-Programmed Reduction) analysis, using 1% H_2 in He, and XPS were also performed to quantify the level of Ag oxide as well as its interaction with the support. $^{18}O_2$ TPO and isothermal $^{18}O_2$ exchanges were performed to detect the nature of the active oxygen species involved in soot oxidation. Cycled TPO experiments were realized to determine the stability of the catalyst. Finally, a last generation ETEM (TITAN 80-300 kV from FEI™) equipped with an aberration corrector was used to in-situ observe the soot oxidation on Ag/YSZ catalyst.

3. Results and discussion

TPO experiments under loose contact (fig. 1) show that 1%Ag/YSZ displays far better performance than YSZ with a CO_2 selectivity higher than 95%. Catalytic performances of Ag/YSZ catalyst was found to increase with the oxygen partial pressure. $TP^{18}O$ experiments demonstrate that the presence of Ag promotes the fuel-cell-type electrochemical mechanism of YSZ which takes place during soot combustion. Similar experiments have been performed with SiO_2, ceria-zirconia and ZrO_2 supported catalysts to highlight the synergy between the Ag nanoparticles and YSZ.

E-TEM allowed in-situ observations of soot oxidation by Ag/YSZ, in conditions similar to those of a DPF. Recorded movies show silver nanoparticles tunneling through the soot and consuming it (figs. 2 a, b, c). They appear to adopt the shape of the soot and deform themselves to cover the particle surface. This demonstrates, for the first time, the high mobility of Ag nanoparticles in contact with soot. However, when all PM is burned, some Ag particles, no more in interaction with the YSZ support, can sinter and, even worse, evaporate (figs. 2 d, e, f). Therefore, the thermal and cycling stability of Ag/YSZ catalyst have been investigated under DPF exhaust conditions.

4. Conclusions

Ag/YSZ catalysts display remarkable performances for high oxygen partial pressures. Isotopic exchanges confirm the crucial role of YSZ bulk oxygen species while in-situ E-TEM observations have underlined the fast mobility of Ag nanoparticles. A mechanism will be discussed according to all the characterizations techniques.

Keywords: soot combustion, manganese, iron, cobalt oxides, alkali, promotion, nanostructurization, work function, DFT

1 Introduction

The aim of this study is to develop an innovative robust catalytic material for soot combustion in the low temperature regime. The proposed materials are comprised of model 3*d*-metal (manganese, iron, cobalt) oxides, surface decorated or intercalated by alkali ions, which act as promoters. The guiding hypothesis consists in exploration on how the catalytic reactivity can be associated with the work function and surface/bulk status of alkali. The effect of the alkali promoters location on the surface vs. bulk (intercalation) was elucidated. The study focuses on the exploration of the key parameters governing the catalytic process: surface alkali dispersion, formation of new phases (nanostructurization), soot-catalyst interaction, topology of the soot molecular framework and the influence on the Fermi level caused by alkali doping of Mn, Fe and Co oxides. The methodology combining the experimental investigations and DFT molecular modeling allows for the establishment of rational principles for designing the optimal soot oxidation catalyst based on manganese (layered birnessite KMn_4O_8 and cryptomelane KMn_8O_{16}), iron (layered $K_2Fe_{22}O_{34}$, tunneled $KFeO_2$) and cobalt (layered $KcoO_2$) oxides.

2 Experimental/methodology

A series of potassium nanostructured manganese, iron and cobalt oxides were prepared by the reaction of stoichiometric amounts of K_2CO_3 with α-Fe_2O_3 or $KMnO_4$ and $Mn(CH_3COO)_2$ (for cryptomelane) or glucose (for birnessite) as well as KOH with Co_3O_4. The samples were thoroughly characterized by several methods including XRD, SEM-EDX, HR-TEM/FIB, XPS, RS, BET. The electronic properties and alkali dynamics were probed by the surface work function (Kelvin Probe) and ionic conductivity measurements. The stability and surface state of alkali dopants was investigated by the Species Resolved Thermal Alkali Desorption. Catalytic activity in soot combustion (loose and tight contact) was determined by TPRS and isothermal oxidation (TG/DTA – QMS) for various catalyst/soot ratios. The cluster DFT modeling of coronene as a robust molecular epitome of soot particles was performed using the $Dmol^3$ program package with a rPBE functional and a DNP basis with polarization functions. Transition states were located using a LST/QST with BFGS refinement. The postulated reaction intermediates were confirmed experimentally by the SIMS-TOF and XPS measurements.

3 Results and discussion

Structural and morphological XRD, SEM/TEM, RS investigations revealed that the addition of alkali led to the nanostructuration of Mn, Fe and Co oxides by the formation of tunneled ($KFeO_2$) and layered ($K_2Fe_{22}O_{34}$, KMn_4O_8, KMn_8O_{16}, $KcoO_2$) structures. It was found by SR-TAD studies that such structures are beneficial for the high mobility of the potassium promoter

(bulk diffusion, surface segregation and desorption), allowing for the remote activation of soot by alkali transfer from the surface to the soot particles. The comparison of the soot combustion activity of the investigated catalysts shows a strong promotional effect (dramatic lowering of the reaction temperature window) of alkali additions (Fig. 1). The transformation of iron oxide into ferrites by potassium addition lowers the light off temperature by about 70°C and 100°C for $K_2Fe_{22}O_{34}$ and $KfeO_2$, respectively, whereas for the transformation from manganese spinel to nanostructured potassium oxides leads to the temperature decrease of 130°C and 150°C for KMn_4O_8 and KMn_8O_{16}. The nanostructuration of the cobalt oxide has a similar effect, lowering the light of temperature by 80°C.
The observed correlations reveal that the unique, concise parameter – the catalyst work function – plays the key role in the soot combustion process.

For the most combustion reluctant graphitic soot, epitomized by coronene, the role of the termination topology and strain induced by local carbon rehybridization on oxygen attack mechanism was discussed based on the quantum chemical modeling. Quantum chemical modeling was used to discuss the role of the termination topology and strain induced by local carbon rehybridization during an oxygen-attack mechanism for the most combustion reluctant graphitic soot, which was epitomized by coronene. It was found that the reactivity sequence increases as armchair, zig-zag, free-edge, as gauged by the activation energies: E_{act} = 30.5/76.5, 43.5/90.5, 116.1 kcal/mol for singlet/triplet pathways, respectively.

The energetic profiles of the oxidation cascade revealed that the reaction occurs by the sequence of oxidation, thermal fragmentation steps. The most demanding is the primary dioxygen attack and the preferred focus on the free-edge sites of the graphitic soot. The key intermediates appearing during the reaction progress are featured by C=O, C-OH, and COOH functionalities, redistribution of the carbon rings and the formation of new carbon-oxygen rings, as revealed additionally by XPS and SIMS. The computational and experimental results show that the rate determining the first attack of a O_2 molecule can be facilitated by the alkali transferred from the catalyst surface to the soot particle.

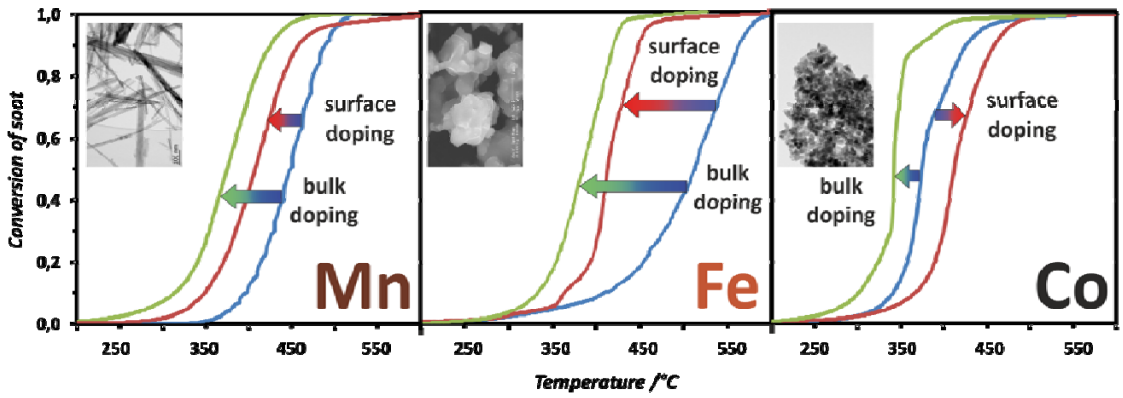

Fig. 1. The results of soot combustion for Mn, Fe and Co oxides bulk (intercalated) and surface (decorated) by potassium and the SEM/TEM images of the most active phases.

4 Conclusions

Based on the experimental and molecular modeling results an integral picture of the soot combustion process over alkali promoted catalyst was advanced and the crucial multifaceted role of alkali promotion was elucidated in detail. It allows for establishment of rational guidelines for designing robust materials for DPF applications based on ternary metal oxides.

Keywords: soot oxidation, iron oxide, diesel exhaust

1 Introduction

Diesel particulate filters (DPF) represent a state-of-the-art technology for the removal of soot from diesel exhaust. However, the continuous regeneration of these filters remains a considerable challenge, as the trapped soot causes backpressure effects potentially decreasing the engine efficiency. While the DPF regeneration with NO_2 is already established for heavy duty vehicles, the catalytic soot oxidation by O_2 is considered to be a promising procedure for passenger cars, ships and working machines. Since iron based catalysts are known to reveal high potential for soot oxidation [1], the present paper addresses the targeted design of efficient iron oxide samples implying the evaluation of physical-chemical characteristics driving the catalytic activity.

2 Experimental

Seven bare iron oxide catalysts were evaluated towards their soot oxidation activity under oxygen-rich conditions. The catalytic studies were performed by temperature programmed oxidation (TPO) using tight contact mixtures of catalyst and soot. A home-made carbon black originated from propene combustion was taken as model soot. The catalysts were thoroughly characterised by employing powder X-ray diffraction (PXRD), N_2 physisorption, high resolution transmission electron microscopy (HRTEM), temperature programmed reduction by H_2 (HTPR), temperature programmed desorption of NH_3 (NH_3-TPD), temperature programmed desorption of O_2 (O_2-TPD) and thermogravimetry coupled with difference thermal analysis (TG/DTA). Special notice was put on the NH_3-TPD data, which were used for the modelling of the NH_3 adsorption and desorption. This model included elementary reactions and implied the specific number of Bronsted and Lewis acid sites.

3 Results and discussion

For the assessment of the catalytic performance, the temperature of maximum CO_2 production (T_{max}) was taken. T_{max} of the catalysts appeared between 330 and 415°C, whereas the Fe_2O_3 sample prepared by flame spray pyrolysis (FSP) indicated highest activity (T_{max} = 330°C). For reference, $T_{CO2,max}$ of bare soot was found at 570°C clearly demonstrating the effect of the catalysts.

In the correlation of the soot oxidation efficiency and determining physical-chemical characteristics, a connection between proportion of Lewis acid sites as well as relative crystallinity of the catalysts was deduced as shown in Figure 1. This contour diagram demonstrates highest activity for moderate crystallinity (ca. 0.5) and a high amount of specific Lewis acid sites, whereas a moderate quantity of specific Lewis bond NH_3 and high (1.0) or low (ca. 0) crystallinity reveal poor activity. The importance of Lewis acid surface sites is ascribed to their capability of transferring oxygen, whereas the constructed NH_3 adsorption/desorption model points to very similar nature of these surface sites for the iron oxides investigated.

Moreover, our mechanistic studies with $^{18}O_2$ reported lately [2] suggest that oxygen is pumped from the iron oxide to the soot by physical contact points thus leaving oxygen vacancies on the catalyst surface, i.e. Lewis acid sites. These vacancies are refilled by diffusion of surface and bulk oxygen. In surface diffusion, oxygen migrates from neighbouring Lewis acid sites, whereas diffusion of bulk oxygen occurs along lattice vacancies. The present structure-activity study confirms the importance of the transport of crystalline oxygen, as the amorphous iron oxide sample shows rather low catalytic activity, although it exhibits a medium surface concentration of Lewis acid sites. This finding is associated with faster oxygen diffusion in crystalline structures as referred to amorphous domains.

Hence, the derived correlation of Lewis acid sites, crystallinity and catalytic activity coincides with the mechanistic suggestions thus accounting for the highest efficiency of the Fe_2O_3 sample originated from FSP. This catalyst implies the largest number of surface defect sites as well as moderate crystallinity both evoking fast diffusion of oxygen to contact points. This knowledge on determining characteristics identified in this paper is considered to be an important tool for the rational development of advanced iron oxide catalysts for soot oxidation.

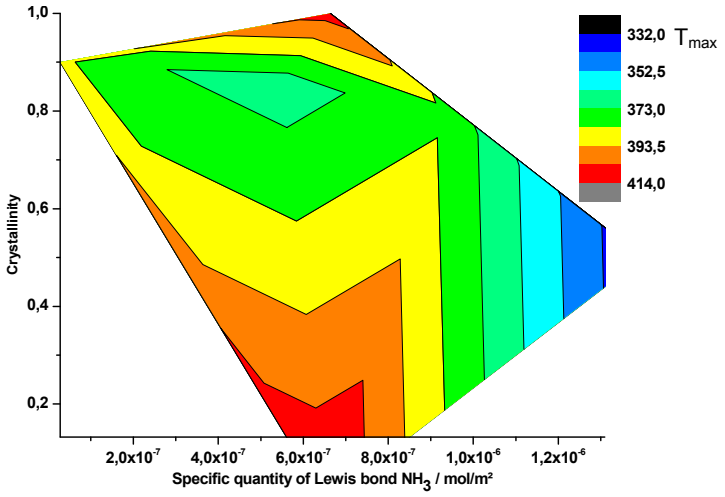

Figure 1: Correlation of T_{max}, quantity of specific Lewis bond NH_3 and crystallinity of the iron oxide catalysts [3].

4 Conclusions

The correlation of structure and activity of iron oxides for soot oxidation shows Lewis acid sites and moderate crystallinity of the catalysts to be crucial. These results coincide with mechanistic studies thus representing the base for the targeted design of advanced catalysts.

Keywords: three-way catalysis, perovskites, active sites, stability, redox cycling

1 Introduction

Noble-metal doped perovskites have been recently studied as catalysts for redox reactions, e.g. N_2O decomposition [1], selective reduction of NO [2, 3], and methane oxidation [4]. Particular attention has been paid to their application as three-way catalysts [5], which has already found commercial application [6]. The catalysts were described as intelligent materials because of their presumed capability to accommodate the state of Pd on the timescale of the λ fluctuations, with segregation into nanoparticles in lean regime and re-sorption of Pd^{2+} into the perovskite under rich conditions [7].

We present here a study of the active sites of Pd-substituted $LaFe_yCo_{1-y}O_3$ perovskites and of their response to thermal stress. It will be shown that activity in the oxidation reactions is largely contributed by the perovskite surface while NO reduction is most effectively catalyzed by Pd-X (X = Co and/or Fe) alloy particles, which are also highly active in N_2O decomposition.

2 Experimental

$LaFe_{0.65}Co_{0.35-x}Pd_xO_3$ perovskites were prepared with the dry citrate method, with final calcination at 700°C for 3 h. Pt and Rh containing catalysts (x = 0.025) were made for comparison. The samples were tested in a flow reactor under stationary conditions at temperatures between 50 and 500°C under stoichiometric, lean, and rich conditions (1,1 % CO, 1000 ppm NO, 1000 ppm propene, with 9500 ppm O_2 (stoichiometric), 8500 ppm O_2 (rich), 10500 ppm O_2 (lean), balance He, GHSV – 60,000 h^{-1}). In addition, experiments were made with oscillating feed compositions (0.4 and 2 Hz). The catalyst was conditioned with a redox cycling treatment (15 min O_2 (2 %/He) alternating with CO (2 %/He), 5 cycles) at 400°C, 650°C, or 900°C. Reference measurements were made with a commercial Pd-rich three-way catalyst. The catalysts were characterized by XRD, N_2 physisorption, TPR, and XAFS: in-situ XANES for monitoring of reduction/reoxidation processes, ex-situ fluorescence EXAFS of characteristic states.

3 Results and Discussion

Conditioning at 400°C resulted in a drastic increase of activity for all reactions when studied in stationary regime. This was accompanied by a significant increase of the BET surface area. Comparison with Rh and Pt containing samples, but also with Pd-substituted perovskite after more severe treatments suggests that activity in CO and propene oxidation is dominated by the contribution of the perovskite surface while NO reduction proceeds exclusively on the metal. The activated Pd perovskite outperformed the commercial TWC in CO oxidation but was somewhat less active in propene oxidation and NO reduction.

In TPR, the first reduction event related to the formation of Pd metal occurred at ≈140 °C, but with a H_2 consumption largely exceeding the quantity required to reduce all Pd^{2+}. XAFS and XRD of reduced perovskites indicated the formation of an alloy phase containing Pd and

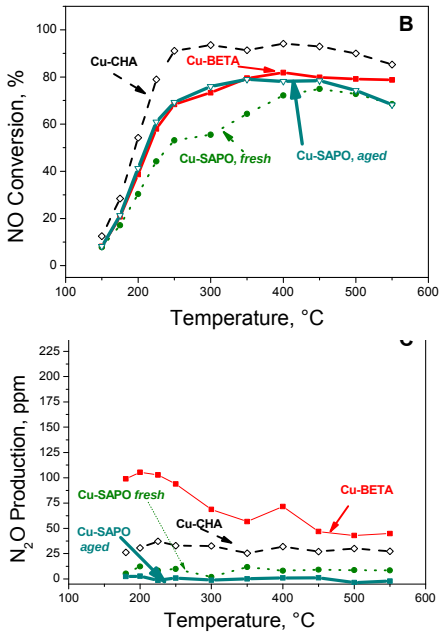

Fig. 1. EXAFS of Pd substituted perovskite after different treatments

either of the reducible perovskite components (for XAFS see Fig. 1a). The formation of this alloy phase may explain the drastic activation of the initial perovskite for NO reduction: While NO conversion in stoichiometric feed remained below 50 % in the initial state (Fig. 2), light-off temperatures (T_{50}) around 330 °C were found after conditioning at 400 °C. The alloy was also highly active in N_2O decomposition. Upon reoxidation at 400 °C, the alloy was destroyed, but Pd returned to the +2 state only partially while Pd metal particles remained on the surface as well (Fig. 1b).

Redox cycling at 650 °C resulted in moderate deactivation, in particular regarding CO oxidation and NO reduction while the same treatment at 900 °C affected the oxidation of propene rather than that of CO, but shifted T_{50} of NO reduction propene conversion beyond 500 °C for Pd-containing perovskites. The degree of reoxidation decreased with increasing temperature of treatment, and after reoxidation at 650 °C and 900 °C even the alloy phase could be still be detected (Fig. 1b). The low activity in presence of a stable alloy phase suggests that the latter is not accessible for the feed. Notably, upon reduction at 900 °C, about two thirds of Fe and Co were reduced, but the perovskite lattice was still detected in XRD.

While periodic variation of the feed composition had no strong influence on the conventional TWC, it changed the catalytic behavior of the initial Pd-doped perovskite completely (Fig. 2): complete NO conversion was achieved without redox conditioning. Such effect of the dynamic regime was not observed when the catalyst was activated previously, which suggests that the active Pd-X alloy may be formed from the initial catalyst in the phases of rich feed composition or with CO, which is abundantly stored on the perovskite surface.

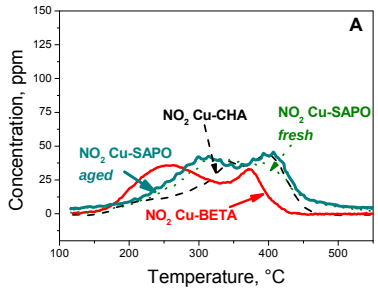

Fig. 2. Conversions over initial Pd-substituted perovskite in stationary and dynamic (0.4 Hz) regimes

4 Conclusions

The noble-metal doped perovskites were somewhat inferior to the reference TWC with respect to activity and, in particular, to stability, but exhibited high activity for all reactions of three-way catalysis. Upon reduction, Pd formed alloy nanoparticles with reducible elements of the perovskite matrix, which are highly active in NO reduction and in N_2O decomposition. Redox cycling of Pd was not completely reversible at 400°C, and irreversibility was enhanced with increasing temperature.

Three-Dimensionally Ordered Macroporous Perovskite Catalysts: Controllable Alignments and Approach for Catalytic Applications

Arandiyan H.*, Scott J., Amal R.

Particles and Catalysis Research Group, School of Chemical Engineering, The University of New South Wales, Sydney, Australia

* h.arandiyan@unsw.edu.au

Keywords: three-dimensionally ordered macropore, perovskite, supported noble metals, self-assembly

1 Introduction

Noble metal nanoparticle (NPs) is one of good choices for enhancing the intrinsic catalytic activity of 3DOM metal oxides [1]. Compared to the bulk La-based perovskite-type oxides, the Pt NPs embedded in three-dimensionally ordered macroporous-mesoporous (3DOM-m) counterparts display unique physicochemical properties due to their porous structures, high surface areas, and strong redox ability that are favourable for the improvement in catalytic performance. Previously, we observed that 3D macroporous La-Sr-Mn-O derived with PMMA as hard template and DMOTEG, EG, P123, L-lysine, and PEG400 as surfactant and stabilizer showed exceptional catalytic activity for the CH_4 combustion. Recently, we have extended our attention to the fabrication and catalytic properties of noble metal NPs embedded in 3DOM-m perovskite-type oxides with mesoporous walls. In this work, we demonstrate, for the first time, the facile dual-template preparation of 3DOM-m $La_xCe_{1-x}CoO_3$ (LCCO) with formation of highly crystalline mesoporous walls by employing polymethyl methacrylate (PMMA) microspheres as hard template and of its supported Pt nanoparticles (NPs) by adopting the gas-bubbling cetyltrimethyl ammonium bromide (CTAB)-assisted reduction route.

2 Experimental/methodology

The well-arrayed monodispersed PMMA microspheres with an average diameter of ca. 260 nm were synthesized according to the procedure described elsewhere [2]. The rhombohedral *x* wt% Pt/3DOM-m $La_xCe_{1-x}CoO_3$ (*x* wt% Pt/3DOM-m LCCO; *x* = 0-6 wt%) with crystalline mesoporous walls were fabricated using by the gas-bubbling cetyltrimethyl ammonium bromide (CTAB)-assisted reduction route described previously [3]. The dried sample was calcined to remove the impurities after calcination in furnace according to two steps: heated in a N_2 flow of 50 mL/min at a ramp of 1 °C/min from RT to 300 °C and calcined at this temperature for 3 h; and then the solid was heated in an air flow of 50 mL/min at a ramp of 1 °C/min from RT to 800 °C and kept at this temperature for 4 h. For comparison purpose, we also prepared a bulk-LCCO catalyst using the sol-gel method and after calcination at 850 °C for 5 h. Physicochemical properties of the materials were characterized by a number of analytical techniques.

3 Results and discussion

It is found that the CTAB acted as the stabilizing surfactant of Pt NPs and the promoting agent for mesopore formation. Hence, this work provides a facile synthesis of thermally stable Pt NPs supported on high-surface-area 3DOM LCCO, as illustrated in Figure 1. By controlling the synthesis conditions (CTAB added amounts and $H_2PtCl_6/NaBH_4$ mass ratio), high-density Pt NPs could be successfully loaded on the surface of hierarchically ordered macro/mesoporous LCCO, thus obtaining the *x* wt% Pt/3DOM-m $La_xCe_{1-x}CoO_3$ nanocatalysts (Figure 1). More

than 98% of the particles identified in the HRSEM images displayed a high-quality 3DOM structure with high degree of alignment perpendicular to the first layer (Figure 1). The introduction of an excessive amount (6 wt%) of Pt had no significant effects on the quality of 3DOM structure. It was found that the obtained *x* wt% Pt/3DOM-m $La_xCe_{1-x}CoO_3$ catalysts have attracted much attention because of their unique properties, such as high surface areas, controllable compositions, crystallinity, thermal and chemical stability, high porosities, narrow pore size distributions as well as their excellent catalytic performance for oxidation of hydrocarbons .

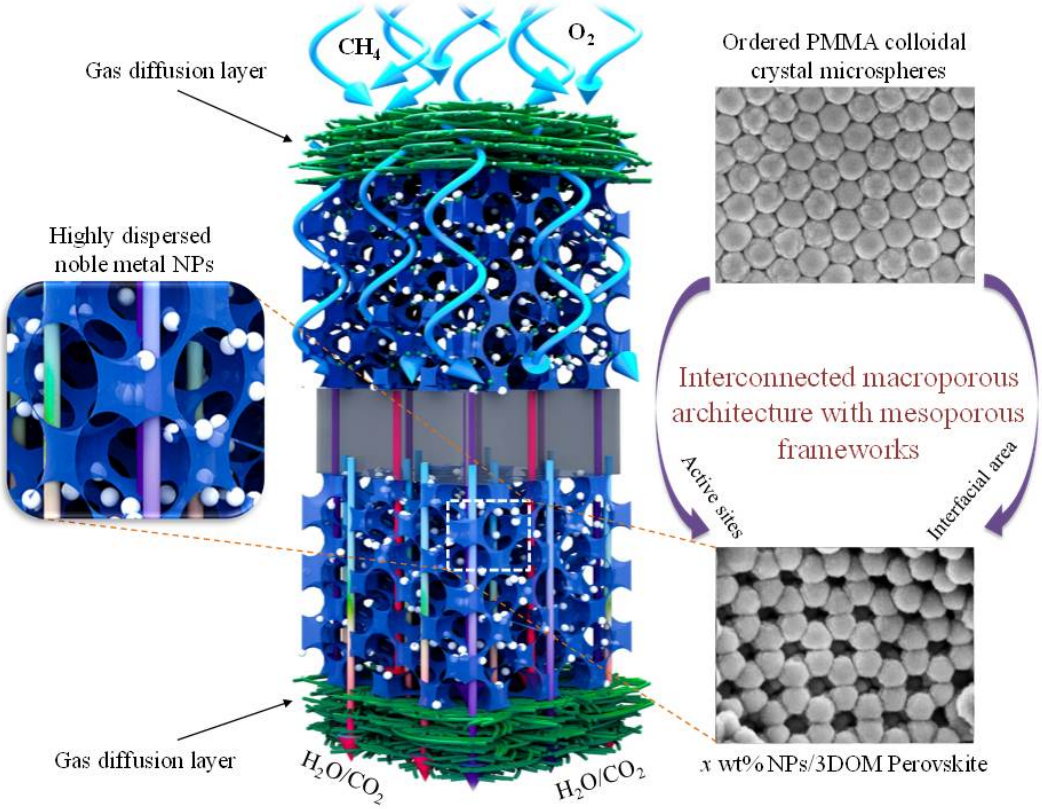

Fig. 1. Schematic illustration of loading noble metal NPs on 3DOM perovskite catalysts.

To the best of our knowledge, besides CH_4 oxidation [1-3], there even have been no reports on combining all of the above features into a single promising NPs/3DOM-m perovskite for other reactions such as oxidative coupling of methane (OCM), methane partial oxidation (MPO), methane dry reforming (MDR), the methane combustion reaction (MCR), steam methane reforming (SMR), and autothermal methane reforming (ATR). Simple substitution of a foreign cation into the nanohybrid make-up at either the A- or B-sites, and/or metal NPs can be employed to tune the catalyst to the specific reaction.

4 Conclusions

In summary, we have demonstrated a facile synthesis of 3DOM LCCO with mesoporous walls and a high surface area and *x* wt% Pt/3DOM-m $La_xCe_{1-x}CoO_3$ with high dispersion of ultrafine Pt NPs by the gas-bubbling CTAB/P123-assisted reduction method.

Highly Active $LaKCoO_3$ Perovskite-type Complex Oxide Catalysts over Alumina Washcoated Monolith for the Simultaneous Removal of Diesel Soot and Nitrogen Oxides

Tang L., Zhao Z.*, Wei Y., Liu J., Li K.

China University of Petroleum, Beijing, China

* zhenzhao@cup.edu.cn

Keywords: perovskite-type oxides, washcoat monolithic, cordierite, diesel soot, catalysts, simultaneous removal of diesel soot and nitrogen oxides

1 Introduction

In recent years, it is known that diesel particulate emissions cause serious problems for human health. Many automobile companies and research institutes have tried to develop various methods to solve this problem. At present, the widely accepted solution is the diesel particulate filter (DPF), which is one of the most effective systems to reduce particulate matter. The preferred material is called cordierite, Honeycomb cordierite is the substrate in common use because of high mechanical strength, stability at high temperatures and temperature shocks and low thermal expansion coefficient. Various methods, e.g. dip-coating, direct synthesis chemical vapor deposition, have been applied to deposit catalytic coatings on cordierite substrate. the slurry coating is the most popular one. Typically, the slurry consists of small particles (dp<5 m) in order to penetrate into the macropores of cordierite, so that a good anchoring of the layer is obtained. In fact, in our previous works we reported high activity and selectivity towards N_2 and CO_2 for several catalytic systems containing the nanometric $La_{1-x}K_xCoO_3$ and $La_{1-x}K_xMnO_3$[1] perovskite oxides are good candidate catalysts for the simultaneous removal of diesel soot particle and NOx reaction under loose contact conditions. For the purpose of practical application, we investigated the catalytic performance of $LaKCoO_3$ perovskite oxide surported on cordierite monoliths.

2 Experimental/methodology

The monolithic catalysts were prepared by impregnating the as prepared monolith with aqueous solution of metal salt ($La(NO_3)_2.6H_2O$, $Co(NO_3)_2.6H_2O$, KNO_3, citric acid) in an evaporator at the constant temperature. The aqueous solution of metal salt was stirred at 25 ^oC for 2-4h.The impregnated sample was mixed well and then evaporated in a rotary evaporator at constant temperature of 120 ^oC overnight and calcined at 650 ^oC with the heating and cooling rate of 1 ^oC /min in flowing air for 4h. Finally, a typical preparation process of $LaCoO_3$/ɤ-Al_2O_3/cordierite or $LaKCoO_3$/ɤ-Al_2O_3/cordierite was proceeded to form the monolithic catalyst.

3 Results and discussion

As shown in Fig. 1, compared with the DPF coated with perovskite $LaKCoO_3$ catalyst, the blank DPF obviously has excessive accumulation of carbon smoke particles, it will reduce the service life of the DPF and the combustion efficiency of engine. The combined system shows high catalytic performance, the emmitions of PM, CO, hydrocarbon can meet the need for the Chinese National V standard under different conditions, NOx emissions decreased, and can reach the Chinese National IV standard. The results are shown in Table 1.

The cordierite substrate has irregular flat surface, as seen in Fig.1, and such structure is good for dip-coating. After dip-coating, the crystal grains with different regular shapes

completely and compactly cover the irregular surface of cordierites so that the irregular surface of cordierite substrate could not be observed any more (Fig. 2a). The layer thickness is quite uniform with a minimum value of about 8μm on the walls (Fig. 2b), SEM analysis confirmed an adequate and quite homogeneous coating of the cordierite surface.

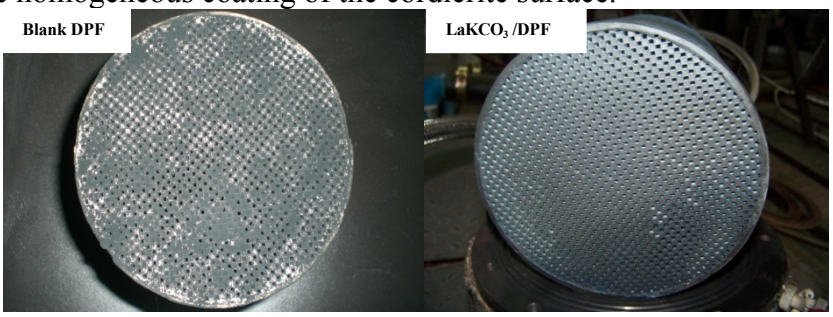

Fig.1. Photographs of the blank DPF compared with the one coated with perovskite $LaKCoO_3$ catalyst after the bench testing.

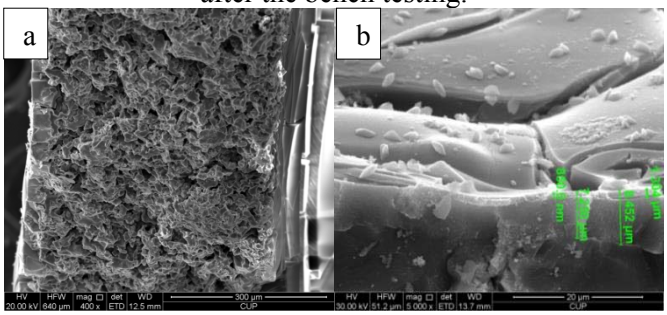

Fig.2. SEM images of different samples: longitudinal section of the channel (a); details of the longitudinal view of the channels (b).

Table 1 Activity results for the bench testing

	PM $gkw^{-1}h^{-1}$	NO_X $gkw^{-1}h^{-1}$	CO $gkw^{-1}h^{-1}$	THC $gkw^{-1}h^{-1}$
Before the exhaust gas purification	0.48	4.85	4.08	0.34
After the exhaust gas purification	0.03	3.28	0.32	0.13

4 Conclusions

Cordierite-monolith-supported $LaKCoO_3/\gamma$-Al_2O_3 catalysts were prepared using the alumina precursor. Their activity was assayed in the simultaneous removal of soot (carbon black) and NOx. The precursor result in good layer adherence and in lower tendency towards the formation of cracks. On the other hand, the alumina catalysts presented a less uniform and less stable coating of the cordierite surface. Therefore, it demonstrated that the monolithic catalysts prepared in this work will be promising for many catalytic reactions including VOCS oxidization and automobile exhaust treatment, and it also offered a new route for more efficient utilization of the quick-developing nano-catalysts.

Identification of Low-T Standard SCR Reaction Intermediates on Fe-, Cu-Zeolite Catalysts by Chemical Trapping Techniques

Ruggeri M.P., Selleri T., Nova I., Tronconi E.*

Dip.Energia, Politecnico di Milano, Milano, Italy

* enrico.tronconi@polimi.it

Keywords: NO oxidation, standard SCR, zeolite catalysts, chemical trapping, nitrites, nitrates

1 Introduction

Metal promoted zeolites are efficient SCR (Selective Catalytic Reduction) catalysts, exhibiting peculiar behaviours depending on the exchanged metal, Fe- or Cu- [1]. Low temperature activity of these systems is essential in order to comply with the current NO_x emission limits for Diesel vehicles. The catalytic mechanism governing the low-T SCR performance of the Standard SCR reaction on Fe-, Cu- promoted zeolites is however still debated. Despite a general agreement that the Standard SCR reaction is initiated at low T by the oxidative activation of NO, diverging proposals about the nature of the related reaction intermediates have been recently published, including NO^+/nitrites (formal N oxidation state = +3) [2, 3] and nitrates (N = +5) [4]. Chemical trapping techniques, combined with both transient response methods and ex-situ IR spectroscopy, have been already applied successfully to identify the primary products formed in the oxidative activation of NO over a Fe-zeolite catalysts [5]. In this work the same techniques are applied to a Cu-zeolite catalyst and the results compared to the Fe-zeolite, in order to rationalize differences in the catalytic chemistries.

2 Experimental/methodology

Transient $NO+O_2$ and NO_2 adsorption runs were performed at 120°C on mechanical mixtures of Fe-ZSM-5 (22 mg) or Cu-CHA (16 mg) + BaO/Al_2O_3 (44 mg) powders, as well as on their individual components. The use of the mechanical mixture was designed to capture onto BaO, a well-known NO_x trap, unstable reaction intermediates resulting from NO activation over Fe or Cu and from NO_2 adsorption. The trapped intermediates were then identified by i) analyzing their thermal decomposition products by TPD runs; ii) probing their reactivity with NH_3; iii) ex-situ FTIR analysis of the BaO/Al_2O_3 phase unloaded and separated from the test reactor mixture.

3 Results and discussion

Figure 1A shows TPD profiles collected on the Fe- and Cu-zeolite containing mixtures after isothermal adsorption of $NO+O_2$ at 120 °C. The catalysts exhibited similar behaviours. Notably, NO and NO_2 were desorbed in equimolar amounts with a maximum at 200°C, and with a greater NO_2 evolution above 200 °C. These results are in line with the thermal decomposition of Ba nitrites/HONO [5]. The same experiments were carried out also on the individual components of the mixtures, where no appreciable storage of NO_x was observed: this suggests that nitrites are initially formed on the metal active sites, and then trapped and stabilized on the barium phase. The interaction between the two phases may proceed via gaseous HONO (in equilibrium with nitrites) or via direct solid phase interaction. Presence of nitrites is also confirmed by ex-situ FTIR analyses of the BaO/Al_2O_3 phases separated from the physical mixtures after exposure to $NO+O_2$. For the Fe- and Cu-based mechanical mixture, respectively, Figures 1B and 1C show FTIR spectra collected over the BaO/Al_2O_3 phase: in both cases, several bands are evident (1100, 1220, 1270, 1350 cm^{-1}) which can be assigned to different nitrite species or to free nitrite ions [4], with a greater presence of nitrates species (1380-1410 cm^{-1}) on the BaO/Al_2O_3 phase

coming from the Cu-CHA containing mixture. Chemical trapping techniques thus enable direct observation of unstable reactive nitrites intermediates, which are particularly hard to detect over metal exchanged zeolites due to the overlapping of their IR bands with the zeolite features.

Nitrites storage on the BaO phases was eventually confirmed by their reactivity with NH_3 at 120 - 140 °C (temperatures at which nitrates are not reactive) to give Standard SCR products (N_2 and H_2O). Differences between the reactivity of stored nitrates with NH_3 over the two catalysts are ascribed to a greater stability of nitrates species formed on Cu-CHA.

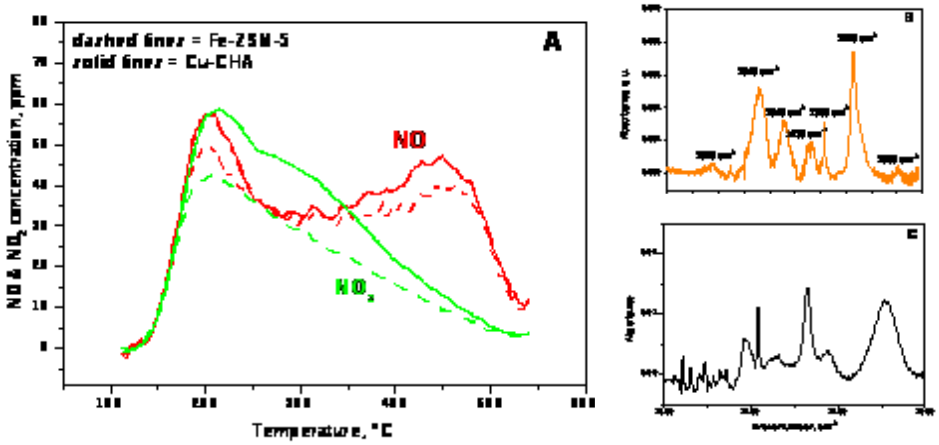

Fig. 1. TPD run in He (T=120-550°C; heating rate=15°C/min) following NO+O_2 adsorption at 120°C (NO=500 ppm; O2=8%) A) gas phase results on Fe-ZSM-5+BaO/Al_2O_3 and on Cu-CHA+BaO/Al_2O_3; Ex situ IR analysis of B) BaO/Al_2O_3 component from the Cu-CHA containing mixture; D) BaO/Al_2O_3 component from the Fe-ZSM-5 containing mixture.

The collected data: i) provide direct evidence of nitrites formation in the oxidative activation of NO over both Fe- and Cu-zeolites; ii) rule out nitrates as potential reaction intermediates in the low-T Standard SCR reaction; iii) suggest a possible equilibrium between nitrites and HONO in the gas phase. On such a basis, low-T redox mechanisms for NO oxidation and Standard SCR over Fe- and Cu- zeolite catalysts, consistent with the new experimental observations, are proposed and discussed, iv) evidenced differences in the relative abundance of nitrites/nitrates species on Fe- and Cu zeolites, in line with the greater stability of NOx adspecies already reported for Cu zeolites [1].

4 Conclusions

Nitrites have been identified as the primary products of the NO oxidative activation over Fe- and Cu-zeolites. The improved understanding of the Standard SCR chemistry at low temperature will play a key role in the development of more effective metal exchanged zeolite catalysts and of more detailed and realistic simulation models.

Keywords: low-temperature activity, high-temperature activity, NOX, reduction, solid-state ion-exchange, SSZ-13 copper

3 Introduction

Copper-exchanged zeolites offer promising perspectives to many technological applications. An example is the reduction of nitrogen oxides in the exhaust from diesel engines through selective catalytic reduction using ammonia as a reducing agent (NH_3-SCR) [1]. The conventional way to introduce copper into zeolites is by aqueous ion exchange or by high-temperature solid-state ion exchange (SSIE). However, there are several drawbacks using these methods [2]. Shwan et al. [2] showed in a recent publication that highly active copper-exchanged zeolites can be prepared by exposing a physical mixture of copper oxide and zeolite to NO and NH_3 at 250°C, so called [NO+NH_3]-SSIE. The method is new and not yet fully developed.

This presentation will focus on optimizing the copper oxide concentration used in the physical mixture before treatment. Furthermore, we are showing that Cu-CHA prepared by [NO+NH_3]-SSIE can possess high low- and high-temperature NH_3-SCR activity compared to Cu-CHA prepared by conventional aqueous-based ion-exchange, even by using lower copper content [3].

2 Experimental

The zeolite CHA was prepared in F^- media using the molar composition of the synthesis gel as follows: 1.0 SiO_2 : 0.05 Al : 0.5 OSDA : 0.5 HF. The gel was transferred to a Teflon lined autoclave and heated to 150 °C for 3 days without agitation, whereafter the product was recovered by centrifugation and washed excessively with milli-Q water. To perform Cu-SSIE, dry mixtures of the CHA and either 0.5%, 1.0% or 2.0% CuO were grinded, whereafter placed in a quartz tube and exposed to a gas mixture of NH_3 and NO (850 ppm each) in Ar, at 250 °C for 5 hours. For the comparison, one sample with 3.0% Cu content was additionally prepared by conventional aqueous-based ion-exchange as described in ref [3]. All prepared samples were tested for NH_3-SCR, NO oxidation and NH_3 oxidation, and characterized extensively with NH_3-TPD, NO-TPD, NO_2-TPD, H_2-TPR, BET, XRD, UV-Vis, SEM, TEM and ICP.

Figure 1 Results and discussion

Figure 1 shows the NO conversion for the different Cu-CHA samples during NH_3-SCR together with the XRD pattern of the 2.0% Cu-CHA sample before and after the [NH_3+NO]-SSIE. For the [NO+NH_3]-SSIE-prepared catalysts the activity for NO reduction increases with increasing copper content. Moreover, it is clearly seen that using the [NO+NH_3]-SSIE method allows us to prepare a catalyst (2.0% Cu-CHA) which shows higher NH_3-SCR activity both at low and high temperatures compared to the conventionally prepared one. Moreover, the XRD study shows strongly pronounced decrease of the reflections intensities related to presence of CuO (2theta 36.2 and 39.6°) in the mixture after the [NH_3+NO] treatment. That means that CuO

is consumed during the treatment likely forming mobile copper species which migrate to ion-exchange sites in the zeolite forming copper species active for NH_3-SCR. It is remarkable that the 2.0% Cu-CHA sample prepared by the [NO+NH_3]-SSIE method does not only show higher low-temperature NH_3-SCR activity compared to the sample prepared by conventional aqueous-based ion-exchange but it is also more active and stable at high temperatures reaching full NO conversion at the broad temperature range of 255-500 °C, unlike the 3.0 % Cu-CHA sample. The usage of less amount of Cu in this case makes it even more remarkable and allows to reduce the cost for the catalyst synthesis.

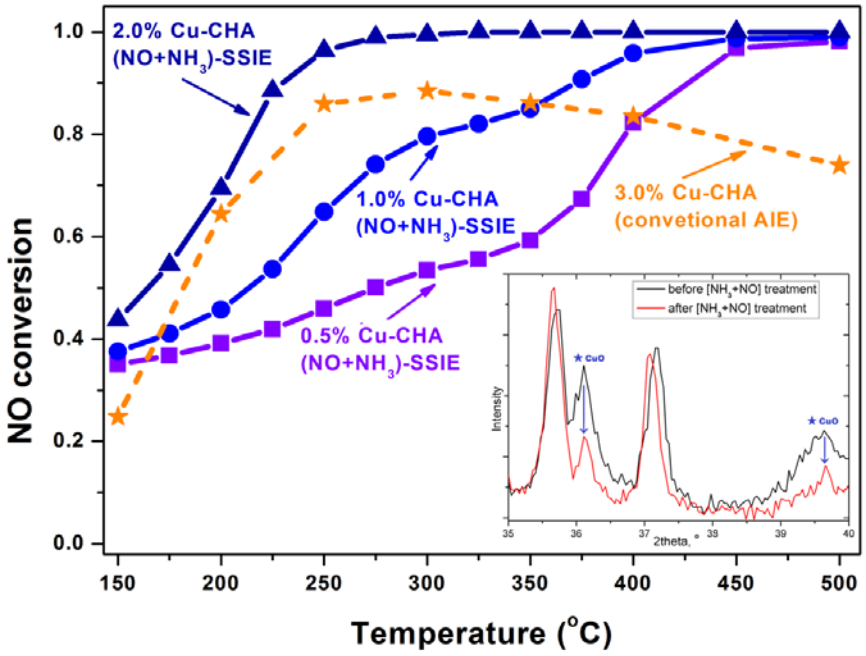

Fig. 1. NO conversion for Cu-CHA samples with 0.5 – 3% copper loading prepared using conventional aqueous ion-exchange and by solid-state ion-exchange in presence of NO and NH_3. The insert shows the X-ray diffraction patterns for the 2.0% Cu-CHA sample prepared by solid-state ion-exchange with decreased intensities of the CuO reflections after the [NH_3+NO] treatment.

4 Conclusions

We have shown that Cu-CHA prepared by [NO+NH_3]-SSIE can possess relatively high activity both for low- and high-temperature NH_3-SCR compared to Cu-CHA prepared by conventional aqueous-based ion-exchange, even by using lower copper content [3]. The study shows that the 2.0% Cu-CHA sample prepared by the [NO+NH_3]-SSIE method possesses the highest NH_3-SCR activity among the studied catalysts.

Keywords: NH_3-SCR, Cu-Zeolite, chabazite, aging, NOx conversion, N_2 selectivity

1 Introduction

Diesel engines have the highest thermal efficiency, and consequently release less CO_2 into the atmosphere as main gas contributing to global warming. The engine operates in excess of oxygen, making conventional three-way catalysts ineffective [1]. Among different alternatives, engine manufacturers and catalyst suppliers are considering the use of SCR with NH_3 as reductant for NO_x removal in end-of-pipe technologies. Non-noble metals like copper or iron supported on ZSM5 and BETA zeolites are among the most active catalysts for NH_3-SCR process, although most recently Cu-Chabazite are appearing as very promising catalysts [2].

2 Experimental/methodology

SCR catalysts consisted of copper-supported zeolites. Cu-BETA and Cu-ZSM5 catalysts were prepared by ion exchange [3] on commercial zeolites supplied by Zeolyst International, namely CP414E (BETA, Si/Al=12.5) and CBV5524G (ZSM5, Si/Al=25), and the optimal copper contents were determined. Cu-CHA catalyst was prepared by ion exchange on a synthesized CHA with a Si/Al ratio of 10.5 [4]. The prepared powdered catalysts were then pelletized, crushed and sieved to 0.3-0.5 mm. The prepared catalysts were submitted to accelerated aging under 5% H_2O in Ar during 16 h at 750 ºC. Physical and chemical properties of the catalysts before and after aging process were determined by N_2 physisorption, NH_3-temperature programmed desorption, H_2-temperature programmed reduction, XRD and ICP/AES.

The SCR experiments were performed in a down flow stainless steel reactor with 1.0 g of pelletized catalyst. The composition of the feed gas mixture was 750 ppm NO, 750 ppm NH_3 and 6 % O_2 using Ar as balance gas. Total flow rate was set at 3000 ml min^{-1}, which corresponded to a space velocity (GHSV) of 90,000 h^{-1}. The NO, NO_2, NH_3 and N_2O concentrations at the reactor exit were monitored every 40 ºC, once the gas composition had been stabilized for at least 10 min, by an online FTIR multigas analyzer (MKS 2030).

Table 1. Copper content, surface area, acidity and reducibility of fresh and aged catalysts.

Catalyst	Cu content, wt%	Surface area, m^2/g		Acidity, ml NH_3		Reduced area, ml H_2	
		Fresh	Aged	Fresh	Aged	Fresh	Aged
Cu-BETA	2.1	501	362	2.44	1.13	6.56	7.11
Cu-ZSM5	1.4	381	274	1.68	1.22	19.35	17.21
Cu-CHA	3.9	579	481	3.31	2.95	25.95	24.26

3 Results and discussion

Figure 1 shows NO_x conversion for the three prepared catalysts before and after aging. All fresh catalysts achieve very high NO_x conversion, but Cu-CHA resulting in the best catalytic performance due to the wider temperature windows (140-380 ºC) even with high N_2 selectivity

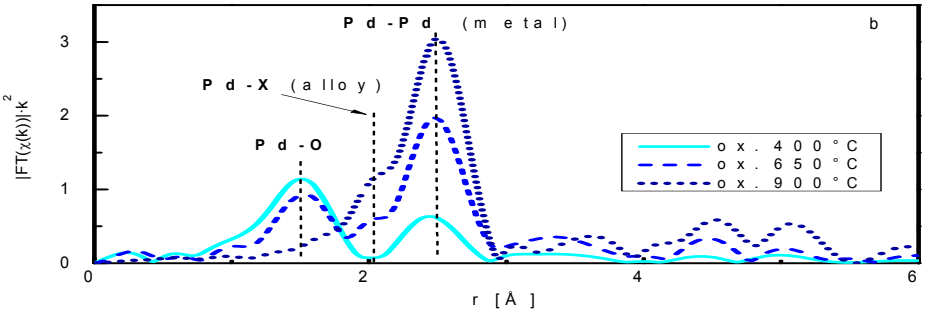

Fig. 1. NO_x conversion for a) Cu-CHA, b) Cu-BETA and c) Cu-ZSM5 before (black line) and after hydrothermal aging (red line).

(not shown). Moreover, NO_x conversion profile is practically maintained the same up to 380 ºC, with a drastic reduction above that temperature, achieving only 10% conversion at 500 ºC. This effect is related with the moderate loss in the BET surface (17%) or acidity (11%) of this catalyst after aging. This fact is also suggested to be responsible of some reduction in N_2 selectivity (around 10%), due to promote formation of N_2O and NO_2 at intermediate and higher temperatures, respectively.

On the contrary, hydrothermal aging of Cu-BETA and Cu-ZSM5 provokes a savage decrease in their catalytic performance. The aged BETA supported catalyst never achieves more than 50% NO_x conversion while the aged Cu-ZSM5 can achieve 60% conversion at 380 ºC, but produces NO at intermediate temperature, emitting even more than the amount introduced. Concerning selectivity, same tendency as with Cu-CHA catalyst were observed, with formation of N_2O at intermediate temperature and NO_2 at high temperature, e.g. 12% NO_2 selectivity with Cu-ZSM5 above 420 ºC. This trend is related to the loss of specific surface, acidity and reducibility of the catalysts as observed in Table 1.

4 Conclusions

The superior performance both in NO_x conversion and selectivity to N_2, especially after accelerated hydrothermal aging, for NH_3-SCR reaction is demonstrated. The main advantage corresponds with practically total NO_x conversion in a wider temperature window, from 220 to 380ºC, which is practically maintained after severe aging treatment. On the contrary, the aging process provokes a savage decrease in the catalytic activity of Cu-ZSM5 and Cu-BETA in the whole range of temperature. The activity loss is suggested to be related with the loss in BET surface, acidity and surface reducibility provoked by the thermal aging of each catalyst.

Dual Function Catalyst for SCR and CO-Oxidation

Pedersen K.H.*, Castellino F., Jensen-Holm H., Thøgersen J.R.

Haldor Topsoe A/S, Lyngby, Denmark

* kihp@topsoe.dk

Keywords: dual funcion catalyst, DeNOx, CO oxidation, combined cycle, power plants, HRSG

1 Introduction

Combining SCR and CO-oxidation functionality into one catalyst allows combined cycle power plants to meet their CO and NOx emission regulations with the lowest possible pressure drop. The classic layout is to equip the heat recovery steam generator (HRSG) with two different catalysts, i.e. an SCR catalyst and an oxidation catalyst with the latter usually located before the ammonia injection grid. Combining these two catalysts into one will lead to a reduction in total catalyst volume, thus decreasing the pressure drop as well as the SO_2 oxidation and this in turn will be beneficial for both the overall plant efficiency and maintenance. Moreover, retrofitting plants with SCR-only can in certain cases be simplified, i.e. the existing SCR catalyst can simply be replaced with the dual function catalyst to achieve CO oxidation as well. Haldor Topsøe A/S has developed such catalyst, the DNX® GTC-802, which is specially designed for combined cycle gas turbines. Its performance in terms of high activity and low pressure drop is recognized as state-of-the-art technology for removal of CO and NOx.

2 Experimental and results

Selective catalytic NOx reduction (SCR) in flue gas is mostly carried out by vanadium pentoxide (V_2O_5) catalyst on a titanium dioxide (TiO_2) carrier. In this process, NH_3 mixed into the flue gas reacts with the NO and NO_2 on the catalyst, forming nitrogen and water. Typical operation temperatures are around 300-400°C and the catalyst is shaped as a monolith, i.e. long straight parallel channels to ensure high surface area and low pressure drop. To achieve CO oxidation activity, it is common to apply noble metals from the Pt group which shows high activity at temperatures above 200°C. The CO oxidation catalyst is also shaped as a monolith.
Obviously, combining SCR and CO oxidation activity in one catalyst will be highly beneficial. This has also been attempted in the industry where commercial SCR catalysts have been "doped" with noble metals, e.g. Pt and Pd, and thus functionalized with CO oxidation activity. However, impregnation by simple dipping in noble metal solutions gives rise to an uneven distribution through the monolith and thus in an ineffective and thereby costly use of the noble metals. The reason is that e.g. Pd adsorbs very fast on the vanadia-sites of the SCR catalyst and therefore excess amounts of noble metals must be applied to reach a sufficiently high concentration in the part of the catalyst element that has the shortest contact time with the impregnation liquid. Moreover, Pd will be depleted from the impregnation liquid depending on the contact time between catalyst and liquid. The consequences of the strong affinity of Pd for vanadia-sites are shown in Fig. 1a. where SCR catalyst has been submerged into a Pd solution for different times. The Pd load obtained on the catalyst is much higher than that estimated from the liquid conc. and the porosity of the catalyst (in this case 110 ppm wt), e.g. after 5 minutes the Pd load is 4 times higher. Therefore, simply dipping a monolith with a length of for instance 50 cm in a Pd solution would result in longitudinal gradients caused by the difference in contact time between the first part submerged in the liquid and the last part. The difference in Pd load may be up to 5 times. However, at the temperatures relevant for the dual function operation, the CO oxidation rate is controlled by external mass transfer. This implies that high concentrations of Pd in regions of the monolith would not enhance the oxidation activity but would instead

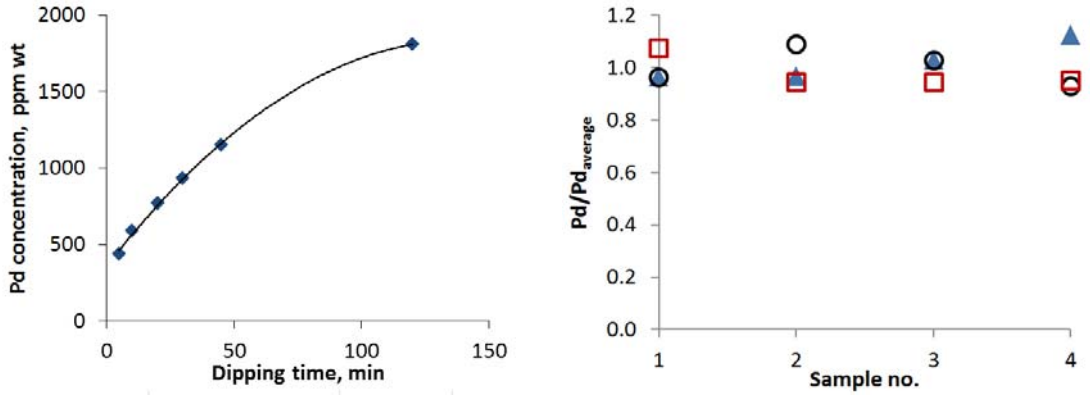

Figure 1: (a) Effect of dipping time in a $PdNO_3$ solution on the Pd bulk concentration of a vanadia-based SCR catalyst. **(b)** Pd concentration on 4 different DNX® GTC-802 monoliths relative to the average concentration of the same four monoliths. The monoliths were all 50 cm long and the three concentrations correspond to top, middle and bottom of the monoliths, respectively.

compromise the DeNOx activity because the catalyst will be more prone to convert the NH_3 into N_2 or even to NOx as a result of the enhanced oxidation activity (NH_3 oxidation rate is not controlled by external mass transfer alone). This is, of course, an unwanted scenario since the reduced SCR activity has to be compensated by using an increased catalyst volume.

The GTC-802 has been designed to provide the same high SCR activity as an SCR-only catalyst by keeping the noble metal contents at a low level throughout the catalyst (Pd for this catalyst). On the other hand, this level is still high enough to provide the same oxidation activity as an oxidation-only catalyst. A new proprietary method for adding the active sites for the SCR and CO oxidation reactions to a titania support has been developed. With this method both the distribution and level of noble metals are controlled. Fig. 1b. illustrates the normalized Pd concentrations on four different monoliths being 50 cm long and prepared by this method. The deviation in Pd concentration from monolith average is maximum 12% which is negligible compared to what can be obtained by simple dipping of the monolith into a Pd solution.

Table. Test conditions. Gas inlet composition: 50 ppmv NO_x, 55 ppmv NH_3, 100 ppmv CO, 15 %vol O_2, 10 %vol H_2O, N_2 balance. Temperature: 350 °C.

	Catalyst	DeNOx, %	DeCO, %	NH_3 slip, ppmv
SCR only	GT-201	93.5	0	5.7
Dual function	GTC-802	92.9	97.8	4.4

The dual function catalyst has been compared with an SCR-only catalyst (Table 1). High NOx removal efficiencies have been obtained in both cases but the dual function catalyst additionally combines the SCR activity with a high CO oxidation. Thus, with this catalyst the required catalyst volume and thereby the resulting pressure drop will be reduced compared to using single catalysts dedicated for NOx removal and CO oxidation.

3 Conclusions

Haldor Topsoe has developed GTC-802, a dual function catalyst with the same SCR activity as an SCR-only catalyst but with CO oxidation functionality as well. In this way the total required catalyst volume to achieve a desired NOx and CO removal efficiency can be significantly reduced, thereby reducing pressure drop and in turn improving plant efficiency. With respect to plants that have to comply with CO emission limits but today has an SCR catalyst only, the dual function catalyst may simply replace the existing SCR catalyst in the HRSG. Finally, it can be added that the dual function catalyst provides an option for VOC removal as well.

Keywords: mercury, oxidation, NOX effect, HCl effect, temperature effect, V_2O_5 catalyst

1 Introduction

Among the various air pollutants emitted from coal-fired power plants, elemental mercury is a major environmental issue that has attracted considerable attention in recent years. It is now well known in literature that the presence of a SCR-DeNO_X unit affects mercury speciation, since the SCR catalyst favors the highly desired conversion of Hg^0 to the ionic species Hg^{2+} in the presence of HCl according to the stoichiometry: $Hg+2HCl+1/2O_2 \rightarrow HgCl_2+H_2O$. Several studies have investigated Hg oxidation over V-based catalysts; a number of macroscopic kinetic effects have been unanimously recognized, but the mechanism and kinetics behind them are still under study. For instance, the temperature dependence of Hg^0 conversion is typically reported as moderate or even negative [1]; this phenomenon, though broadly observed, has been little addressed and understood. It is known that external mass transfer limitations and the thermodynamics of the oxy-chlorination of Hg^0 play a role at high temperatures (> 400°C) [2, 3]. Also, the surface interaction of the chemical species typically present in the SCR reactor can modify the availability and strength of the active sites and thus affect the kinetics of Hg^0 oxidation. For example, it is well known that NH_3 adsorption inhibits the Hg oxidation.

This work aims at deepening the comprehension of the complex surface interactions that occur on the SCR catalyst in the presence of NO (whose effect has been reported by other studies to be either positive or negative [4]) and HCl under different operating temperatures as the initial step toward a systematic kinetic investigation of this complex reacting system.

2 Experimental/methodology

Experiments were performed over a $V_2O_5/MoO_3/TiO_2$ catalyst in a plug-flow plate-type reactor. This consisted of a rectangular quartz tube (section 32x22 mm), wherein a sample holder allowed for the placement of four plates of catalyst (400x25x1 mm) in a parallel configuration. The feed mixture consisted of 3.5% O_2, 10.5% H_2O, 0-10 ppm HCl, 0-300 ppm NO, 10 μg/Nm^3 of Hg^0 in N_2 with AV = 21 Nm/h; the temperature was varied in the range 170 – 400°C. Mercury balance and speciation were analyzed by an on-line Tekran instrument.

3 Results and discussion

Hg^0 oxidation reference tests were performed in the absence of the DeNOx reactants; Figure 1, panel A shows the results in black symbols. In the whole temperature range, Hg^0 conversion progressively increased with temperature, contrarily to what is commonly reported in the literature (where tests are usually performed in the presence of NO and NH_3); here, we estimated an apparent activation energy of 4.8 Kcal/mol. Since this weak temperature dependence was observed even at temperatures as low as 175°C, it seems informative of the surface kinetics, rather than being the result of full external mass-transfer control (which may be expected at higher temperatures [2]); in other words, it could be associated with the relevance of adsorption-desorption steps of the reacting species.

Experiments were then performed with NO co-feed (Figure 1, panel A, red symbols). A

promotion of Hg^0 conversion (about 5-10%) was observed up to 325°C; at increasing temperature, though, conversion declined. Thus, above 350°C, a progressively important loss of conversion was observed in comparison with the reference tests and a negative T-dependence appeared.

To better comprehend the surface interactions behind this evidence, we performed experiments at varying HCl inlet concentration, with and without NO. Tests were first performed at 300 and 400°C without NO (Figure 1, panel B). At both temperatures, no Hg^{2+} was formed in the absence of HCl, but Hg^0 conversion grew with increasing HCl content with asymptotic trends. Notably, below 3 ppm HCl, the conversion curves were almost coincident, thus insensitive to temperature; this suggests that, at very low HCl concentration, HCl adsorption was not equilibrated and was the kinetically controlling step. Above 5 ppm HCl, surface saturation was apparently reached and the weak positive T-dependence was confirmed.

Similar experiments were performed in the presence of 300 ppm NO (Figure 1, panel C). At 300°C, NO co-feed enhanced Hg^0 conversion over the whole range of HCl concentration studied. Surprisingly, a net conversion of Hg^0 to Hg^{2+} was observed in the absence of HCl and it amounted to about 43%; thus, an additional route of oxidation to HgO was active in the presence of NO. This demonstrates that at 300°C NO or, more likely, NO-related surface or gas phase species (e.g. nitrites, nitrates and NO_2) promoted the oxidation of Hg^0 to ionic Hg. Indeed the formation of NO_2 and surface nitrates is expected to pass through a maximum at 300-350° due to the kinetics and thermodynamics of NO oxidation.

At 400°C, instead, the co-feed of NO strongly inhibited Hg^0 conversion. The effect was dramatic at low HCl concentration and such that the conversion curve lost the typical asymptotic trend, while it assumed an increasing trend. This suggests that the formation of NO-related surface species competed with and hindered HCl adsorption.

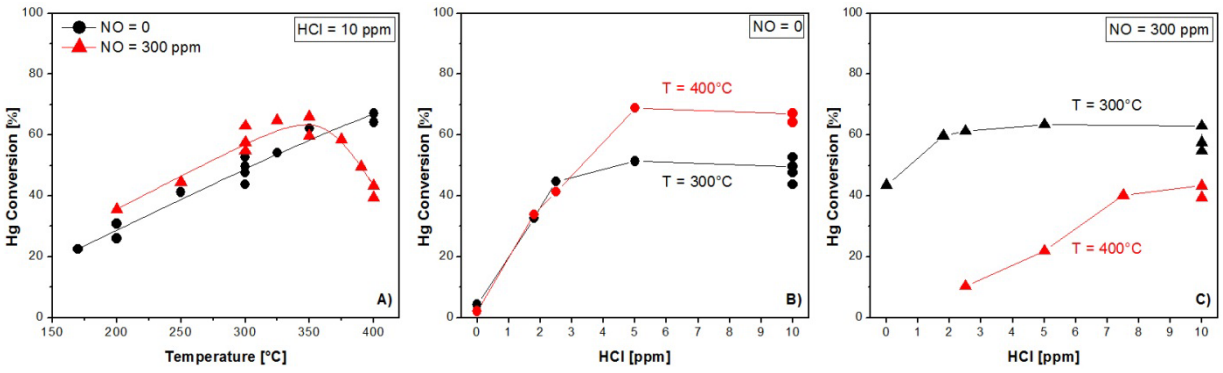

Fig. 1. Panel A: Hg^0 conversion over temperature; panels B and C: Hg^0 conversion over HCl inlet concentration with or without co-feeding 300 ppm NO at 300°C and 400°C.

4 Conclusions

The rate of Hg oxy-chlorination is strongly affected by surface coverage effects, thus the apparent activation energy is highly sensitive to the feed composition. The adsorption of HCl plays a key kinetic role and seems the RDS at low HCl concentration. NO (directly or indirectly) promoted Hg conversion up to 325°C but it had a negative effect at higher temperatures.

Absorption and Oxidation of NO_x from Flue Gasses to Nitric Acid – An Atom Efficient NO_x Abatement Strategy Using Ionic Liquids

Thomassen P.L.*, Fehrmann R., Mossin S.L.

Center for Catalysis and Sustainable Chemistry, Department of Chemistry, Technical University of Denmark, Lyngby, Denmark

* pett@kemi.dtu.dk

Keywords: NOx abatement, alternative, DeNOx, Ionic, liquids, nitric acid

1 Introduction

Formation of NO_x during high temperature combustion with air is inevitable and of increasing environmental concern. NO_x participates in detrimental photochemical reactions in both the stratosphere and the troposphere, depleting the ozone layer and contributing to the greenhouse effect [1]. Furthermore, higher NO_x concentrations cause severe health conditions, such as cancer and several respiratory diseases. The main constituent of NO_x in flue gas is nitric oxide (NO).

In larger installations, NO_x is removed by selective catalytic reduction (SCR) using a transition metal catalyst to facilitate reduction of NO_x with ammonia. SCR exhibits excellent conversions and selectivity, when run at temperatures around 300ºC.

In order to reduce their carbon footprint, several countries have begun experimenting with, and implementing, biomass firing in power plants. The catalytic activity of the traditional high dust SCR setup decreases significantly within the first few hundred operating hours, when firing biomass. The poisoning of the catalyst is mostly due to alkaline aerosols. The deactivation can be overcome by placing the SCR reactor at the tail end of the flue gas treatment system, the low dust position. At this point however, the temperature of the flue gas has decreased significantly and a costly heat exchange becomes necessary. The deactivation is also a problem for the maritime industry, in waste incineration plants etc.

As described above, there is a demand for alternative deNO_x solutions. Several alternatives exist; fast SCR, low temperature SCR catalysts and absorption and oxidation with ionic liquids (ILs). This work revolves around the latter possibility.

Previous studies have shown that several ILs can absorb and oxidise NO_x species to nitric acid, at room temperature [2]. This oxidation can be done using only the excess oxygen and generated water present in the flue gas. This work presents a detailed spectroscopic study into the mechanism and kinetics of the reaction, mainly carried out by attenuated total reflectance Fourrier-transform infrared (ATR-FTIR) spectroscopy

2 Short experimental section

The *in-situ* ATR-FTIR experiments were conducted by placing a thin IL film on top of a temperature controlled ATR plate (Specac Golden Gate, High Temperature Diamond ATR). A specially designed gas cap was placed on top of the IL film, allowing a pre mixed simulated flue gas to be passed over the IL film. The reaction was monitored using a Nicolet iS5 FTIR spectrophotometer, with a resolution of 2-4 cm^{-1}, in the range 600-4000 cm^{-1}, and with a scan rate of 4-32 scans per spectrum, depending on the rate of reaction. The specific peaks for nitric acid were deconvoluted using Peakfit 5.0, giving a time resolution of the total rate of the reaction. Furthermore, the spectra were analysed to identify possible reaction intermediates. In all cases, the IL was regenerated under air flow at 125ºC [3].

3 Results and discussion

The overall reaction for the oxidation of NO to nitric acid in ILs follows the reaction scheme shown in (1) [2]:

$$4\ NO + 3\ O_2 + 2\ H_2O <--> 4\ HNO_3 \quad (1)$$

The kinetics of the reaction were determined by monitoring the rate of formation of nitric acid, when exposing the IL to a constant gas flow of varying concentrations. The IL is insignificant in size compared to the gas flow, thus the gas composition is considered constant. The reaction order in NO was determined to be 2, which is consistent with the proposed rate equations for autoxidation NO in different reaction media [4].

Spectroscopic investigations revealed several likely reaction intermediates. Three different N_2O_4 species, two with N-O-N bonds (both a cis- and a trans- conformation) and one species with a N-N bond. The presence of these three species suggests that NO associates with the nitrate of the IL, giving an NO-NO_3 adduct with an N-O-N bond, which can exist in both a cis and a trans conformation. The N-N is consistent with dimerisation of gaseous NO_2 being dissolved in the IL as N_2O_4. NO_2 can likely undergo dimerisation both as a dissolved species in the IL or by being released to the gas phase and subsequently dissolved as N_2O_4.

We believe that the oxidant in the reaction is molecular oxygen, since the reaction is highly reversible. The observed reversibility strongly suggests that no atomic oxygen radicals are present during reaction, as these would likely oxidise the IL. In order to utilise all 4 oxidation equivalents either a dimeric species of N^{III} or a singular N^{I} species would be expected as intermediates in the oxidation step. The first of the two seems as the most likely and spectroscopic evidence of HONO, a N^{III} species formed from reaction between NO_2 and water, was found in the spectra. All in all, the above findings have led to the proposed catalytic cycle presented in Figure 1 below.

4 Conclusions

Different techniques have shown that a variety of ILs can absorb and oxidise NO from a simulated flue gas, utilising the excess oxygen and water already present. This reaction is highly reversible. A rate law has been experimentally determined, and was found to be in accordance with the ones proposed in literature. *In-situ* spectra were examined and several reaction intermediates have been proposed. The findings have been collected and presented as a catalytic cycle with reaction coefficients amounting to that of the total reaction known from the literature.

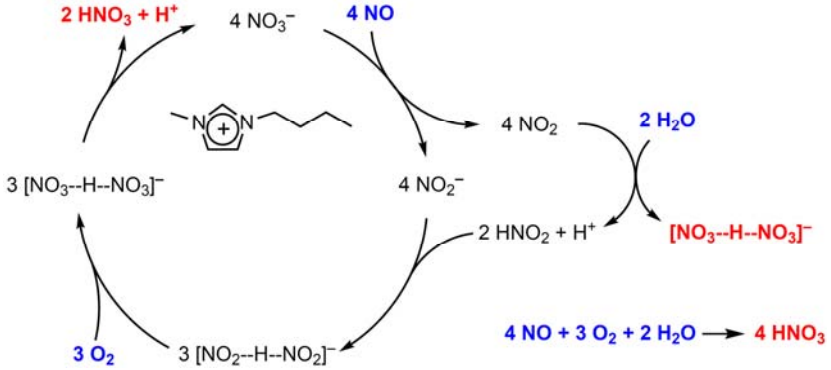

Figure 1: Catalytic cycle for the oxidation of NO in ionic liquids. In this case the 1-butyl-3-methylimidazolium cation is depicted, but research has shown other cations to also be active in this reaction.

Keywords: reaction mechanism, DFT, modelling, redox sites, isotopic labelling, surface reactive oxygen species, kinetics

1 Introduction

Spinels are excellent redox model catalytic materials of wide fundamental and practical interest due to their well-defined structure, ability to facile morphological variations and high flexibility in modifying their electronic properties via non/off-stoichiometry and site selective doping. Depending on the synthesis method, faceted nanocrystals of spinels expose well-defined planes, allowing for sensible investigations into structure-reactivity relationships at both model and practical conditions. This fact assists in designing of redox-tunable active sites of high performance and preferential development of surface terminations of high site density and optimal structure. The central points of our study consist in synthesis of the Mn, Fe, and Co nanospinel catalysts of controlled grain morphology and size, identification and in-depth characterization of the active sites, their redox tuning for optimal performance and catalytic kinetic studies of N_2O decomposition. The experiments are interpreted by means of DFT molecular modeling.

2 Experimental/methodology

Nanostructured Mn_3O_4, Fe_3O_4 and Co_3O_4 catalysts of controlled morphology were obtained via microwave assisted. The samples were characterized with XRD, XPS, RS, UV-Vis, EPR, SQUID, BET, FE-SEM/HR-TEM/EDX/EELS, and TPR/TPO as well as $^{16}O/^{18}O2$ isotopic exchange techniques. The catalytic measurements of N_2O decomposition were performed in a quartz flow reactor with GHSV of 5000-7000 h^{-1} in the range of 300 – 1000 K and in pulse mode using isotopically labeled reactants. The work function was measured by contact potential difference (Kelvin probe). For all computations (VASP package) a spin resolved DFT and DFT+U level of theory with B3LYP and PBE correlation-exchange potentials and PAW were used. For inclusion of pressure and temperature effects the interaction of the spinel surface with the reactants was modeled within the atomistic thermodynamics approach.

3 Results and discussion

The synthesized spinel samples regardless their morphology (retrieved by inversed Wulff construction) were monophasic and exhibit the (100), (111) and (110) facets only, as revealed by XRD and HR-TEM and Raman investigations. TPSR measurements showed that all samples exhibited large differences in N_2O decomposition activity, reaching full conversion below 450 ^oC, 700 ^oC, and 850 ^oC for Co_3O_4, Fe_3O_4, Mn_3O_4, respectively. Selective substitution of tetrahedral and octahedral parent cations, constituting the spinel (verified by XRD, RS, SQUID and EPR) revealed that octahedral ions, play the role of prime active sites in deN_2O reaction. The catalytic performance of the nanospinel was analyzed in terms of the redox properties of the catalyst probed by TPR/TPO and pulsed CO/O_2 surface titration and work function

measurements and the catalysts stoichiometry. In the case of the most active stoichiometric cobalt spinel, the well-balanced redox properties of the octahedral Co^{3+} sites account well for the high sustainable N_2O turnover. For the inverse spinel Fe_3O_4 the octahedral sites are occupied by mixed valence Fe^{2+}/Fe^{3+} cations, resulting in enhanced susceptibility for deep oxidation leading to transformation of the magnetite phase to maghemite at the surface region. As a result the observed steady state deN_2O catalytic activity is characteristic for the surface maghemite stable at the reaction conditions. Similar transformation was observed for Mn_3O_4 catalyst, but its lower activity is additionally constrained by the strong Jahn-Teller effect of octahedral Mn^{3+} cations. As a result, the change of the Mn^{3+} redox state during the catalytic cycle is accompanied by strong structural relaxation which enhances the activation barrier. Isotopic experiments revealed complex interfacial mechanism of recombination of oxygen adspecies produced by N_2O decomposition into final O_2, which involve the surface O^{2-} anions.

Detailed structure of the exposed (100), (110) and (111) facets, surface composition and specific coordination of all exposed metal and oxygen ions were established, with special emphasis on the electronic structure of the surface active sites. The projected electronic density of states where analyzed in terms of the electronic and magnetic structure of the investigated spinels, with emphasis on the edge-sharing octahedra, forming regular strips responsible for redox properties, crucial for their catalytic behavior. The redox properties of the spinels were discussed in terms of the spin and charge transfer polaron dynamics for M^{2+}/M^{3+} and M^{3+}/M^{4+} redox couples. The obtained results allowed for an in-depth rational account of the catalytic behavior of the manganese, iron, and cobalt spinel catalysts for decomposition of nitrous oxide.

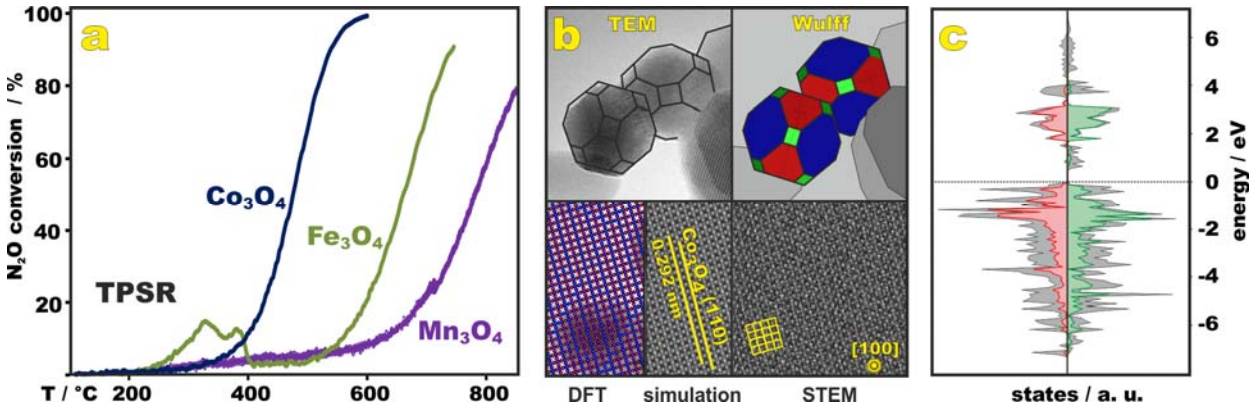

Fig. 1. deN_2O conversion profiles for Co, Fe, and Mn nanospinel catalysts (a), morphology of the Co_3O_4 grain and structure of the active (100) plane (b), DOS structure of cobalt spinel (grey) showing the contribution of the active octahedral Co sites shown in green and red (c).

4 Conclusions

A comprehensive multi-techniques experimental and theoretical DFT approach allowed for identification and quantification of the manganese, iron and cobalt spinel active sites, explaining their nature and redox properties, to provide an integral account of the observed large differences in the N_2O decomposition activity and the reaction mechanism.

Keywords: environmental catalysis, mixed spinels, N_2O decomposition

1 Introduction

For a worldwide decrease of greenhouse gas emissions not only CO_2 but also other strong greenhouse gases such as e.g. CH_4, N_2O and SF_6 have to be considered. Especially by decreasing N_2O emissions, a high number of CO_2 equivalents can be reduced, as N_2O has a 310 times higher global warming potential compared to CO_2[1]. Main sources of N_2O are emissions from agriculture due to the use of fertilizer. Also industrial processes such as HNO_3 production and combustion processes contribute significantly to the overall N_2O emissions. For complete removal of N_2O emissions, current strategies rely on additional heating of the gas streams for a complete decomposition of N_2O into N_2 and O_2 out of tail gases from HNO_3 production. To avoid such energy inputs, suitable catalysts should enable high N_2O decomposition activity below 500°C in the presence of O_2, NO and H_2O. An industrially applied catalyst is Fe-ZSM-5. This catalyst achieves 50 % conversion at a temperature ($T_{50\%}$) of 430 °C in ideal reaction conditions [2]. Compared to the average temperatures of the tail gases (T = 250 – 500 °C) the activity is still too low for quantitative conversions without additional energy input. Herein, we present a promising catalyst with high activities below 500°C in realistic reaction conditions.

2 Results and discussion

Co_3O_4 shows already high activities for N_2O decomposition into N_2 and O_2.[3] In order to enhance the catalytic activities varying amounts of Co were exchanged by several metals (Mg, Cu, Co, Cr, and Zn) in the spinel phase. Using these materials as catalysts shows that the integration of Cu highly increases the catalytic activity compared to Co_3O_4. Furthermore, a strong dependency of the catalytic activity on the degree of metal exchange in $Cu_xCo_{3-x}O_4$ was found (Figure 1a)).[4] For lower Cu amounts higher catalytic activity is achieved. Reducing the amount to x = 0.25 results in highly active catalysts which show higher activities than pure Co_3O_4. For $Cu_{0.25}Co_{2.75}O_4$ full conversion was already achieved at 410°C in ideal reaction conditions ($c(N_2O)$ = 1000 ppm, GHSV = 54000 h^{-1}). These findings point to a strong synergetic effect between Cu and Co if Cu is applied in the proper ratio.

To increase the catalytic activity even more a series of doping metals (Ba, K, Sr, Na) was tested. Using various amounts of dopants shows that the strongest promotional effect was achieved with a molar ratio of n(K) to n(Cu)+n(Co) of 0.01. In ideal reaction conditions 0.01K-$Cu_{0.25}Co_{2.75}O_4$ shows full conversion at 330 °C. This is 80 °C lower than for the undoped catalyst. To investigate the performance of this catalyst in industrial conditions, additional gases (O_2 (c = 2 %) , NO (c = 200 ppm) and H_2O (c = 0.5 %); GHSV = 54000 h^{-1}) were first added single wise and later all together to reconstruct real reaction conditions (Figure 1b).

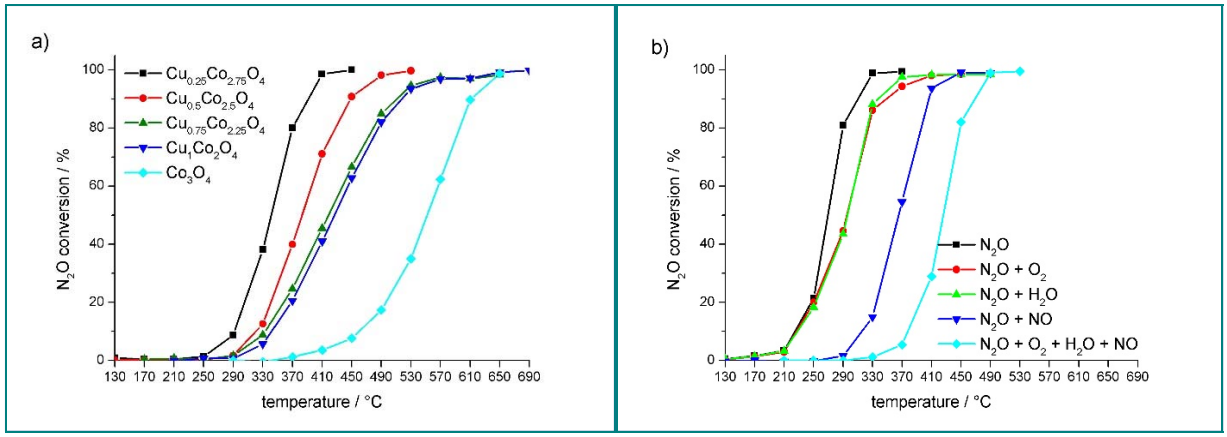

Fig. 1. a) Influence of the amount of Cu in $Cu_xCo_{3-x}O_4$ on the N_2O decomposition activity in ideal reaction conditions ($c(N_2O)$ = 1000 ppm in N_2, GHSV = 54000 h^{-1}). b) Performance of 0.01K -$Cu_{0.25}Co_{2.75}O_4$ in real reaction conditions ($c(N_2O)$ = 1000 ppm, $c(O_2)$ = 2 %, c(NO) = 200 ppm, $c(H_2O)$ = 0.5 % in N_2; GHSV = 54000 h^{-1}) and in the presence of the single gases.

In the presence of H_2O and O_2 the necessary decomposition temperatures increases only slightly, while the presence of NO has a strong influence. But still, at a high GHSV of 54000 h^{-1} and in the presence of all inhibitory gases (NO, O_2, H_2O) present under realistic reaction conditions, the catalyst K-$Cu_{0.25}Co_{2.75}O_4$ shows full conversions at temperatures as low as 490 °C. In the case of the not doped catalyst a much stronger inhibition by O_2 and H_2O was observed. This emphasises that desorption of oxygen is facilitated due to doping with K.

In long term experiments under stable reaction conditions and high GHSV (54000 h^{-1}) 0.01K-$Cu_{0.25}Co_{2.75}O_4$ shows no deactivation and a stable N_2O conversion of at least 72 % at 400 °C in realistic exhaust stream conditions. Even an increase of the gas flow rates leads only to minor changes of the conversions. First results on supported catalysts emphasise that the amount of active species can be highly reduced by the use of proper supports without significant loss of activity.

3 Conclusions

The introduced 0.01K-$Cu_{0.25}Co_{2.75}O_4$ catalyst shows high activities in the conditions of exhaust gases of HNO_3 production. Introducing this catalyst after the $DeNO_x$ unit in the reaction plant could enable operating temperatures of the DeN_2O stage as low as 330 °C. Overall, this development facilitates a more environmentally benign production of HNO_3 with minimum energy requirement for treatment of the exhaust gases.

Keywords: N_2O decomposition, $CuO\text{-}CeO_2$ mixed oxides, impregnation, precipitation, exotemplating

1 Introduction

Nitrous oxide (N_2O) is one of the most significant greenhouse gases, due to its high global warming potential (~300 times higher as compared to CO_2). Moreover, it has a very long lifetime in the atmosphere (about 150 years), severely contributing to the depletion of the stratospheric ozone layer [1]. Hence, considerable efforts have been devoted on the N_2O emissions control from anthropogenic sources, with the catalytic decomposition to be considered as one of the most efficient and cost-effective technologies [1].

In spite of the excellent catalytic performance of noble metals (NMs)-based catalysts, their high cost and sensitivity to off gases constituents (i.e. O_2, NO, SO_2, H_2O) limits their widespread industrial application. Therefore, the development of NMs-free catalysts of low cost and adequate de-N_2O performance is of paramount importance. Recently, it has been reported that mixed oxides could possibly act as candidates for N_2O degradation, with CeO_2 to be a key component due to its unique redox properties. Furthermore, Cu-based catalysts have received considerable attention in heterogeneous catalysis due to their adequate performance and low cost. Thus, it has been shown that $CuO\text{-}CeO_2$ mixed oxides confer a synergistic interaction effect toward enhanced reducibility and catalytic performance [2].

In the present work, the effect of preparation procedure on the N_2O decomposition is investigated by employing three different catalysts types, *i.e.*, i) bare CeO_2, ii) Cu supported on CeO_2 and iii) Cu-Ce mixed oxides. In all three cases, impregnation, precipitation and exotemplating methods were employed, whereas commercial samples were also used for comparison. All materials were characterized by BET, XRD, H_2-TPR, SEM and XPS in order to correlate the de-N_2O performance with the morphological, structure and surface properties.

2 Experimental/methodology

Three different types of materials were synthesized: i) bare CeO_2 prepared by precipitation (Ce-pp) and exotemplating (Ce-exo) in comparison to commercial CeO_2 (Ce-com), ii) Cu/CeO_2 oxides synthesized by impregnation of the above materials with CuO (Ce-pp+Cu, Ce-exo+Cu, Ce-com+Cu), iii) Ce-Cu mixed oxides prepared in one stage by precipitation (Ce-Cu-pp) and exotemplating (Ce-Cu-exo) using cerium and copper nitrates as precursors. For comparison, a material prepared by mechanical mixing of commercial CeO_2 and CuO (Ce-Cu-com) was also

examined. The as prepared materials were characterized by N_2 adsorption at 196 ºC, temperature programmed reduction (TPR), X-ray photoelectron spectroscopy (XPS), scanning electron microscopy/energy-dispersive X-ray spectroscopy (SEM/EDS) and X-ray diffraction (XRD).

3 Results and discussion

Figure 1 depicts the de-N_2O performance, in the absence of O_2, over the single CeO_2 and Ce-Cu mixed oxides prepared by different routes.

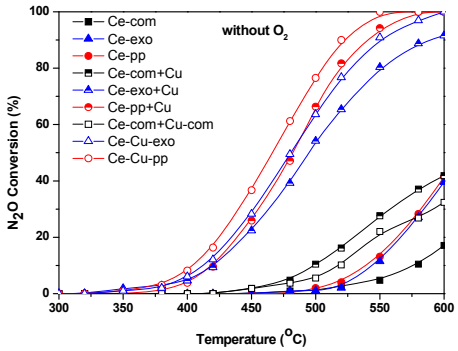

Fig. 1. N_2O conversion in the absence of O_2. Reaction conditions: 1000 ppm N_2O, GHSV=40000 h^{-1}.

The results clearly show the inferior N_2O conversion performance of single oxides, never exceeding 40% at 600°C. On the contrary, a superior de-N_2O performance was obtained by mixed oxides. The optimum performance was observed for Cu-Ce mixed oxides prepared by co-precipitation, which achieves complete N_2O conversion at 550ºC. The remarkable activity of Cu-Ce-pp samples can be ascribed to their superior reducibility at low temperatures in conjunction with the high concentration of Ce^{3+} sites. These factors are crucial for N_2O decomposition, since they contribute to the facilitation of oxygen desorption from the catalyst surface as well as to the regeneration of active sites.

4 Conclusions

The N_2O decomposition over bare or mixed CeO_2 and CuO oxides was investigated, with particular emphasis on the impact of synthesis procedure (impregnation, precipitation, exo-templating) on the surface and redox properties. The obtained results revealed that the superiority of Cu-Ce mixed oxides prepared by precipitation compared to all other composites, can be ascribed to its excellent redox properties linked to Ce^{4+}/Ce^{3+} and Cu^{2+}/Cu^{+} redox couples.

Keywords: CuO/CeO_2, nanoshaped catalyst, N_2O decomposition, CeO_2 nanocubes, CeO_2 nanorods

1 Introduction

Considerable industrial emissions of N_2O into the atmosphere (about 400 million tons of CO_2 equivalent annually), its high global warming potential (310 times higher as compared to carbon dioxide), long atmospheric lifetime (approx. 120 years) and contribution in ozone layer depletion stimulate scientist to develop new, low-temperature technologies for N_2O degradation in exhaust gases [1,2]. Among efficient catalysts for N_2O decomposition, CuO/CeO_2 materials show very promising results [3,4]. It was reported, that nanoshaped ceria (nanocubes and nanorods) with well-defined [100] and [110] reactive planes possess higher catalytic activity than conventional polycrystalline ceria nanoparticles [5]. Therefore, the main purpose of this work was to investigate in detail the influence of nanoparticle shape and exposed crystal planes of CeO_2 supports on catalytic property of CuO/CeO_2 solids in low temperature N_2O degradation.

2 Experimental and methodology

Nanoshaped CeO_2 supports were synthesized by hydrothermal method. Briefly, 0.15 M $Ce(NO_3)_3 \cdot 6H_2O$ (99 % purity, Sigma-Aldrich) solution was added to 6M NaOH (99 % purity, Merck) for synthesis of ceria nanocubes (CeO_2-C) and nanorods (CeO_2-R), or to 1M NaOH solution for preparation of polycrystalline CeO_2 (CeO_2-P). Suspensions were aged at 180 °C (CeO_2-C) or 100 °C (CeO_2-R and CeO_2-P) for 24 hours, centrifuged, dried at cryogenic temperature and finally calcined at 400 °C for 4 h. In order to prepare CuO/CeO_2 catalysts, 2-8 wt. % of Cu was deposited by precipitation from $Cu(NO_3)_2 \cdot 3H_2O$ (99.5 % purity, Sigma-Aldrich) by Na_2CO_3 (99.999 % purity, Merck), followed by freeze-drying and calcination at 400 °C for 4 h. Synthesized solids were marked as X-Cu/CeO_2-M (where X represents nominal Cu content in wt. %, M represents morphology of utilized CeO_2 supports – cubes (C), rods (R) or polycrystalline (P)). Prepared materials were thoroughly characterized by N_2-sorption, SEM, HR-TEM, XRD, H_2-TPR, *in-situ* DRIFTS and *operando* DR UV-Vis techniques. Catalytic activity was investigated in a fixed-bed reactor operating in the temperature range from 300 to 550 °C with N_2O feed concentration of 2500 ppmv (WHSV = 120 L/(g_{cat} h)).

3 Results and discussion

Prepared CeO_2 supports significantly differ in BET specific surface area. The highest S_{BET} was measured for CeO_2-P sample – 115 m^2/g, while increasing NaOH concentration to 6M and hydrothermal temperature to 180 °C result in lower surface areas: 87 m^2/g for CeO_2-R and 29 m^2/g for CeO_2-C, correspondingly. Cu loading as well as utilized support greatly influence the physical-chemical, redox and catalytic properties of investigated catalysts. Accordingly to the results of H_2-TPR, TEM and DR UV-Vis analyses, several copper species are present on the

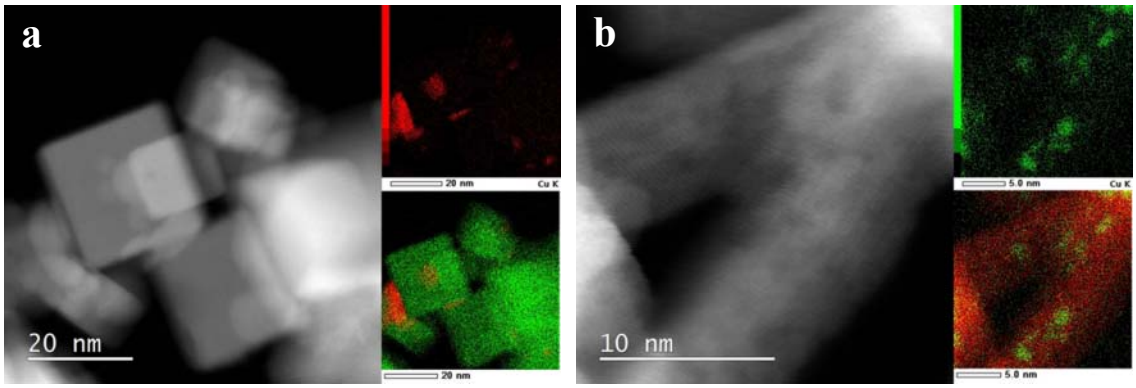

Fig. 1. BF-STEM image and EDX mapping of Cu, as well as overlay of Ce and Cu distribution observed for 4-Cu/CeO_2-C (a) and 4-Cu/CeO_2-R (b) samples

surface of CuO/CeO_2 oxides. By increasing copper loading from 2 to 8 wt. %, the growth of CuO particles from highly dispersed Cu species, through small CuO clusters and finally to bulk CuO phase takes place. Utilizing high surface area CeO_2-R and CeO_2-P supports resulted in higher Cu dispersion and smaller CuO clusters (less than 5 nm for 4-Cu/CeO_2-R, see Fig. 1b). Existence of both Cu^{+1}/Cu^{+2} and Ce^{+3}/Ce^{+4} ionic pairs in all studied samples was proved by means of DR UV-Vis examination. *In-situ* DRIFT spectroscopy with adsorbed CO also confirmed presence of Cu^{+1} and Cu^0 species, which are believed to be active sites for catalytic N_2O decomposition.

The highest N_2O conversions were achieved by catalysts based on CeO_2-R (exposed [100] and [110] facets are less stable and more reactive, S_{BET} = 87 m^2/g). Among them, 4-Cu/CeO_2-R resulted in highest activity per copper loading (3.8 mol $N_2O/(mol_{Cu}$ h) at 375 °C). At the same time 4-Cu/CeO_2-C (exposed [100] planes, S_{BET} = 27 m^2/g) and 4-Cu/CeO_2-P (exposed least reactive [111] planes, S_{BET}=110 m^2/g) resulted in lower activity as compared to 4-Cu/CeO_2-R (3.5 and 1.7 mol $N_2O/(mol_{Cu}$ h) at 375 °C, respectively). Long-term tests (100 h) with 4-Cu/CeO_2-R catalyst at 400 °C confirmed exceptional catalytic stability of the investigated catalysts even in the inhibiting atmospheres (presence water vapor/NO/O_2), which can be attributed to its ability to regenerate active sites by desorption of molecular oxygen from the catalyst's surface. Finally, mechanism of N_2O degradation over Cu/CeO_2 catalyst was proposed based on results of *operando* DR UV-Vis, DRIFTS and alternating N_2O/N_2 thermogravimetric examinations.

4 Conclusions

We have shown that activity of CuO/CeO_2 materials in catalytic N_2O degradation depends on both shape induced activity of CeO_2 ([100] and [110] facets are more reactive) and its BET surface area. Developed catalysts are stable for 100 h even in the presence of NO, O_2 and H_2O, which makes them appealing for potential industrial application. By using surface-sensitive *operando* techniques, the mechanism of studied reaction over CuO/CeO_2 catalyst was proposed.

Keywords: Pd-Cu bimetallic catalyst, water-phase, nitrate reduction, dehalogenation of chlorophenols

1 Introduction

The increasing of food demanding as a natural result of world population growth determined a large use of fertilizers and phytosanitary products in agricultural practices Nitrates and adjacent pesticides, especially organochlorine pesticides and their degradation by-products, are the main concerned pollutants found in natural waters originating from agricultural areas [1]. A series of physico-chemical and biological methods were developed for nitrate removal from water. Among these, liquid-phase catalytic reduction of the nitrates seems to be a convenient technique applied in this situation [2]. For organochlorine pesticides, characterized by high toxicity and persistence, several approaches like adsorption or advanced oxidation processes has been proposed [3]. An alternative approach for the reduction of the ecotoxicity of water polluted with organochlorine compounds could be the catalytic hydrodechlorination. Usually, the research studies are dedicated to a single or a class of pollutant (e.g. nitrates or organochlorine pesticides). This work is focused on the simultaneous removal of nitrate and organochlorine compounds from aqueous media through a catalytic reduction process, which could contribute to the protection and remediation of natural water resources.

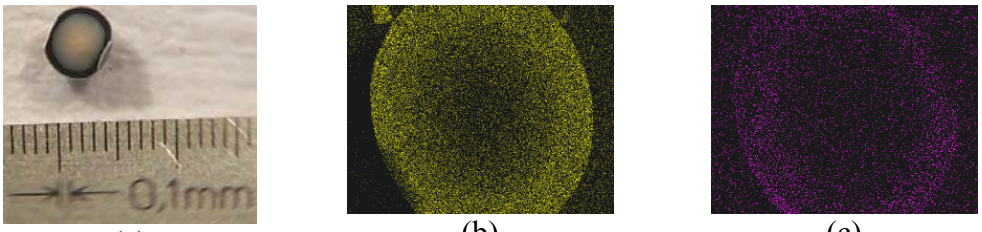
2 Experimental

In this purpose, a bimetallic Pd-Cu catalyst supported on an anion exchange resin (*A-520E Purolite*) was prepared by successive deposition of the metals (2%Pd and 0.5%Cu). In the first step, palladium was introduced by ion exchange with the functional groups $-N(CH_3)_3^+Cl^-$ present onto the styrene–divinylbenzene polymeric matrix of the resins, using as precursor the $[PdCl_4]^{2-}$ complex. In order to enhance the interaction Pd-Cu, the second component was deposited by a controlled surface reaction, in which Cu^{2+} was reduced by the hydrogen adsorbed on the pre-reduced Pd surface [4]. The morphological and structural characterisation of the catalyst was achieved by means of: Scanning Electron Microscopy with Energy Dispersive X-ray spectroscopy (SEM-EDX), X-Ray Diffraction analysis (XRD), X-Ray Photoelectron Spectroscopy (XPS), microphotography and Atomic Absorption Spectrophotometry (AAS). The catalytic tests were carried out in a continuous flow system with a fixed bed reactor (0.4 g catalyst) in which the aqueous solution (0.25-1.0 $mL.min^{-1}$) circulates concurrently with the hydrogen flow (10-100 $mL.min^{-1}$). The initial concentrations of nitrate and 4-chlorophenol (4-CP) were 100 $mg.L^{-1}$ and 50 $mg.L^{-1}$ respectively.

3 Results and discussion

The successive deposition of the palladium and copper on the anionic resin, as described

previously, resulted in peripheral distribution of the both active phase components (Fig. 1). The similar distribution of copper and palladium revealed by the SEM-EDX analysis, confirm the deposition of the second metal by a controlled surface reaction.



(a) (b) (c)

Figure 1. Micro-photos of Pd-Cu/A-520E (a) and SEM EDX images of Pd (b) and Cu (c) distribution on support

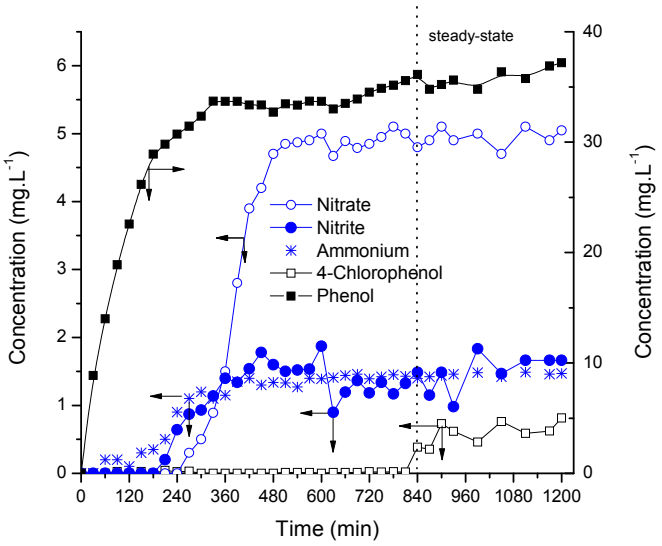


Figure 2. Catalytic performance of Pd-Cu/A-520E for simultaneous removal of nitrate and 4-CF

Firstly, the catalysts were tested in the reduction of NO_3^-. At the beginning the nitrate was eliminated by ion exchange and catalytic reduction. When the steady-state was attained, depending on operational parameters, the conversion of nitrate could reaches 95%, with 93% selectivity on N_2. The hydrodechlorination of 4-CP in the presence of nitrate was almost complete (conversion higher than 98%) while removal of nitrate was maintained at the same level of conversion with only a very small decrease in selectivity (Fig. 2).

The stability of the catalyst was assessed by determining the amount of palladium and copper in the used catalyst (100 h test) compared to the fresh one. The Pd load decreased insignificant (less than 0.015%). The cooper leaching was higher but not exceeding 0.50% of the initial amount.

4 Conclusions

A Pd-Cu catalyst supported on strong base anion resin was prepared by successive deposition of the metals (ion exchange for Pd and controlled surface reaction for Cu). The as-synthesized catalyst exhibited high catalytic activity in the simultaneous selective reduction of nitrate to nitrogen and hydrochlorination of 4-CP to phenol, attended by a good stability.

Structured Cartridges with Glass-fiber Catalysts: New Trend in the Design of Catalytic Reactors for Pollution Control

Lopatin S.A.[1,2], Zazhigalov S.V.[1,2], Mikenin P.E.[1,2], Pisarev D.A.[1,2], Baranov D.V.[1,2,3], Zagoruiko A.N.[1,2,4*]

Keywords: glass-fiber catalyst, pressure, drop, mass transfer, reactor design

1 Introduction

Development of the new and improvement of existing heterogeneous catalytic processes for pollution control is an actual task of great practical importance. One of the possible paths for the progress in this area is development and application of new geometrical forms of catalysts, characterized with low pressure drop and, simultaneously, with high heat and mass transfer efficiency, thus providing the maximum use of the catalytic potential of its active components. Many various new forms of catalysts, e.g. wire mesh catalysts, foam catalysts, micro-fibrous catalysts are currently discussed [1].

One of the promising directions of development in this area includes application of the catalysts on the base of the flexible micro-fibrous supports, e.g., glass fibers. Glass-fiber catalyst (GFC) is a new type of catalytic systems, where the support represents itself the glass microfibers, structured in form of threads in the woven or knitted fabrics. The possible active components may include noble metals and/or oxides of transient metals, depending upon the requirements of the target catalytic process [2,3].

2 Design of catalytic reactors for glass-fiber catalysts

From engineering point of view, the GFCs are specific due to their original geometry and flexibility, opening the unique possibilities for creation of new types of structured catalytic beds [4,5]. In turn, this makes possible the creation of principally new designs of catalytic reactors.

The numerous methods of GFC layers arrangement were proposed during last two decades [4]. They include flat multi-layer [6], radial [7] and axial [8] structured packings. The most efficient among them are the prismatic structured cartridges, which may be used for creation of the catalyst beds of any size and geometry (Fig.1).

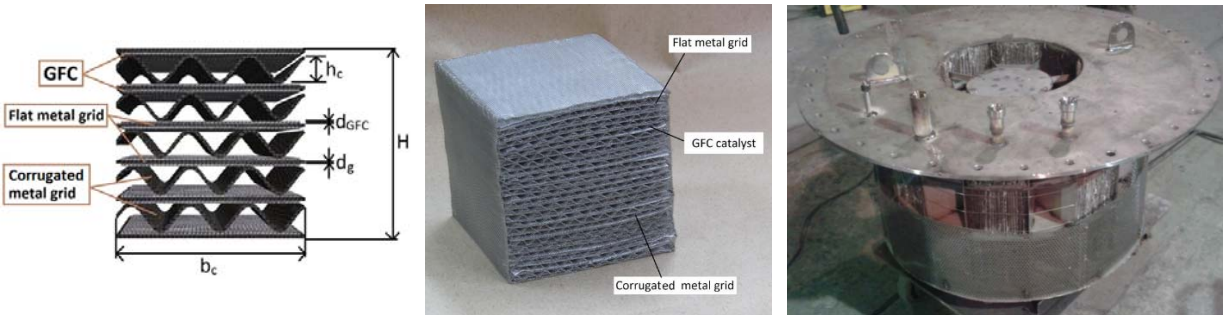

Fig.1. Different designs of axial GFC cartridges: prismatic GFC cartridge (left and center), radial block from prismatic axial cartridges (right).

3 Pressure drop and mass transfer properties of the structured GFC cartridges

Prismatic axial GFC cartridges are characterized with the very low pressure drop [5], slightly exceeding that for the monolith catalyst. At the same time, GFC cartridges are more efficient in terms of mass transfer due to more intensive turbulization of the flow in the cartridge. The mass transfer in packed bed of granulated catalysts is even more intensive, but such beds are characterized with much higher pressure drop. Obviously, the pressure drop and mass transfer are in contradiction and in this case the objective comparison may be based on the relationship between value of the mass transfer coefficient and unit pressure drop. Such relationships for different types of catalysts are plotted in Fig.2 [9].

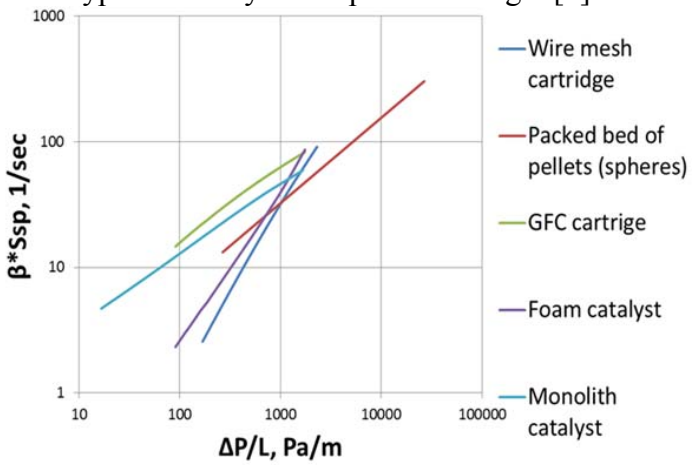

Fig.2. The relationship between mass transfer coefficient and unit pressure drop for different types of catalyst beds under variation equivalent diameter of the gas passage [9].

As seen from Fig.2, GFC cartridges provide the best compromise between high mass exchange and low pressure drop than all other forms of existing catalysts in the wide range of flow velocities and passage sizes, thus highlighting the superb engineering potential of structured fiber-glass catalytic systems.

Such cartridges may find the wide application in the pollution control processes, where the intensive mass transfer is important for the overall process efficiency.

Catalysts on the Base of Ceramic Highly-Porous Block-Cellular Carriers

Gasparyan M.D., Liberman E.Yu., Grunsky V.N.*, Obukhov E.O.

Russian Mendeleev University of Chemical Technology, Moscow, Russia

* migas56@yandex.ru

Keywords: ceramic highly-porous cellular, materials, active layer, catalytic activity

1 Introduction

At the last 20-30 years, a ceramic highly-porous cellular materials (HPCM) or foam ceramics obtained by different technologies of pore formation are widely used as filters for refining metal melts, heat insulation materials, carriers of catalysts and sorbents in metallurgy, chemistry and petrochemistry, transport and nuclear industry.

Small volume catalytic systems based on ceramic HPCM developed in Russian Mendeleev University of Chemical Technology are used in various liquid-phase catalytic processes: nitration of aromatic and reduction of nitrocompounds, hydrorefinement of petroleum products, waste water from nonionic surfactants, as well as in gas-phase environmental catalysis for the conversion of toxic products of burnout of motor fuels and localization of volatile radionuclides in exhaust of special manufactures.

2 Experimental/methodology

Ceramic HPCM with different composition are produced using the slip technology by the method of replication structure of the polymer matrix of polyurethane foam (PUF). The essence of the method is thermodestruction of the polymer matrix impregnated with a ceramic slurry, and subsequent sintering of the components of the slip at high temperature to produce a solid framework that duplicate the original shape of the PUF with the porosity of 10÷80 ppi. Electrocorundum, aluminomagnesium spinel, zirconia, silicium carbide, etc. are used in the slurry as a dispersed phase; as the main binder - fine ground alumina or porcelain mass; sintering and hardening additives are: MgO, TiO_2 and SiC.

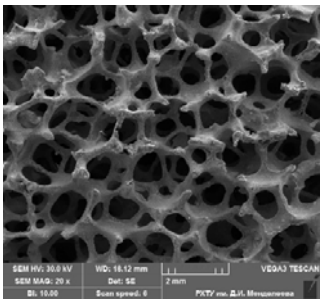
Next, to develop surface, improve the strength characteristics and to make future catalysts specified properties the active substrate is applied on the ceramic frame by the method of successive impregnation and heat treatment. It may contain the following components or their combinations: γ-Al_2O_3, SiO_2, SO_4^{2-}/ZrO_2 (super acid), hydrophilic or hydrophobic zeolites.

The final stage of preparation of catalysts is the application by different methods (impregnation from solutions and suspensions, chemical precipitation) a wide range of catalytically active compositions: from monometallic layers of Ni, Co, Pd, Pt, Cu, Ag etc., or oxides of these metals to compositions of a complex structure of type $Au/Ce_{0,72}Zr_{0.18}Pr_{0.1}O_2$ or $Me_{0,1}Zr_{0,18}Ce_{0,72}O_2$, where Me - rare earth metals.

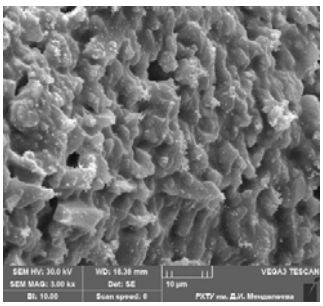
Thus obtained catalysts have the extremely high available external surface (up to 2700 m^2/m^3), low hydro- or gas-dynamic resistance, high specific surface of the active layer (up to 450 m^2/g), high coefficient of external diffusion, a high degree of mixing and dispergation. These characteristics in combination with traditional for ceramics characteristics: high mechanical strength and durability, chemical and thermal stability, the possibility of forming products of any configuration allow to activate mass transfer processes with the high efficiency and load on the catalyst and with high speeds at low concentrations of reacting substances, and also to eliminate abrasion and fly ash of catalyst in the reaction zone.

3 Results and discussion

As an example, characteristics of highly-porous block-cellular catalyst for the oxidation of hydrogen with the palladium active layer applied by chemical precipitation [1] are presented. Figure 1 shows electron micrographs of the sample of catalyst, indicating the formation of the compact palladium coating on the surface of the ceramic frame (Fig.1b), consisting of coarse aggregates with well-developed external surface and a significant amount of micropores. The cellular structure of HPCM after application of palladium remains stable (Fig.1a).



a



b

Fig. 1. SEM micrographs of the sample of ceramic catalyst with applied palladium active layer: a - the frame structure, b - the surface of partition cell

This block catalyst shows the ultra-high catalytic activity in the process of hydrogen oxidation, passing in the kinetic area. The rate constant of the oxidation reaction of hydrogen with the concentration of 600-1500 ppm in the air with a volume flow rate of 0.5-10 m^3/h in the temperature range of 70-150°C reaches the value 130 s^{-1}, and the stable operation of the catalyst starts at a temperature 110°C.

Catalytically active compositions on the base of rare-earth metals, containing, for example, nano-dispersed multi-component solid solution $Pr_{0,1}Zr_{0,18}Ce_{0,72}O_2$ with crystallite size 8-15 nm (Fig.2) have been designed for oxidation of hydrocarbons and carbon monoxide in the exhaust gases of vehicles. Their use allows to achieve 100% conversion of CO and CH at temperatures of 280-300 °C and to minimize the content of precious metals in the catalysts [2].

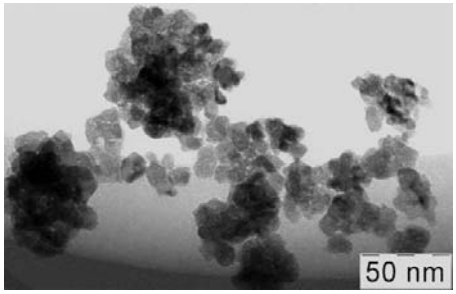


Fig. 2. TEM micrographs of the crystallites $Pr_{0,1}Zr_{0.18}Ce_{0.72}O_2$ in catalyst active layer

4 Conclusions

Applied highly-porous block-cellular catalysts demonstrated the high catalytic activity and specific productivity in a number of processes of catalytic oxidation, reduction, and hydrogenation, exceeding the similar parameters of the bulk and honeycomb catalysts.

The Synthesis Charcterization and Catalytic Performances of Three-Dimensionally Ordered Macroporous x-CeO_2/Al_2O_3 Catalysts for Diesel Soot Combustion

Jin B.F., Wei Y.C., Zhao Z.*, Liu J., Duan A.J.

State Key Laboratory of Heavy Oil Processing, China University of Petroleum, Beijing, China

Keywords: three-dimensionally ordered macroporous, materials, x-CeO_2/Al_2O_3, catalysts soot combustion

1 Introduction

Diesel engine vehicles are a promising power source for light vehicles owing to good power performance and high fuel efficiency[1]. However, the emission of soot particle matter (PM) can cause human carcinogen[2]. Thus, it is crucial to reduce emissions of particulate matter before the wide utilization. The combination of traps and oxidation catalysts in the continuously regenerating particulate trap (CRT) appears to be one of the most efficient and economic after-treatment techniques for diesel engines. This key challenge is to find effective catalysts for soot combustion that operates at low temperature. In our work, a series of three-dimensionally ordered macroporous (3DOM) x-CeO_2/Al_2O_3 catalysts were prepared by the method of micropores-diffused precipitation (MDP) using ammonia solution as the precipitation. These catalysts were estimated for catalytic oxidation of soot. They were characterized by the techniques of SEM, XRD, H2-TPR, and TEM.

2 Experimental

3DOM Al_2O_3 support was prepared via a precursor thermal decomposition-assisted colloidal crystal templating method. The synthesis of 3DOM x-CeO_2/Al_2O_3 catalysts was carried out by the method of micropores-diffused precipitation (MDP) in our lab[3]. Typically, $Ce(NO_3)_3 \cdot 6H_2O$ and distilled water were mixed in a precursor tank (Beaker I). The solution containing ammonia was stored in another tank (Beaker II) as precipitation agent. The precursor solution (Beaker II) was diffused into the membrane reactor via the holes distributed on the wall of the ceramic membrane tubes by a constant flow pump, and the precipitation of Ce^{3+} occurred while meeting precipitation agent in membrane reactor, yielding $Ce(OH)_3$. The slurry mixture was deposited, filtered, dried and calcined. Finally, 3DOM x-CeO_2/Al_2O_3 were obtained.

3 Results and discussion

From XRD patterns (Fig. 1), four main characteristic diffraction peaks of 3DOM x-CeO_2/Al_2O_3 catalyst (x=10-40%) shifted to high angle in comparsion with pure CeO_2 catalyst. The result demonstrates the formation of Al-Ce-O solid solutions. The H_2-TPR profiles (Fig. 2) indicates that the enhancement of the reducibility of supporting ceria prepared by MDP method. SEM (Fig. 3) and TEM (Fig. 4) images exhibit a well-defined three-dimensional ordered macroporous structures. The long-range order of the inverse opals remain. The structure is favorable for the mass tranfer because of their connectivity.The values of T_{10}, T_{50} and T_{90} for soot combustion over catalysts under conditions of loose contact between soot and catalyst are listed in Tables 1. Compared with pure Al_2O_3, the catalytic activity for soot oxidation is remarkably enhanced after supporting CeO_2 on the surface of 3DOM Al_2O_3 catalysts.

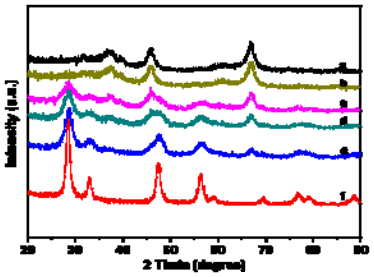

Fig. 1. XRD patterns of the prepared catalysts: (a) Al_2O_3; (b)2%CeO_2/Al_2O_3;(c) 10%CeO_2/Al_2O_3; (d) 20%CeO_2/Al_2O_3 ; (e)40% CeO_2/ Al_2O_3;(f) CeO_2

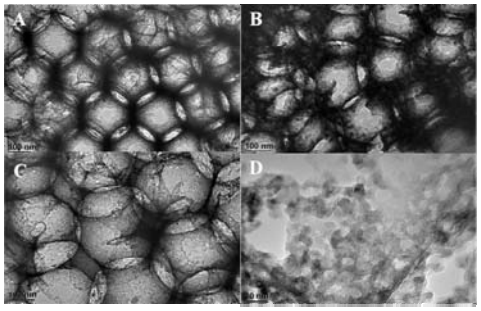

Fig. 4. TEM images of the catalyst samples (A) Al_2O_3; (B) CeO_2; (C)-(D) 40%CeO_2/Al_2O_3;

Table 1. The catalytic performances of 3DOM catalysts for soot combustion.

Catalyst	T_{10}/℃	T_{50}/℃	T_{90}/℃	S_{CO_2}
CeO_2	305	384	425	85.1
40%CeO_2/Al_2O_3	293	379	425	79.6
20%CeO_2/Al_2O_3	291	384	430	73.7
10%CeO_2/Al_2O_3	283	386	436	80.9
2%CeO_2/Al_2O_3	283	408	478	73.5
Al_2O_3	362	530	586	57.5

4 Conclusions

We successfully fabricated 3DOM CeO_2/Al_2O_3 catalysts by micropores-diffused precipitation (MDP) method using ammonia solution as the precipitation agent There exists a synergistic effect between CeO_2 and Al_2O_3, leading to the formation of Al-Ce-O solid solutions. The synergistic effect is crucial to enhancing the catalytic performance.

Are Perovskite Materials Efficient for Tree Way Catalysis? A Theoretical Study of $LaFeO_3$

Paul J.-F., Berrier E.*, Blanck D.

Unité de Catalyse et de Chimie du Solide, Université Lille 1, Villeneuve d'Ascq, France

* dimitri.blanck@ed.univ-lille1.fr

Keywords: de-NOx, $LaFeO_3$, reactivity, DFT, particle, morphology

1 Introduction

Automotive exhaust gas depollution is performed through Tree Way Catalysis (TWC) using supported nanoparticles of platinum-group metals (PGM) metal as catalysts. Because of their price and their availability issues, the reduction of PGM content in catalysts is a key economic and environmental requirement.. While perovskites are used from mid-70 [1] in catalysis as support, this class has attracted a recent interest [2] in the design of active phases with reduced noble metal content. Particularly in TWC, the intrinsic redox capacity of iron makes $LaFeO_3$ (LFO) a good candidate for NO_x reduction and CO oxidation. However, the mechanism of TWC reaction on this noble-metal free catalyst is still lacking. A better understanding of this catalyst is needed to access an improved activity.

2 Methodology

First-principle calculations were performed within the framework of DFT+U[4] using the Vienna Ab-initio Sofware Package VASP[4]-[7]. Pseudopotentials Projected Augmented Wave (PAW)[4] were used. The spin-polarized generalized gradient approximation functional parameterized by Perdew, Burke, and Ernzerhof (GGA-PBE) is used to describe exchange and correlation energies of electrons[8].

3 Results and discussion

The formation energies of several surfaces were first calculated for identifying the relevant LFO surfaces. Accordingly, the LFO (100) and (121) surfaces were found to be the most stable ones, which is in good agreement with experimental data. The particle morphology was thus computed as is shown in Figure 1.

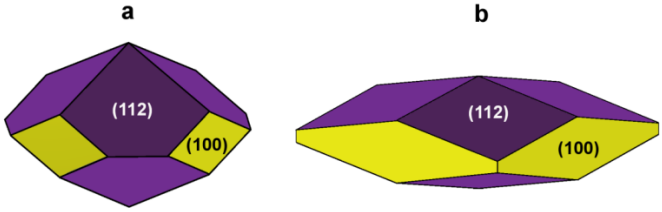

Figure 1. Wulff reconstruction of a LFO crystal in contact (a) with a partial pressure of 0.15bar of H_2O at 300K and (b) in vacuum

The influence of water, which is present in the feed, on the relative stability of LFO surfaces was also investigated. We found that the two most stable surfaces found in vacuum were still the most stable under a partial pressure of water. To be more precise, water adsorption was found to slightly change the shape of the particles but not the nature of the exposed surfaces.
Eventually, we have considered the adsorption and reactivity of target molecules of high relevance for TWC, namely CO and NO on the two most stable surfaces the (100) and (112). The most probable mechanism involves the formation of an oxygen vacancy in a first step

followed by the dissociation of NO on this site. The computed activation energy of the rate-determining step was found to reach 135 kJ.mol^{-1}, as shown in Figure 2.

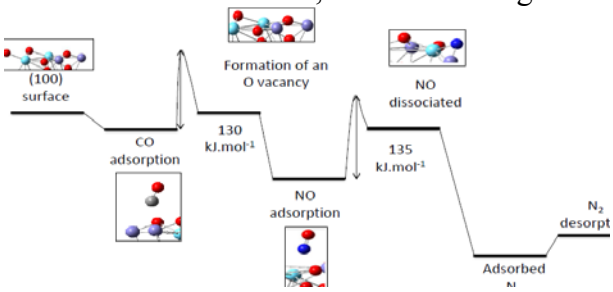

Figure 2. Reactional mechanism proposed for NO dissociation

4 Conclusions

The most stable surfaces of LaFeO3 perovskite are proposed in the present work to be the (112) and the (100) ones. This trend is plausibly generalizable for other III-III perovskite materials. A reactional mechanism for NO reduction has been proposed over these surfaces, featuring a low activation energy (135 kJ.mol-1). NO dissociation is mediated by the formation of an oxygen vacancy. In a second step this vacancy is regenerated by NO. This mechanism is similar to a Mars Van Krevelen mechanism typical for oxide materials.

Soot Oxidation on Manganese Oxide Catalysts in Diesel and Gasoline Exhaust

Wagloehner S., Nitzer-Noski M., Kureti S.*

Technical University of Freiberg, Institute of Energy Process Engineering and Chemical Engineering, Chair of Reaction Engineering, Freiberg, Germany

* kureti@iec.tu-freiberg.de

Keywords: soot oxidation, manganese, oxide, diesel exhaust, gasoline exhaust

1 Introduction

Diesel engines and gasoline engines with direct fuel injection represent very effective combustion motors. However, a critical issue is the output of harmful soot particles, which are carcinogenic and contribute to the greenhouse effect. For the abatement of soot, particulate filters are widely employed, particularly for diesel engines. Particulate filters operate in the wall flow mode including the mechanical deposition of soot onto the porous filter walls. But, as a result of soot filtration, the loaded filter can cause backpressure potentially decreasing the engine efficiency. Hence, a regeneration step is mandatory to remove the soot deposits from the filter. Catalytically coated particulate filters aiming the activation of the soot/O_2 reaction are developed since many years. However, their efficiency is related to tight proximity of soot and catalyst, whereas under practical conditions loose contact mostly predominates. Thus, the soot oxidation catalysts known so far exhibit rather limited benefit in real driving scenarios [1, 2]. To overcome this issue our paper addresses the development of novel highly active manganese oxide catalysts for the regeneration of diesel as well as gasoline particulate filters.

2 Experimental

A series of bare manganese oxide samples was evaluated towards their soot oxidation activity in synthetic diesel and gasoline model exhaust. The catalysts were thoroughly haracterized by powder X-ray diffraction (XRD), N_2 physisorption, scanning electron microscopy, temperature programmed reduction by H_2 and temperature programmed desorption of NH_3. For the catalytic tests performed by temperature programmed oxidation (TPO) tight contact catalyst/soot powder mixtures were taken, while a home-made soot originated from C_3H_6 combustion was employed. Additionally, for practical assessment, the best catalyst was coated onto a laboratory-scaled particulate filter followed by soot deposition and catalytic testing.

Furthermore, the transfer of oxygen from the gas-phase to soot was investigated by TPO with $^{18}O_2$. After this isotopic TPO, a HTPR was performed to quantify the accumulation of ^{18}O in the catalyst.

3 Results and discussion

As a result of the TPO tests, Mn_3O_4 prepared by flame spray pyrolysis (FSP) was identified as the best catalyst tested providing soot combustion already at 300°C under diesel and gasoline exhaust conditions (Fig. 1). The correlation of physical-chemical characteristics of the catalysts with their soot oxidation kinetics showed that the number of surface oxygen vacancies and particle size determine the catalytic performance by affecting the supply of oxygen. These results substantiate the high efficiency of the Mn_3O_4 obtained from FSP.

Additionally, clear enhancement of soot oxidation was observed when performing tests with the laboratory-scaled particulate filter coated by the FSP-Mn_3O_4 catalyst. Moreover, the FSP-

Mn_3O_4 catalyst revealed high thermal stability. After hydrothermal exposure at 750°C and thermal treatment at 1050°C its activity did not alter significantly in the TPO tests carried out with the catalyst/soot powder blends [3].

The isotopic TPO studies of FSP-Mn_3O_4/soot suggested that oxygen was transferred from the surface and bulk of the catalyst to the soot by physical contact points. A strong contribution of bulk oxygen (ca. 60%) occurred for tight as well as loose contact. The role of gas-phase O_2 was found to refill the oxygen vacancies of the catalyst [3].

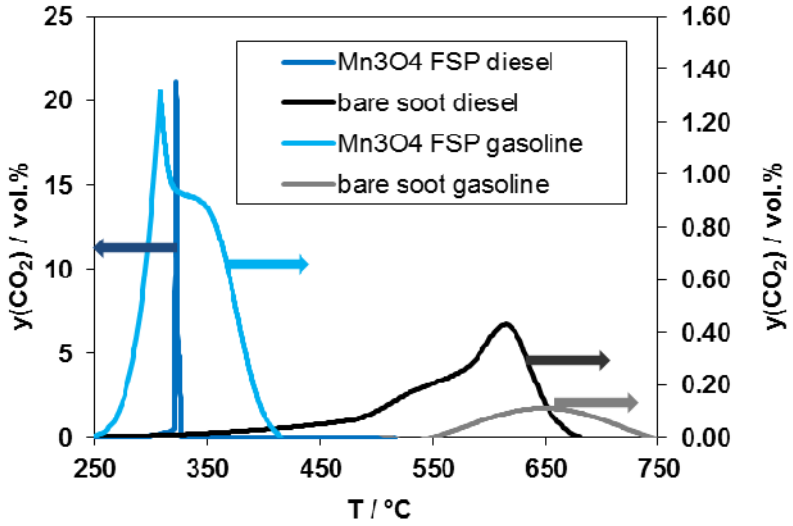

Figure 1: TPO study with bare soot as well as tight contact mixtures of soot with FSP-Mn_3O_4 under diesel and gasoline exhaust conditions. m(soot) = 0.12 g, m(cat.) = 0.96 g; gasoline conditions: $y(O_2)$ = 1%, $y(H_2O)$ = 2%, N_2 balance; diesel conditions: $y(O_2)$ = 10%, N_2 balance [3].

4 Conclusions

We evaluated bare manganese oxide catalysts for the oxidation of soot. The best catalyst was the FSP-Mn_3O_4 sample implying high activity in diesel as well as gasoline model exhaust. Additionally, FSP-Mn_3O_4 only slightly changed its performance after hydrothermal and thermal exposure.

The correlation of the physical-chemical properties and the soot oxidation activity of the catalysts showed that high amount of surface oxygen vacancies and small particle sizes are crucial for the oxidation of soot. These findings coincide with the mechanistic studies of FSP-Mn_3O_4/soot suggesting that the supply of oxygen occurs from the gas-phase and catalyst bulk via the surface of the catalyst to the contact points of the soot. The contribution of the bulk is very pronounced indicating strong mobility of inner oxygen, particularly when comparing with other catalysts, e.g. iron oxides.

Moreover, the test of a laboratory-scaled DPF coated with FSP-Mn_3O_4 indicates soot oxidation activity below 350°C indicating the potential for continuous soot conversion in real exhaust.

Keywords: CWO, mineralization, purification, MnOx catalyst, heterogeneous catalysts

1 Introduction

The increasing alarm on environmental issues is drawing worldwide a great scientific and technological concern on the development of new purification technologies. In the specific case of water, this would enable extensive reclaim and/or recycle of civil and industrial wastewaters to reduce the overall water consumption [1-9]. In fact, the disposal of wastewater streams containing toxic and/or recalcitrant pollutants requires proper decontamination treatments to accomplish the even stricter regulations. Among the various technologies, involving the exploitation of biological, physical or chemical treatments, proposed during last decades, Catalytic Wet Air Oxidation (CWAO) processes is the most versatile one, ensuring very large operative ranges both in terms of rate and organic load [1,3]. Metal leaching, active radical generation, catalyst deactivation, pollutants chemistry, and reaction conditions still representing the main obstacle of the process scale-up, the discovery/improvement of cheap, robust and active catalyst would represent the main challenge of heterogeneous CWAO technology [1-11].

Co-precipitated catalysts, employed in previous works, allowed us to determine the mechanism and main requirements for a CWAO catalyst; notably, structural, morphological and redox properties of the active phase altogether determine the CWAO efficiency of the system [2,10-13]. Improving surface exposure and redox pattern, by a proper tuning of the structure and dispersion of the active phase, is a benchmark for enhancing the performance of the $MnCeO_x$ system. Then, we developed a new class of MnO_x catalysts dispersed on CeO_2 by a new preparation method to better control the oxidation state of manganese and the "oxide-support" interaction, enhancing the synergistic effect of ceria on the MnO_x redox features [12-15].

2 Experimental

$MnCeO_x$ catalysts with Mn/Ce atomic ratio between 0.3 and 3.0 were synthesized *via* the novel *redox-precipitation* method [12], while a reference sample was prepared *via* the classic co-precipitation route [2,10-12]. Solids were dried at 373K (16h) and further calcined in air at 673K (6h). The list of the catalysts used in this work is reported in Table 1.

Samples were characterized by XRF, XPS, N_2-physical adsorption, XRD and TPR techniques, while the "used" catalysts were probed by TGA measurements. The testing in the CWAO of various model polluting substrates has been performed at 423K in a batch reactor fed by a continuous O_2 flow. Substrate and total organic carbon (TOC) conversion, and CO_2 formation were monitored by HPLC, TOC, and gravimetric analyses, respectively.

3 Results and discussion

Surface area values of redox catalysts sensibly higher than co-precipitated one evidence at

once strong improvement of the main requirements of CWAO catalyst (Table 1). XRD data evidence two very broad peaks spanned in the ranges of 20-38° and 40-60°, respectively, for all the "redox-precipitated" systems, indicating a prevalently amorphous arrangement [12-15], while the co-precipitated sample shows some resolved peaks of the cerianite and pirolusite phases [12-15]. CO-TPR measurements show that the peculiar structure of redox-precipitated systems reflects in significantly lower temperature of onset reduction and peak maximum than co-precipitated one [12-15].

Catalytic tests in the CWAO of phenol show that a Mn/Ce atomic ratio of 1 is the optimal catalyst composition, ensuring at 150°C and 1.5 MPa a complete phenol removal in ca. 10 min and a CO_2 production corresponding to a mineralization extent of 80% (6h) [4-7]. Acetic acid is the most refractory substrate, attaining total removal only after 2 hours, according to the fact that this is the most stable by-product formed during the CWAO of heavy organic compounds [1-7].

TGA analyses of the used samples well match with CO_2 selectivity for a satisfactory C-mass balance, and confirm that the pollutants are firstly removed by adsorption on the catalyst surface and, then, slowly (*r.d.s.*) oxidized to CO_2 [2,4-7].

Table 1. List of the studied catalysts and their main performances in the CWAO of phenol.

Catalyst	$(Mn/Ce)_{at}$[a]	SA_{BET} ($m^2 \cdot g^{-1}$)	t_{Conv}[b] min	S_{CO2} %
M1C3	0.34	168	60	45
M1C2	0.47	161	30	62
M1C1	0.98	154	10	80
M2C1	2.12	140	18	74
M3C1	2.76	114	30	68
M1C1-P	1.00	101	60	35

[a] From XRF analyses
[b] Time of 100% phenol conversion at 150°C

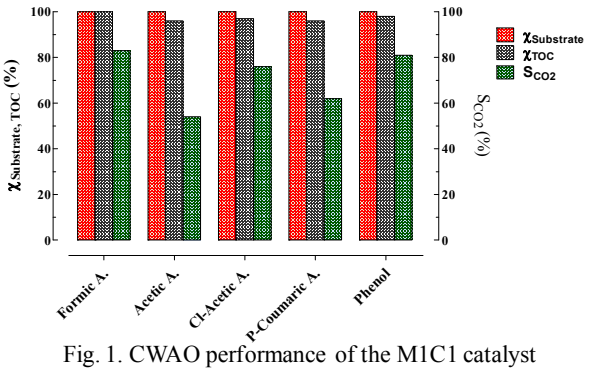

Fig. 1. CWAO performance of the M1C1 catalyst on different substrates.

4 Conclusions

CWAO tests confirm the high activity of $MnCeO_x$ catalysts for the liquid-phase mineralization of different organic recalcitrant compounds. The "redox-precipitated" catalysts show better performances than co-precipitated ones at any Mn/Ce atomic ratio, worthy of potential industrial exploitation.

Keywords: manganese, calcium, oxide, hydroxyapatite, catalytic oxidation, VOC

1 Introduction

The research of new catalytic materials requires available cheap and non-toxic components. Phyllomanganates such as birnessite, buserite and related phases are amongst the strongest known natural oxidants and Mn is an easily reducible/oxidable element. Hence such materials represent an efficient class of catalysts for total oxidation of volatile organic compounds. Among them well dispersed Ca manganese oxides have not been studied so far. A new and original synthetic pathway may involve hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$ (HAP) which is a safe and non-toxic material [1]. HAP can play both the role of a catalyst support and a Ca supplier agent to get Ca manganese oxide phases. Indeed HAP is recognized for its ability to easily exchange calcium ions exposed on the surface at site I (coordinated by 9 oxygen ions) and site II (coordinated by five oxygen ions and one hydroxyl group). A previous work reported on efficient Mn-HAP catalysts for direct imine formation by oxidative coupling of alcohols and amines but mainly focused on the acido-basic properties of the catalyst [2]. Pioneering work in this field aiming to dope HAP with a Cu active phase has been very recently reported [3]. The hypothesis of 5 possible sites for Cu location has been proposed on the features of HAP structure and experimental results. Additionally it was found that the Cu location and species can be adjusted owing to the method of preparation.

In the present work, the wet impregnation has been adopted to disperse 10 Mn wt% species on HAP. The main challenging task is to be able to determine the location and nature of Mn species taking into account that HAP flexible structure offers a wide range of possible cationic as well as anionic substitutions.

2 Experimental/methodology

The reference Al support supplied by Alfa Aesar (gamma-Al_2O_3, purity: 99.97%; S_{BET} = 72 m^2/g) was used as received. The HAP was synthesized from a previous experimental procedure [1]; the Ca/P was found to be 1.60 (elementary analysis) and the S_{BET} was 94 m^2/g. Mn was added to the supports by wet impregnation using $Mn(NO_3)_2.4H_2O$ from Sigma Aldrich. The resulting powders were calcined at 400°C for 4h to get Mn-Al and Mn-HAP samples.

Numerous techniques of characterization such as XRD, Raman spectroscopy, BET, SEM, H_2-TPR, O_2-TPD experiments, XPS and ToF-SIMS have been used to identify the Mn species and its location in Mn-HAP. Catalytic total oxidation of toluene in air was studied and the catalytic performance of Mn-HAP was compared with those of Mn-Al.

3 Results and discussion

XRD analyses only show the characteristic peaks of HAP for Mn-HAP while it is found the presence of the pyrolusite phase beta-MnO_2 (PDF n°24-0735) along with phases of gamma-

Al_2O_3 (PDF n°10-0425) and AlO(OH) (PDF n°83-1505) in the Mn-Al sample. The non-observance of related Mn oxide phases over the surface indicates amorphous or/and well dispersed Mn oxides. Laser Raman spectra are characterized by 3 weak peaks at 505, 550 and 630 cm^{-1}. These features are very similar to those reported for related Mn layered oxides such as birnessite-pristine type materials [4].

Investigation by XPS of the Mn $2p_{3/2}$ core level having an apparent maximum at a binding energy of 642.4 eV well agrees with a Mn^{4+} oxidation state. ToF-SIMS measurements performed in static conditions clearly identify $Ca_xMn_yO_z^+$ ions of significant intensity such as $CaMnO_2^+$, $Ca_2MnO_3^+$ and $Ca_2MnO_2^+$ ions (Fig.1). The detection of such ions supports the existence of some Ca-Mn oxides at the outermost layers of the catalyst in agreement with layered oxide structures (birnessite-pristine) suggested by Raman study.

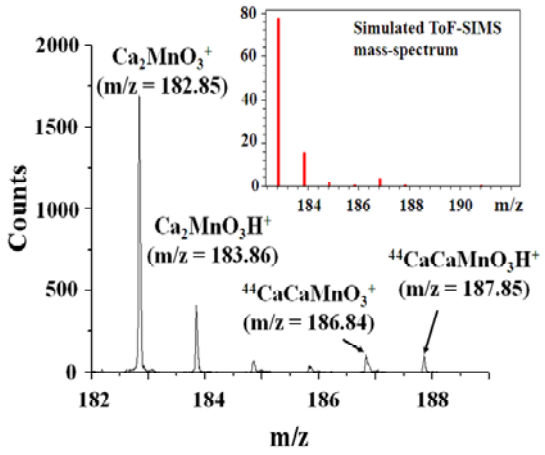

Fig. 1. ToF-SIMS mass spectrum of Mn-HAP m/z: 182-189 range.

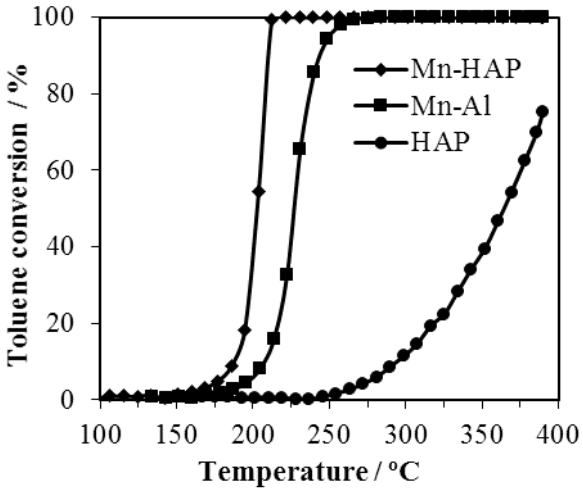

Fig. 2. Toluene conversion over the catalysts (800 ppmv toluene in air)

Hence the lower Mn average oxidation state values obtained from H_2-TPR and O_2-TPD experiments, of 3.3 and 3.5 respectively, suggests the substitution of some Ca^{2+} from surface and bulk sites of HAP by Mn^{2+} ions. The toluene conversion in function of temperature is given over the different catalysts (Fig.2). The specific activity based on T_{50} (°C) decreases as follows: HAP (365) < Mn-Al (227) < Mn-HAP (203). The best activity achieved on Mn-HAP can be rationalized by the formation of well dispersed/amorphous high valence Mn phases partially in interaction with Ca^{2+} expelled from the HAP channels on the support.

4 Conclusions

HAP has been shown to be a Ca^{2+} supplier agent to get partially well dispersed/amorphous Ca-Mn oxide phases on HAP. This catalyst is an efficient catalyst for toluene total oxidation.

Keywords: DFT, kinetic Monte Carlo, charge transfer, metal-oxide, support effects, poisoning

1 Introduction

The CO oxidation reaction is of key importance in the development of catalytic converters for emissions control. Gold has attracted significant attention in this context since the late 80's, after experimental evidence by Haruta and co-workers suggested that Au, while inert in bulk, exhibits high activity at the nanoscale [1]. Despite the intense research on Au-catalysed CO oxidation during the past 30 years, the underlying reaction mechanisms are still debated [2], and it is difficult to decouple the effects of support versus particle size/morphology. An emerging consensus is that under-coordinated Au sites are active towards CO oxidation. Yet, the experimentally observed magic number activity of Au nanoclusters supported on defective MgO contradicts this consensus [3]. For instance, Au_6 appears as almost inert towards CO oxidation, Au_8 is highly active and Au_{10} exhibits lower activity than Au_8. Motivated by this complexity, we employ first-principles-based kinetic modelling to elucidate the physico-chemical phenomena that give rise to the magic number activity. We discover that various factors determine the CO oxidation activity of sub-nanometer Au, in particular: charge transfer, size and shape effects, reconstruction, adsorbate binding configurations, and cluster poisoning by carbonate.

2 Methodology

We first investigated the electronic and structural properties of MgO-supported Au_6, Au_8 and Au_{10}, using the Becke-Perdew86 (BP86) functional, the resolution of the identity approximation and the sv(p) basis set implemented in Turbomole 6.5. For each cluster, we considered three different cases for the support: defect-free, with an O-vacancy, and with a Mg-vacancy. We then isolated the cluster from the MgO support maintaining its structure and charge state, and investigated the CO oxidation pathways on the different sites at the B3LYP/LANL2DZ level, using Gaussian 09. The data from these calculations served as input to *Zacros* (http://zacros.org), our graph-theoretical kinetic Monte Carlo (KMC) simulation package [4, 5]. This input consists of a lattice structure, an energetics model, a reaction mechanism, and the conditions of the simulation along with controls such as the frequency of sampling and reporting. We explicitly modelled the top and bridge sites of the clusters, and the binding of multi-dentate species, such as carbonate. Strong repulsive interactions between O_2 adsorbates were accounted for, since the first-principles calculations showed that at most one oxygen molecule can bind to any of these clusters. More details are presented in [6] and [7].

3 Results and discussion

Au nanoclusters of up to 13 atoms in size exhibit planar geometries. When supported on MgO with O vacancies, they exhibit negative charges close to one electron. Clusters supported on a perfect MgO appear as almost neutral (slightly negatively charged). Mg-vacancies result in

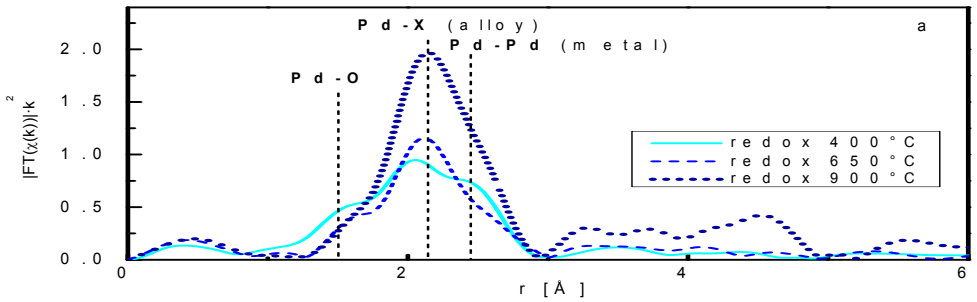

Fig. 1. Average number of CO_2 molecules produced per site in an ensemble of 100 Au_6^- clusters (a). After exhibiting some transient activity Au_6^- is poisoned. The turnover frequencies (TOF) are noted. Ensembles of 10 clusters for Au_8^- (b) and Au_{10}^- (c) exhibit stable activity, with Au_8^- having higher TOF.

positively charged clusters. It was found that only the negatively charged clusters could bind O_2, so we studied the CO oxidation steps ($CO^* + O_2^* \rightarrow CO_2 + O^*$, $CO^* + O^* \rightarrow CO_2$) on Au_6^-, Au_8^- and Au_{10}^-, considering every possible adsorption configuration of CO and O_2. Consequently, our KMC models incorporate approximately 160 elementary steps (adsorption, reaction, diffusion, and desorption). By simulating ensembles of Au nanoclusters for each of the three structures, we obtained estimates of the turnover frequency and provided possible explanations for the experimentally observed magic number activity. Au_6^- was found to exhibit transient activity, followed by carbonate formation which leads to the eventual poisoning of the nanocluster (Fig. 1a). A cluster "breathing" mode was critical in carbonate formation, highlighting the importance of accounting for such reconstruction mechanisms. Both Au_8^- and Au_{10}^- are catalytically active, with Au_8^- exhibiting noticeably higher activity than Au_{10}^- (Fig. 1b, c). The rate determining step (RDS) on Au_{10}^- is the tilting of bidentate O_2 to an active monodentate binding configuration. On Au_8^-, the reaction proceeds via a 4-centre intermediate, whose decomposition is the RDS.

4 Conclusions

Using first-principles kinetic modelling we investigated the CO oxidation behaviour of sub-nanometre Au catalysts consisting of a few metal atoms, unravelling a high degree of complexity in the catalytic behaviour thereof, and elucidating competing physicochemical phenomena that result in the experimentally observed "magic number" activity. Catalysis at the sub-nanoscale, despite being attractive due to the atomic-level precision of the catalysts and its often unprecedented performance, remains an empirical field. Simulations, such as ours, can significantly advance our understanding and lead to better catalysts and processes.

Keywords: design of Cu-Mn/alumina catalysts, gold catalysts, Ag, CO and VOCs oxidation

1 Introduction

The catalytic oxidation of CO and volatile organic compounds (VOCs) has high importance in the field of environmental protection and sustainable chemistry. These catalytic processes have been considered as some of the most efficient ways to reduce harmful emissions from various chemical industries. The design of new catalytic formulations with improved efficiency in the removal of air pollutants is an attractive topic because of the great variety of VOC molecules. Various systems based on transition metal oxides have been reported as efficient catalysts in the oxidation of VOCs. Among the transition metal oxides catalysts, copper and manganese oxides have been considered as some of the most active and promising catalysts for the combustion of VOCs. During the past two decades gold-based catalysts have been proven to be effective for many reactions of environmental significance [1]. The results of our recent study of Au/CeO_2 catalysts for catalytic abatement of VOCs and CO in waste gases motivated present work. The aim was to develop cost-effective and catalytically efficient formulations by promotion of alumina supported Cu-Mn mixed oxides with Au or Ag. The role of Au or Ag on the structural and catalytic properties of $Cu\text{-}Mn/Al_2O_3$ catalysts for simultaneous elimination of different type air pollutants – CH_3OH, $(CH_3)_2O$ and CO in waste gases from formaldehyde production, as well benzene as representative of aromatic hydrocarbons, was examine in detail.

2 Experimental/methodology

A series of mixed oxides of Cu and Mn with different Cu/Mn ratio were prepared by wet impregnation of γ-alumina (0.6-1.0 mm grain size). Prior to the impregnation, the carrier was calcined for 2 hours at 500 ^oC in a ceramic furnace. The impregnated samples were calcined at 450 ^oC. The total amount of transition metal oxides phase was 20 wt. %. Gold and silver-containing (2wt. %) catalysts were synthesized by deposition-precipitation at 60 ^oC and pH 7.0 and 9.0, respectively. After filtering and careful washing, the precursors were dried at 80 °C and calcined in air at 400 °C for 2 h. Catalysts were characterized by means of BET, XRD, HRTEM, TG/DTA, TPR and EPR spectroscopy. The catalytic activity of the samples was measured using continuous flow equipment with fixed bed stainless steel reactor at atmospheric pressure.

3 Results and discussion

The results of the catalytic activity measurements over alumina supported Cu-Mn catalysts showed that the sample with ratio Cu:Mn = 2:1 demonstrated the best performance in the oxidation of CO and MeOH, whiles the sample with ratio Cu:Mn = 1:5 was more active in the combustion of $(CH_3)_2O$. The sample Cu:Mn = 2:1 exhibited also slightly higher activity than Cu:Mn = 1:5 for complete benzene oxidation (CBO) in the whole temperature range. The

highest difference (91 and 82 % conversion, respectively) was registered at 300 °C.

The promotion of Cu:Mn = 2:1 by Au caused improvement of catalytic activity toward oxidation of CO and MeOH. The strongest effect was observed on the CO oxidation activity (Fig. 1A). The addition of gold influenced also MeOH oxidation activity, especially in the low temperature range (Fig. 1 B). In contrast, Au promotion did not affect $(CH_3)_2O$ oxidation (Fig. 1 C). The deposition of Ag affected beneficially MeOH oxidation activity of Cu-Mn mixed oxides (Fig. 1 B), slightly CO oxidation (Fig. 1 A) and negatively $(CH_3)_2O$ oxidation (Fig. 1 C). A slight improvement of CBO over Au/Cu-Mn and Ag/Cu-Mn samples was achieved.

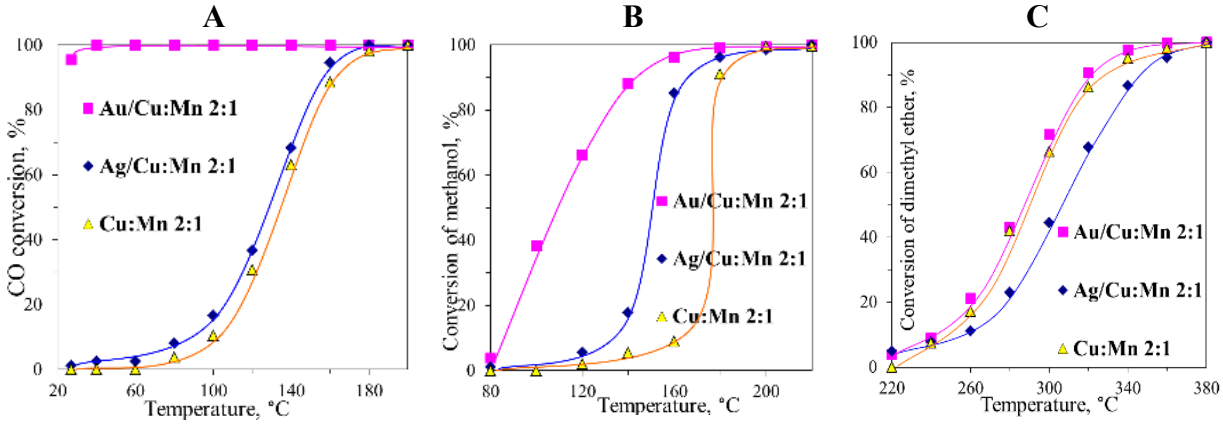

Fig. 1. Catalytic activity in oxidation of CO (A), MeOH (B) and DME (C) over studied samples.

The diffraction lines of γ-Al_2O_3 were clearly identified in the XRD patterns of all samples. Additionally, the lines of CuO were registered. However, the presence of a highly dispersed Cu-Mn spinel phase with a relatively small crystallite size could be suggested. There were no diffraction peaks assignable to Au or Ag. Detailed TEM investigations (SAED, HRTEM and XEDS) revealed that all components are homogeneously distributed on the support crystals. Crystallographic phase's identification will be carried out by measuring the distances among the diffraction fringes in order to extend XRD observations. The comparison of TPR profiles indicated that deposition of Au altered the complex shape of the peak, registered for Cu-Mn support and improves its reducibility. The addition of Ag caused only slight effect on the reduction behaviour. EPR spectroscopic measurement indicated that the spectrum of alumina supported Cu-Mn sample consisted of a signal with g_{II} = 2.3572 и $g_{\perp}$= 2.1025 due to distorted octahedral coordinated Cu^{2+} ions. The presence of resolved hyperfine splitting in parallel region suggested the existence of isolated Cu^{2+} ions on the support. The shape of the EPR spectrum remained the same after Au and Ag deposition, but the intensity of EPR signal decreased due to the trapping of electrons in Cu^{2+} sites, indicating formation of EPR silent Cu^{+} sites.

4 Conclusions

Deposition of nanosized Au particles on alumina supported Cu-Mn oxides enhances significantly CO and MeOH oxidation activity. Promotion by Ag improves only performance in MeOH oxidation. In-depth analysis of XRD, TEM, H_2-TPR and EPR data will be performed in order to clarify the relationship between improved catalytic behaviour and structural features.

Change in the Chemical Composition of an LNT as a Result of its Ageing in Diesel Exhaust Gases: Physical and Chemical Analysis

Dubkov A.A.[1,2*], Carberry B.[2], Schneider M.[2], Linzen F.[2], Smirnov M.Yu.[1], Kalinkin A.V.[1], Salanov A.N.[1], Shmakov A.N.[1], Gerasimov E.U.[1], Bukhtiyarov V.I.[1,3]

Keywords: LNT, deactivation, characterization, XPS, SI-XRD, poisoning

1 Introduction

Use of NOx storage/reduction catalysts (NSR, LNT) is recognized to be one of the efficient methods of removal of nitrogen oxides (NO_x) from diesel exhaust gases. On these catalysts, absorption and subsequent reduction of NOx is taking place. Under lean (normal for diesel engines operation) conditions, nitrogen oxides are absorbed by Ba-components (BaO, $Ba(OH)_2$, $BaCO_3$) of the NSR catalyst, as Ba nitrite and/or nitrate. Then, under rich conditions (artificially created by using special regimes of diesel fuel combustion), these nitrites/nitrates are being reduced to elemental nitrogen. Besides legislative components of the diesel exhaust gases that have to be neutralized (carbon monoxide, hydrocarbons, nitrogen oxides and soot), diesel exhaust gases, in particular, also contain S- and P-compounds, that cause LNT poisoning. Present work is focused on investigation of a nature of the compounds formed in NSR catalyst during its ageing in exhaust of the diesel engine operating under realistic NOx aftertreatment protocol.

2 Experimental

To prepare samples of fresh and aged LNT catalyst, pieces of the same size were cut from the same locations (~ 1.5 cm from the catalyst inlet) of fresh and aged LNT bricks. In the initial (fresh) state, main wash-coat components were Pt, γ-Al_2O_3, $BaCO_3$ and Ce-Zr mixed oxide. Characterization of the samples was performed using XPS (SPECS (Germany) working on MgKα 1253.6 eV irradiation), SEM, XRD with synchrotronic irradiation (SI station in Nuclear Physics Institute, Novosibirsk, Russia), TEM using JEM-2010 machine (Japan), with cell resolution of 0.14 nm, acceleration voltage of 200 kV. XPS spectra were obtained from 2 types of samples: (1) Plates of the monolith catalyst that were carefully cut along the catalyst channels, to represent untouched washcoat in the catalyst channels, and (2) Wash-coat that was carefully scrubbed from the brick substrate and mechanically powdered. Samples for SEM investigation represented a cube of 1×1×1 cm^3. In these samples, channels were filled with epoxy resin, and the plane, which is perpendicular to the channels, was polished. XRD investigations were carried out with plate samples, while TEM studies were performed using powdered samples.

3 Results and discussion

It was found using XPS method, that with progressing into aging of the NSR catalyst, it is accumulating the following impurities: sulfur in form of sulfates, phosphorus in form of phosphates, and Ca and Zn in oxidation state (2+). Moreover, S was found both in plated and in powdered samples, while P, Ca and Zn were found only in plated samples (Fig. 1).

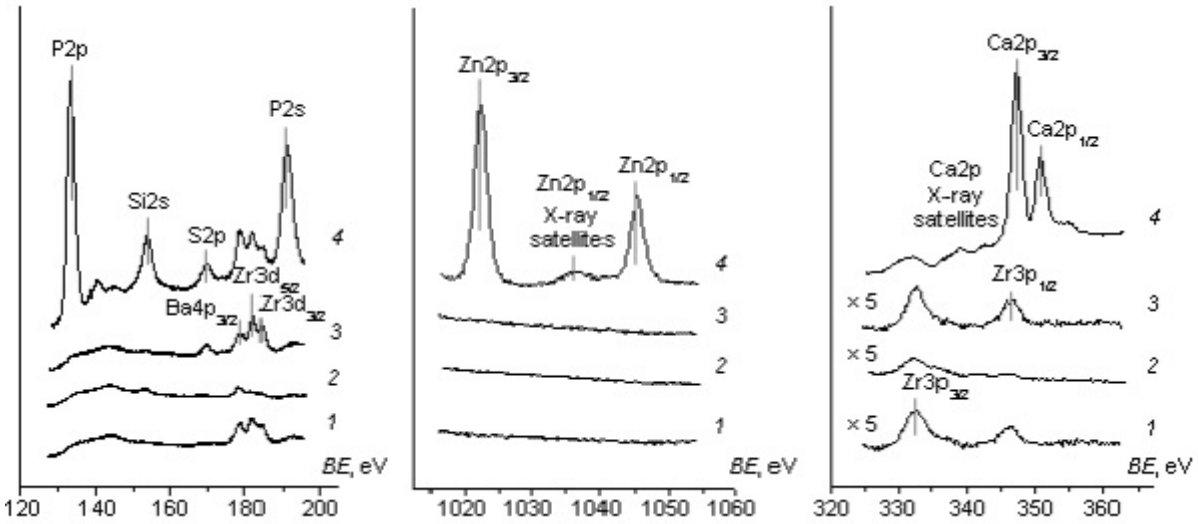

Fig.1. XP spectra of powdered (*1*, *3*) and plated (*2*, *4*) specimens of fresh (*1*, *2*) and aged (*3*, *4*) catalyst, showing accumulation of the impurities (S, P, Ca, Zn) in aged sample.

This means that S is distributed over the whole thickness of the wash-coat layer, while P, Ca и Zn are concentrated only in the very surface layer that is in contact with the exhaust gas flow. Distribution maps of the elements in the cross-section of the wash-coat layer (elemental maps) built based on the SEM measurements, confirm that in aged samples sulfur is distributed over the whole wash-coat layer.

New surface phases appearing in the NSR catalyst during and as a result of ageing and associated with S and P were identified using SI-XRD method. These phases were found to be barium sulfate ($BaSO_4$) and cerium phosphate ($CePO_4$). In aged sample, crystallites of barium sulfate were detected also using TEM method.

4 Conclusions

Using a number of physical and chemical methods, it was found that during the LNT catalyst ageing under real diesel exhaust conditions, accumulating of the impurities such as S, P, Ca and Zn is taking place. Sulfur is being distributed over the whole thickness of the wash-coat layer, while phosphorus, calcium and zinc are being concentrated in the thin sub-surface layer of the wash-coat. Sulfur was found to be bonded into barium sulfate, while phosphorus – into cerium phosphate.

Keywords: hydrogen sulphide, catalyst, oil-associated gas

1 Introduction

More than 40 % or > $70*10^{12}$ nm^3 of the world's hydrocarbon gas reserves are hydrogen sulphide containing natural and oil-associated gases [1]. This feedstock is a significant potential resource for energetics and chemical synthesis. However, high content of hydrogen sulphide (1-30 vol.%) excludes direct application of these gases as fuels or raw materials for downstream production. The currently used flame combustion of such gases leads to air pollution with toxic sulfur di- and trioxides, sulfuric acid, products of incomplete combustion of hydrocarbons, and carcinogenic soot, amount of which attains one million tons a year. Thus, the development of the technical solutions for reliable on-site purification of these gases is a problem of the highest priority for the Russian Federation and the whole world.

2 Experimental/methodology

Technology of direct selective oxidation of hydrogen sulphide

In the Laboratory of Environmental Catalysis of the Boreskov Institute of Catalysis, new processes based on direct catalytic oxidation of hydrogen sulphide were developed [2-3]. The technology is schematically depicted in Fig. 1.

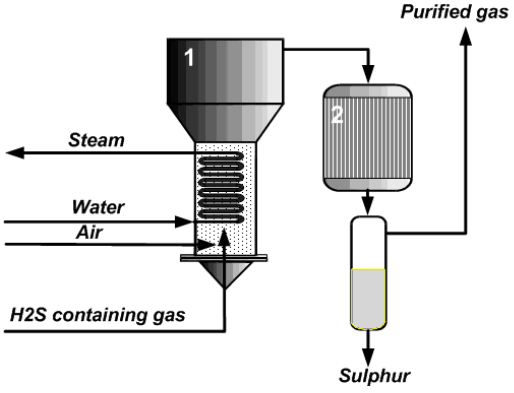

Figure 1: The technology of direct selective oxidation of hydrogen sulphide

A raw hydrogen sulphide containing gas is supplied to the reactor with a fluidized bed of catalyst, simultaneously oxygen (or air) is fed into the catalyst bed as a separate flow. The excessive heat of the exothermic reaction of H_2S oxidation is efficiently removed by a heat-

exchanger immersed into the fluidized bed. The bed temperature is controlled by the regulation of the amount of heat removed from the bed with a heat-exchange agent.

The technology was successfully tested in pilot scale on the largest sour gas fields, refineries and gas processing plants in Russia [3-4]. In 2011 full scale industrial installation was set into continuous operation at the Bavly oil-field (OJSC "Tatneft" – company-operator) [4-6].

Industrial installation of direct selective oxidation of hydrogen sulphide

The general view of the industrial installation is presented in Fig. 2.

Figure 2: Industrial installation for direct selective oxidation of hydrogen sulphide

3 Results and discussion

The efficiency of hydrogen sulphide removal was proved to exceed 99%.

During two years of continuous operation:

- 120 10^6 m^3 of commercial gas were produced;
- 1200 tons of hydrogen sulphide were recovered as elemental sulfur;
- emission of more than 2300 tons of sulfur dioxide and sulfuric acid to the atmosphere was prevented;
- pollution damage for the amount of $ 10 million was averted.

Characteristics of the produced sulfur surpass those specified by Russian National Standard #127.1-93 (commercial grade sulfur 9990).

4 Conclusions

The technology for purification hydrocarbon feedstock based on direct selective oxidation of hydrogen sulphide has been developed. The efficiency of the technology has been proved upon field testing of an industrial installation.

Keywords: hydrodechlorination, MOF-5 palladium catalyst, chlorobenzene, CO oxidation

1 Introduction

Disposal of chlorinated organic compounds, one of the most widespread types of industrial wastes, is between urgent problems for ecological chemistry nowadays. Hydrodechlorination (HDC) provides useful dioxins-free method of chlorobenzenes-containing wastes processing. Pd catalysts supported on different supports are active in HDC. It was found that the presence of Pd both in metal and in oxidized state is profitable for the catalytic performance, and such composition could be provided using appropriate support. It was demonstrated early, that Pd/MOF catalysts are active in some reactions, such as CO oxidation [1]. In this work the attempt was made to prepare Pd/MOF-5 catalysts using two methods, one was aimed on inclusion of Pd to the framework of the support, the other comprised application of Pd by impregnation. Both samples were tested in CO oxidation in pulse microcatalytic system and in chlorobenzene HDC in packed-bed continuous flow gas-phase system.

2 Experimental

Two methods were used to produce Pd/MOF-5: the first one included preparation of MOF-5 (terephtalic acid, $Zn(NO_3)_2.6H_2O$ and $Pd(NO_3)_2$ were used as parent substances, DMF as a solvent, hydrazine hydrate as reducing agent) [2] with further reductive supporting of Pd from palladium nitrate (sample 1); the second way consisted of direct co-precipitation of Pd/MOF-5 from the solution containing Pd^{2+} ions with further reduction under vacuum (10^{-5} atm) at 190ºC according to [3] (sample 2). Pd/MOF-5 were characterized by TGA (449PC Jupiter Netzsch, Netzsch GmbH), XRD (Rigaku MiniFlex 600), AAS (Thermo Fisher Scientific, iCE 3000), SEM (JSM 6490 LV, JEOL), low-temperature N_2 adsorption-desorption (Micometrics ASAP 2000), XPS (Kratos Axis Ultra DLD). Catalytic tests were performed in gas-phase hydrodechlorination of chlorobenzene at 100-250°C (flow-type fixed bad tubular reactor, 51 mg of catalyst, H_2:chlorobenzene = 30 (mol.)), and in CO oxidation by pulse microcatalytic method using the mixture of 2 vol.% CO and 1 vol.% O_2, balance He, pulse value 1 ml; the products were analyzed by GC.

3 Results and discussion

Two preparation methods of Pd/MOF-5 were used to provide Pd sites supported on MOF structure (sample 1) and involved into the framework of MOF (sample 2).

The results of TGA analysis of Pd/MOF-5 (1) and (2) are similar to those reported in literature and confirm the MOF-5 structure, but TG curve of sample 1 includes 3 discrete peaks of mass loss at the temperatures below 300ºC, associated with DMF removal, as it was shown by online MS analysis; whereas for the sample 2 this interval contains no peaks due to vacuum activation as the last synthesis step. The sample 1, according to SEM results includes faceted

particles of cubic structure as well as less crystalline ones; sample 2 consists mainly of needle-shaped particles. All particles have dimensions less than 1 μm.

XRD diffraction pattern for sample 2 is similar to those of MOF-5 described in literature [1]. Diffraction pattern of sample 1, in addition to MOF-5 peaks, contains many additional peaks, some of them could be attributed to the presence of ZnO, NaCl and other admixtures. NaCl presence was confirmed by XPS.

To characterize oxidation state of Zn by XPS a modified Auger parameter (the sum of E_B of $Zn2p_{3/2}$ electrons and kinetic energy of Auger spectrum of ZnLMM) was used. The values of 2009.5 and 2009.4 eV were found for the samples 1 and 2 correspondingly, that is similar to the value of 2010 eV for ZnO [4], but could be attributed also to Zn^{2+} in the other compounds such as carbonic acid salts.

S_{BET} of the samples 1 (87 m^2/g) and 2 (38 m^2/g) was much lower the values characteristic for MOF-5 structure. Taking into account the results of other methods, confirming the formation of MOF structure, it can be connected with the storage of the samples taken for nitrogen adsorption in non-appropriate wet conditions, that lead to partial decomposition before analysis.

The content of Pd found by AAS is very low: $2*10^{-5}$ wt. % of Pd in sample 1, and $4*10^{-6}$ wt. % of Pd in sample 2, which is much less than in similar catalysis described in [2]. As it is shown by XPS-method, both obtained samples contain Pd^0 (E_B of Pd3d electrons of about 335.0 eV, 69 and 63% for the samples 1 and 2) as well as Pd^{2+} in PdO and $PdCl_2$.

Only sample 2 demonstrated catalytic activity in CO oxidation (CO conversion 8% at 100 ºC; 34% at 150 ºC; 79% at 200 ºC; 98% at 250 ºC), in spite of 5 times less Pd content than in the sample 1. It is known that both Pd/MOF [1] and Pd/ZnO_2 [5] are active in CO oxidation, the second due to PdZn alloy formation. So the catalytic performance of the sample 2 could be attributed to the presence of both mentioned systems.

Both samples demonstrated also good performance in chlorobenzene HDC to benzene and cyclohexane in continuous flow system. Stable state chlorobenzene conversion values were 7% at 150ºC, 10% at 200ºC and 13% at 250ºC on sample 2; on sample 1 about 10% both at 150 and 200ºC. Taking into account very low Pd loading the TOF values are very high. In view of contradictory data about the composition of the samples 1 and 2 additional data are desired to describe the nature of the active sites of the samples tested.

4 Conclusions

Two samples were prepared using two methods of Pd/MOF-5 production, with Pd included in framework or supported on it. Characterization by SEM, DSC-TG, and XRD confirms the presence of MOF sructure in both samples, together with other crystalline phases for sample 1, but S_{BET} values are much lower than that for MOF-5 structure. Both samples demonstrate high activity in HDC of chlorobenzene at very low Pd content; sample 2 was active in CO oxidation as well.

Keywords: CO_2 fixation, iron, pyridylamino-bis(phenolate) complex, green polycarbonates, cross linking, cyclic carbonates

1 Introduction

The finite availability of fossil resources is stimulating the production of chemicals from alternative and sustainable carbon resources, among which CO_2 is an attractive (being non-toxic, inexpensive and renewable) yet challenging C_1-feedstock (being thermodynamically very stable).[1] The atom-efficient reaction of CO_2 with epoxides can generate two valuable products: cyclic carbonates and polycarbonates. Cyclic carbonates find application as green solvents, as electrolytes in Li-ion batteries and as intermediates for the synthesis of polymers and fine chemicals, whereas the biodegradable polycarbonates can be used in the synthesis of polyurethanes, thermoplastics and polymer resins.[2] Here, we present a study of iron(III) pyridylamino-bis(phenolate) complexes, FeX[O_2NN'] (**A:** X = Cl; **B:** X = Br), as novel homogeneous catalysts for the coupling reaction between CO_2 and a range of epoxides.[3]

2 Experimental

The synthesis of the iron pyridylamino-bis(phenolate) complexes was performed following a previously reported procedure.[4] The catalytic tests were performed in a high-throughput unit consisting of 24 batch reactors which can operate simultaneously at the chosen temperature and CO_2 pressure. Information on the analysis of the reaction products is provided in Table 1.

3 Results and discussion

Iron(III) pyridylamino-bis(phenolate) complexes are highly active homogeneous catalysts for the reaction of different epoxide substrates and oxetane with CO_2 (Table 1). The addition of a Lewis base co-catalyst allowed significant reduction in the catalyst loading needed to reach high product yields (Table 1, entries 1 and 3-5). The catalysts are remarkably robust, and unpurified substrates can be used without concerns for the presence of water impurities in the reaction set-up. With terminal epoxides, the reaction was fully selective towards the cyclic carbonate product (Table 1, entries 9-11). With cyclic epoxides, the selectivity could be switched between cyclic and polymeric carbonate by tuning the reaction conditions and the catalyst to co-catalyst ratio (Table 1, entries 3&5, and 6&8). Among the studied epoxide substrates, 1,2-epoxy-4-vinylcyclohexane could be converted with nearly complete selectivity to the polycarbonate (Table 1, entry 8). The obtained polymer presents pending vinyl groups, which allow post-synthetic cross-linking with 1,3-propanedithiol (Fig. 1). The cross-linked polycarbonate displayed an increase of 55 °C in the glass transition temperature compared to the as-synthesised polymer (Fig. 1). The improved T_g

value and the enhanced chemical resistance of this cross-linked polycarbonate open new opportunities for the application of these green polymers as thermosetting plastics.[3]

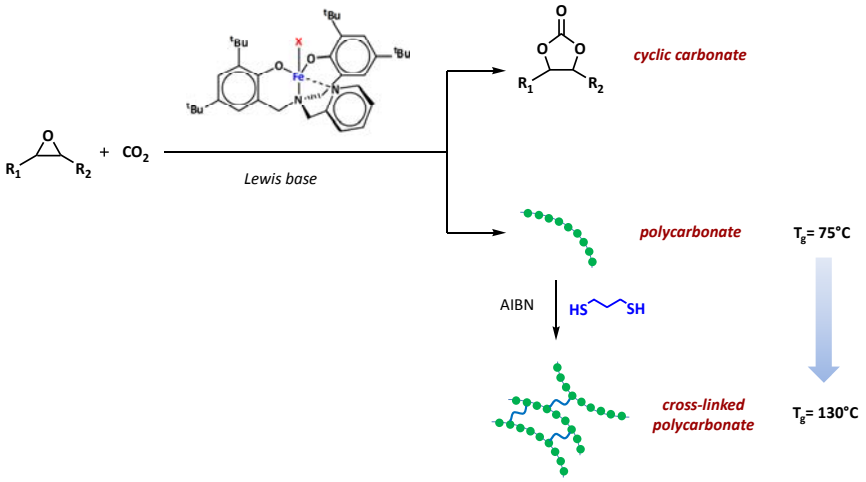

Fig. 1. Reaction of CO_2 with epoxides catalysed by iron(III) pyridylamino-bis(phenolate) complexes and post-synthetic cross-linking of the polycarbonate.

4 Conclusions

Fe[pyridylamino-bis(phenolate)] complexes, alone or in combination with ionic Lewis bases, are highly active and versatile homogeneous catalysts for the coupling reaction of CO_2 and epoxides. The parameters governing the selectivity of the reaction towards cyclic or polymeric carbonates were studied and optimised to control and maximise the selectivity towards each of the two valuable products. The physicochemical properties of the polycarbonate obtained from 1,2-epoxy-4-vinylcyclohexane could be significantly improved by post-synthetic cross linking.

Design of Catalysts of Carbon Dioxide Conversion of Methane

Mironenko A.*, Kazieva A., Mansurov Z., Kudyarova Z.

The Institute of Combustion Problems, Almaty, Kazakhstan

* anamir.48@mail.ru

Keywords: methane, carbon dioxide, syngas, fiberglass, nanostructured catalyst

1 Introduction

The reaction of carbon dioxide conversion of methane (DR) is one way that allowing to convert natural gas – methane into valuable end products, representing the gas mixture of hydrogen and carbon monoxide in different ratios [1]. From this viewpoint, it is the most secure method, in contrast to the partial oxidation of methane by atmospheric oxygen and steam-oxygen conversion.

In this reaction, the contacts on the basis of nickel oxide have maximum spreading, however, in spite of high activity of these catalysts, their use is limited by significant carbonization processes [2, 3]. In this regard, at the present time a search of new catalytically-active compounds is occurred, these compounds can became as an alternative to nickel contacts. From this viewpoint, the catalysts consisting of cobalt oxides and its compounds are modified with other oxides are of interest.

In recent years, the high-temperature fiberglass is used as a basis in the various processes, in spite of the low surface area, its hydraulic, technological characteristics as well as flexibility in application is vastly superior to traditionally used contacts, including block system of catalysts.

2 Experimental/methodology

The synthesis "solution combustion" is carried out according to the equation:

$$Me(NO_3)_2{*}6H_2O + 2NH_2CH_2COOH + 4.5O_2 \rightarrow MeO + 4CO_2 + 11H_2O + 2NO_2$$

Investigations on catalytic activity in reaction of RD of polyoxide catalysts system on the basis of fiberglass consisting of magnesium oxides, nickel and cobalt were carried out. The activity of catalysts was tested on-line with using of gas chromatographic analysis method on device «ХРОМОС ГХ-1000», is equipped with software (SW), and data recording to the computer.

Synthesized samples are examined by XRF, SEM, TEM methods as well as thermo-programmed reduction by hydrogen.

3 Results and discussion

X-ray analysis showed that after passing of synthesis by "solution combustion" method, on the surface of samples, depending on the initial composition of the charge (nitrate salts), there is phase formation of nanostructured systems is occurred: Co3O4, MgO, NiCo2O4, 3CoO • 5NiO, MgNiO2.

The obtained TEM-images have shown that linear dimension of surface structures on the fiberglass is in interval 5-17 nm. The data of TIS indicates on step process for recovery of active components.

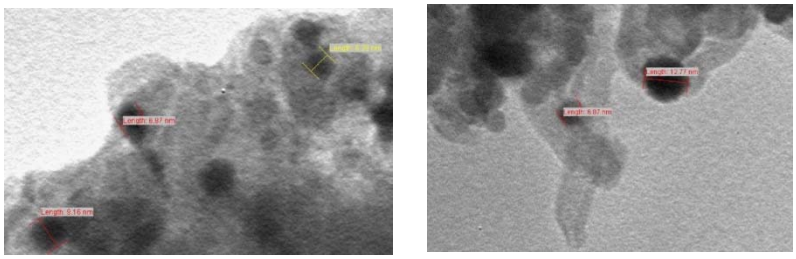

Fig. 1- TEM images from different locations of sample №9

The temperature effect and composition of (MgO, NiO, CoO) polyoxide catalysts on their catalytic activity in the reaction of DR is studied. It was found that the temperature in the interval of 850-900 0C is the optimal temperature of the process.

Variation of sample composition at the temperature 850 ^{0}C has shown that samples containing magnesium oxide – 2 %, nickel – 1,4% and cobalt – 1,6 % have optimal characteristics.

Also, the influence of volume velocity on activity of synthesized samples was investigated. It was found that in the interval of 3200-9600 h-1 the activity of catalyst is almost on the same level: the conversion of initial products is 98-99%, the yield of hydrogen is - 42-43%, and carbon monoxide is - 52-53%.

The analysis of experimental data, is based on the ratio H_2O/CO, shows that most complete conversion of methane and carbon dioxide into reaction products is occurred on the catalyst at temperatures of 850-900 °C: H_2O/CO = 0,092 and 0,072 respectively. The material balance calculations on carbon have shown that the unbalance on carbon average 0.45% and during the tests was almost on a level with a defection of ± 1%.

4 Conclusions

From obtained experimental data it was found that nanostructured catalysts on the basis of high-temperature fiberglass are exhibit the high catalytic activity during the process of carbon dioxide processing of methane (DR) into the synthesis gas, the ratio H_2/CO is close to 1. It is shown that DR process the conversion of methane and carbon dioxide reaches 98-99% and the yields of hydrogen and carbon monoxide comprises 42 and 52%, respectively. Also it was found that the content of magnesium oxide is introduced into catalyst system has a major influence on the basic characteristics of DR process. It was shown that catalytic activity remains almost constant during 30 hours of catalyzator work at 850 ° C.

Thus, inference should be drawn that catalysts on the basis of fiberglass have fairly good perspectives at processing of natural gas - methane into valuable synthesis gas for chemical industry

Keywords: Ni-Al layered double hydroxides, Mg and Cr modifiers, CO_2 removal by methanation

1 Introduction

Utilization of carbon dioxide (CO_2) has become an important global issue due to the significant and continuous rise in atmospheric CO_2 concentrations. Carbon dioxide is a major greenhouse gas and makes a significant contribution to global warming and climate change. Hence, there is an urgent need to reduce its accumulation in the atmosphere. It was specified in our recent study [1], that the co-precipitated Ni-Al layered double hydroxide (Ni^{2+}/Al^{3+}= 3.0/1) is a precursor of effective catalyst for fine CO_2 removal from H_2-rich gas stream through the methanation reaction (hydrogenation of CO_2 to methane).

Ni-Al layered double hydroxides represent a class of layered materials with a chemical composition expressed by the general formula $[Ni^{2+}_{1-x}\ Al^{3+}_{x}\ (OH)_2]^{x+}\ [A^{n-}_{x/n}]\cdot mH_2O$, where Ni^{2+} and Al^{3+} ions are located in the brucite-like hydroxide layers, while the charge compensating exchangeable anions (A^{n-}) and water molecules are situated in the interlayer space of the layered structure. Withal, *x* represents the Al^{3+} fraction and *m* is the number of the water molecules. A wide variety of M^{2+} or M^{3+} cations may be accommodated or substituted in the octahedral sites of the brucite-type sheets by other ones having similar ionic radius, forming different layered compounds [2]. In this study we report on our attempts to further improve the catalytic activity of the Ni-Al catalyst. A modification of the brucite-like layer by partial isomorphous substitution of Ni^{2+} ions with Mg^{2+} as well as of Al^{3+} with Cr^{3+} ones was done. The aim of this study is to elucidate the role of the modifier on the activity in CO_2 removal through methanation by variation of the reduction and reaction temperature as well as the space velocity.

2 Experimental/methodology

NiAl, NiMgAl and NiCrAl layered precursors with molar ratios of M^{2+}/M^{3+} = 3.0, where M^{2+} = Ni or Ni+Mg and M^{3+} = Al or Cr+Al, were synthesized by co-precipitation at constant pH and temperature. The total amount of the adsorbed hydrogen (H_2-chemisorption) was used to determine the specific Ni^0 surface area (Ssp_{Ni}) and the Ni^0 particle size (d_{Ni}) of the reduced precursors (400, 450, 530 and 600°C for 3 h with hydrogen). The metanation activity were performed by means of gaseous mixture of $CO_2/H_2/Ar$=0.65/34.35/65.0 vol. % in the temperature interval 220−400°C and GHSV=3000−22000 h^{-1} after 'in situ' reduction of the precursors by hydrogen at 400, 450, 530, and 600°C for 3 h. A variation of the GHSV was applied at each reaction temperature until registration of 0−50 ppm CO_2 levels.

3 Results and discussion

The catalytic activity is evaluated by the GHSV at which the residual concentration of CO_2 at the reactor outlet was 10 ppm, the latter being an admissible limit in the industrial ammonia production. The catalytic runs show that all catalysts hydrogenate CO_2 successfully to CO_2 levels of 0–10 ppm at reaction temperatures between 400 and 280°C and GHSV within 3000–

22000 h^{-1}. Bearing in mind that the lower temperatures are thermodynamically favorable for the reaction under study, the activity of the catalysts is represented at the reaction temperatures of 260, 240 and 220°C (Fig. 1).

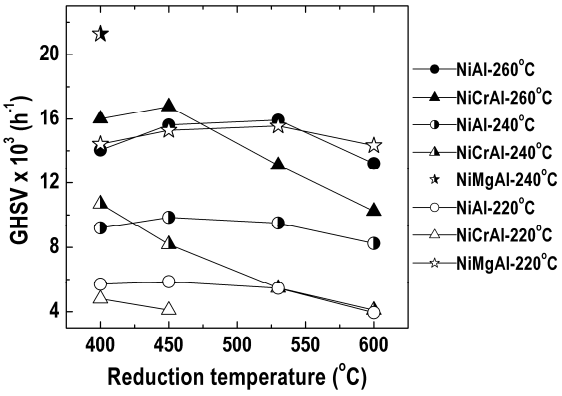

Fig. 1. Catalytic activity

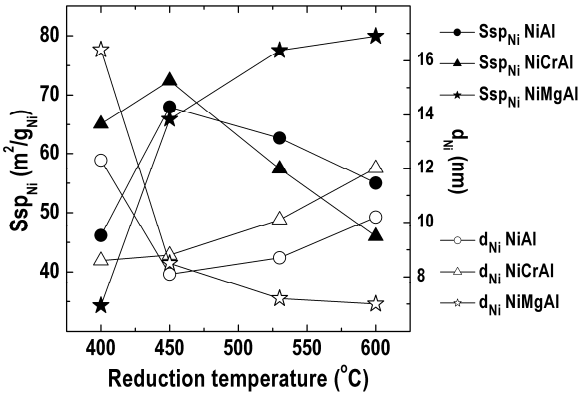

Fig. 2. Ssp_{Ni} and d_{Ni} of metal Ni

NiMgAl catalyst hydrogenates CO_2 completely at 0 ppm level at a reaction temperature of 260°C, raising GHSV to 22000 h^{-1}, irrespective of reduction temperature (Fig. 1). The catalyst purifies the reaction mixture from CO_2 at 10 ppm level at a reaction temperature of 240°C and GHSV = 22000 h^{-1}, only after reduction at 400°C. Further increase of the reduction temperature up to 530 and 600°C brings about a successful purification at 0 ppm level. NiMgAl catalyst dominates in the activity at a reaction temperature of 220°C, also. A possible explanation of the observed catalytic activity may be found in the results obtained from H_2-chemisorption experiments. An increase of the Ssp_{Ni} and decrease of d_{Ni} is observed after reduction above 500°C (Fig. 2) because of the retarding the effect of the Mg on the Ni^0 sintering. It is well-known that Mg acts as spacer/barrier thus minimizing sintering via Ni^0 particle migration. As the Ni^0 particle size becomes smaller, numerous Ni^0 atoms will be exposed to the surface (active sites where the reaction can take place) thus provoking higher catalytic activity.

The differences in the activity of NiCrAl and NiAl catalysts is related to the role of Cr^{3+} ions to stabilize the gamma-Al_2O_3 phase at low temperatures (reduction at 400 and 450°C), thus preventing the formation of hardly reducible $NiAl_2O_4$ spinel-like phase. As a result, the number of the easily reducible Ni^{2+} ions rises and the Ssp_{Ni} increases. At higher reduction temperatures, Cr^{3+} and Ni^{2+} ions form hardly reducible $NiCr_2O_4$ spinel, so Ssp_{Ni} decreases causing the activity loss. The methanation activity of NiAl catalyst after reduction at 400 and 450°C can be ascribed to the presence of readily reducible Ni^{2+}-O species, because the formation of $NiAl_2O_4$ spinel-like phases is realized at temperatures higher than 520°C. Further treatment above 530°C induces aggregation or sintering of the Ni^0 particles, causing diminution of both Ssp_{Ni} and number of Ni^0 atoms on the catalyst surface (Ni^0 dispersion) thus leading to a decrease of the methanation activity.

4 Conclusions

The studied catalytic compositions are found to be promising catalyst precursors for deep CO_2 removal from hydrogen-rich gas streams through the methanation reaction, depending on the technological regime of the catalyst activation: (i) NiCrAl and NiAl catalysts – at low and medium reduction temperatures and (ii) NiMgAl catalyst – at higher reduction temperatures.

Keywords: $SrNb_2O_6$, nanoplate, photocatalysis, carbon dioxide reduction

1 Introduction

The gradual depletion of fossil resources and the growing emission of CO_2 have stimulated the research activities toward the utilization of CO_2 for the production of fuels and chemicals. Among various transformations of CO_2, the photocatalytic reduction of CO_2 with H_2O is one of most attractive but highly difficult routes. The rapid recombination of photogenerated electron-hole pairs and the low adsorption ability and reactivity of CO_2 on catalyst surfaces may cause the lower efficiency [1]. We have demonstrated that the addition of basic oxides or Pt@Cu_2O cocatalyst onto TiO_2 and the using of solid-gas reaction mode can enhance the activity and selectivity for CO_2 photoreduction [2-4]. Here, we report our recent finding that the synthesis of a novel two-dimensional (2D) $SrNb_2O_6$ with high CO_2 chemisorption and enhanced electron-hole separation abilities can accelerate the preferential reduction of CO_2 in the presence of H_2O.

2 Experimental

$SrNb_2O_6$ nanocrystals with different morphologies were mainly synthesized by hydrothermal method, and were denoted as $SrNb_2O_6$−*X*−*Y*, where *X* is the morphology and *Y* is the value of surface area ($m^2\ g^{-1}$). Photocatalytic reduction of CO_2 in the presence of H_2O was carried out in a stainless-steel reactor with a quartz window on the top of the reactor using solid−gas interface reaction mode. Reaction conditions were as follows: catalyst, 0.010 g; CO_2 pressure, 0.2 MPa; H_2O, 4.0 mL; light source, Xe lamp (λ = 300-780 nm); irradiation time, 10 h.

3 Results and discussion

The conditions used for the hydrothermal synthesis determined the product morphology. A higher pH value (pH = 13), higher temperature (≥ 493 K) and a longer hydrothermal time (≥ 24 h) were required for the formation of 2D nanoplate morphology. The $SrNb_2O_6$−plate−105 sample exhibited a lateral size of 50-300 nm and the thickness of nanoplates was ~12 nm, the HRTEM image and the SAED pattern revealed the single crystal nature of this sample (Fig. 1A).

To gain insights into the feature of the $SrNb_2O_6$ nanoplate, we chose 6 representative samples with different morphologies (Table 1) for further studies. These samples were all monoclinic $SrNb_2O_6$ in crystalline structure. The band gap energy evaluated from UV-vis did not change significantly with the morphologies and were 3.7-3.8 eV.

The photocatalytic results displayed in Table 1 suggest that the morphology plays a key role in determining the catalytic activity. For example, the $SrNb_2O_6$−plate−50, which had a similar surface area or CO_2 adsorption amount to the $SrNb_2O_6$−particle−46, produced a significantly larger amount of (CO + CH_4). On the other hand, the comparison of the catalysts with the same

morphology but different surface areas showed that the larger surface area favoured the activity. Thus, the $SrNb_2O_6$−plate−105 exhibited excellent activity for the photocatalytic reduction of CO_2 without any promotes or cocatalysts, which was even better than the Pt−TiO_2. It should be mentioned that the selectivity of consumed electrons for CO_2 reduction was higher for the $SrNb_2O_6$ nanocrystals than that for TiO_2 and Pt−TiO_2.

To understand the effect of morphology deeply, we performed transient photocurrent response measurements. The photocurrent density increased in the following sequence: $SrNb_2O_6$−SSR−2.2 < $SrNb_2O_6$−particle−3.7 < $SrNb_2O_6$−particle−46 < $SrNb_2O_6$−rod−8.5 < $SrNb_2O_6$−plate−50 < $SrNb_2O_6$−plate−105 (Fig. 1B). These results demonstrate that the $SrNb_2O_6$ nanoplate favours the separation of photoexcited charge carriers. The correlation of these results with the catalytic activity (Table 1) suggests that the separation of photogenerated electron-hole pairs is the activity-determining process in our system.

Photocatalyst	Amount (μmol)			Select. for CO_2 reduction (%)	CO_2 chemisorption (μmol g^{-1})
	CO	CH_4	H_2		
$SrNb_2O_6$−SSR−2.2	0.41	0.026	0.098	84	0.45
$SrNb_2O_6$−particle−3.7	0.51	0.054	0.24	75	0.75
$SrNb_2O_6$−rod−8.5	0.76	0.092	0.45	71	1.7
$SrNb_2O_6$−particle−46	0.65	0.062	0.21	81	8.7
$SrNb_2O_6$−plate−50	1.05	0.20	0.38	83	9.2
$SrNb_2O_6$−plate−105	1.66	0.33	0.65	82	21
TiO_2 (P25)	0.14	0.042	0.24	56	-
0.5 wt% Pt−TiO_2	0.12	0.57	3.63	40	-

Table 1. Photocatalytic behaviours of the $SrNb_2O_6$ catalysts for the reduction of CO_2.

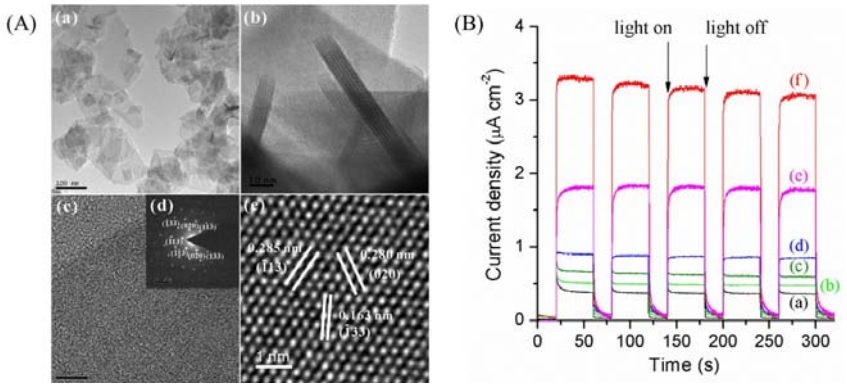

Fig. 1. (A) TEM images of $SrNb_2O_6$ nanoplates. (a) Top view, (b) side view, (c, d) HRTEM image and SAED pattern, (e) HRTEM image. (B) Transient photocurrent responses for (a) $SrNb_2O_6$−SSR−2.2, (b) $SrNb_2O_6$−particle−3.7, (c) $SrNb_2O_6$−particle−46, (d) $SrNb_2O_6$−rod−8.5, (e) $SrNb_2O_6$−plate−50, (f) $SrNb_2O_6$−plate−105.

4 Conclusions

We have succeeded in synthesizing $SrNb_2O_6$ nanoplates by a simple hydrothermal method and demonstrated that the $SrNb_2O_6$ nanoplate is a promising photocatalyst for the preferential reduction of CO_2 to CO and CH_4 in the presence of H_2O vapour. The open 2D structure and high surface area contribute to the photocatalytic CO_2 reduction by enhancing the separation of photogenerated electron-hole pairs. The larger surface area could also enhance CO_2 chemisorption, favouring its subsequent reduction.

Keywords: AC adsorbents, CO_2 removal, CO_2 adsorption, selective CO_2 adsorption

1 Introduction

Thermal power plants fed by fossil fuels, including coal, oil and gas generate CO_2 as a by-product, which accounts for 40% of total CO_2 emissions. Since reducing CO_2 emissions is crucial for environmental concerns, there is a growing interest on CO_2 capture (CC) technologies. CC technologies also provide an advantageous way for many issues, such as selective separation of CO_2 from the natural gas reserves, selective separation of CO_2 from flue gas mixtures, and selective separation of CO_2 from the shifted-syngas ($CO+ H_2$) prior to the generation of electricity. CC is a demanding technology considering the fact that CO_2 concentrations may be lower than 10-15%, like in the effluent stream of WGS units, meaning a limited thermodynamic driving force for the operation. Adsorption seems to be the most promising technology due to its reasonable removal efficiency, especially by using solid sorbents that offers potential energy savings with lower capital and operating costs [1, 2]. In order to be used in pre-combustion and post-combustion technology applications, selective adsorption has attracted great interest.

In this study, activated carbon (AC) based adsorbents, which have large surface area and suitable porosity, were investigated for their CO_2 capturing ability. Structural modification of AC is an important parameter for CO_2 adsorption properties. Different oxidation procedures and alkali impregnation, such as NaOH and KOH impregnation, were applied. Selective adsorption of CO_2 from CO_2-CH_4 mixtures was studied on AC-based adsorbents and the effects of temperature, pressure, and adsorbate gas composition were investigated.

2 Experimental

The AC-based adsorbents used in this study were prepared via different oxidative, alkali and thermal treatments. HNO_3 or air oxidation procedures were applied over AC samples followed by washing with HCl. 10% NaOH or KOH were added to the oxidized samples through using solution impregnation in order to introduce basic groups on the adsorbent surface. Air oxidized-alkali impregnated samples were calcined at 200 ºC, 250 ºC and 300 ºC, whereas HNO_3 oxidized-alkali impregnated samples were calcined at 175 ºC, 200 ºC and 250 ºC. CO_2 adsorption and/or selective CO_2 adsorption performance of the samples were analyzed by using a gravimetric analyzer system integrated to a mass spectrometer. Adsorption and desorption isotherms were obtained in the pressure range of 0-1000 mbar, and the experiments were conducted at room temperature, 120 ºC and 200 ºC. 4 different feed streams were used in order to observe the effect of adsorbate composition: (i) 100% CO_2, (ii) 100% CH_4, (iii) 50% CO_2-50% CH_4 mixture, (iv) 10% CO_2-90% CH_4 mixture.

3 Results and discussion

A comparative analysis of the results of the adsorption experiments conducted under pure

CO_2 and pure CH_4 flow revealed that CO_2 adsorption is more favorable than that of CH_4 on NaOH and KOH impregnated AC-based adsorbents. Studies on selective adsorption of CO_2 from CO_2-CH_4 mixtures were also performed on AC-based adsorbents with high CO_2 adsorption capacity and stability. The amounts of CO_2 and CH_4 adsorbed at room temperature were 4 times higher than those measured at 120 ºC and 200 ºC, and surface saturation was reached at lower pressure values when the experiments were conducted at high temperatures**.** The effect of CO_2 partial pressure, in other words adsorbate gas composition, was investigated. Figure 1 shows that mass uptake on the adsorbent surface increases with increasing CO_2 concentration in the feed stream.

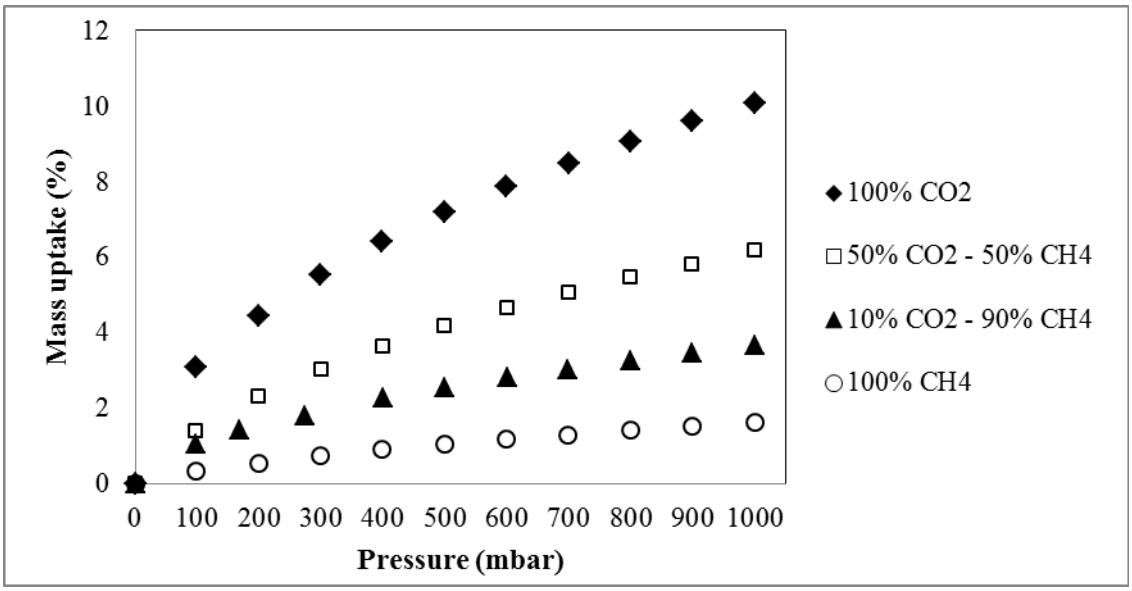

Fig. 1. Mass uptake on an AC-based adsorbent (air oxidized, NaOH impregnated, calcined at 200 ºC) for different feed stream compositions.

4 Conclusions

In preparation of AC-based CO_2 adsorbents, different oxidation procedures, followed by alkali, NaOH or KOH, impregnation, were applied to a commercial AC. The results showed that alkali impregnation enhances CO_2 adsorption capacity, and CO_2 adsorption is more favorable than CH_4 adsorption. However, variations in post-calcination temperature have not showed any significant effect. Alkali impregnated ACs were found to be promising adsorbents as they have both high adsorption capacity and selectivity towards CO_2 adsorption.

Keywords: combined partial oxidation and CO_2 reforming of methane, synthesis gas, Ni catalyst

1 Introduction

The study aims at exploring a concept which can convert coal-bed methane (containing methane, air and carbon dioxide) to synthesis gas. CO_2 reforming of methane (DRM) to produce synthesis gas has attracted interest by the means of environmental and industrial perspectives. The environmental viewpoint stem from the fact that both CO_2 and methane are viewed as harmful greenhouse gases. CO_2 reforming of methane convert the two greenhouse gases into a valuable feedstock: CO and H_2 [1]. The synthesis gas (a mixture of H_2 and CO) is a versatile feedstock for methanol and Fischer-Tropsch synthesis and several other carbonylation, hydrogenation and reduction reactions [2]. Even though the coke deposition rate in CO_2 reforming of methane can be minimized by modification of catalyst, high energy requirement prevents commercialization of the process. On the other hand although partial oxidation of methane (POM) is a highly energy efficient reaction due to its exothermic nature, it is hard to control the temperature of the reaction if the heat transfer from the catalyst surface to the gas phase is poor. Moreover, POM requires pure oxygen which is also costly. An interesting approach is to combine the advantages of DRM and POM results in a reaction called oxy-CO_2 reforming of methane [3]. By coupling the exothermic partial oxidation reaction with the endothermic reforming reaction, the methane-to-syngas conversion can be operated in a safer manner than partial oxidation and more energy efficient manner than CO_2 reforming. Additionally, by changing the feed composition, one can control the product ratio of H_2/CO and thus the selectivity for various Fischer–Tropsch synthesis products. Finally, one can use those natural gas reserves containing substantial amounts of CO_2 [4].

2 Experimental/methodology

10% and 15% (wt.%) Ni loaded on Al_2O_3, MgO, ZrO_2, $MgAl_2O_4$, SiO_2, TiO_2 and CeO_2 catalysts were prepared by impregnating the support with an aqueous solution of $Ni(NO_3)_2.6H_2O$. An appropriate amount of $Ni(NO_3)_2.6H_2O$ that was solved in 25 ml deionized water was impregnated to supports under mixing at 60°C. Slurry was dried at 120°C for 15 h and calcined 800°C for 5h.

Nickel crystallite sizes were calculated by Scherrer's equation and both these results and the surface areas can be seen in Table 1. The catalytic reaction tests were carried out in a conventional micro quartz reactor (Id ¼ 6 mm) under atmospheric pressure at 800°C. The reactant stream consisting of $CH_4/CO_2/O_2/N_2$= 3/1.3/1/3.7 (by volume) was fed in at a gas hourly space velocity (GHSV) of 30000 ml g^{-1} h^{-1}. Prior to reaction, each catalyst was reduced in situ in 10% H_2/N_2 flow at 800ºC for 2 h. Effluent gases were analyzed by on-line gas chromatograph (GC) .

3 Results and discussion

Figure 1 shows the XRD pattern of the fresh Ni/Al_2O_3 catalyst. Ni/Al_2O_3 catalysts shows the characteristic peaks of NiO at $2\theta=43.3^\circ$, 37.2°, 62.9° and $NiAl_2O_4$ at $2\theta=19.1^\circ$, 31.4°, 37°, 45°, 59.7°, 65.5°.

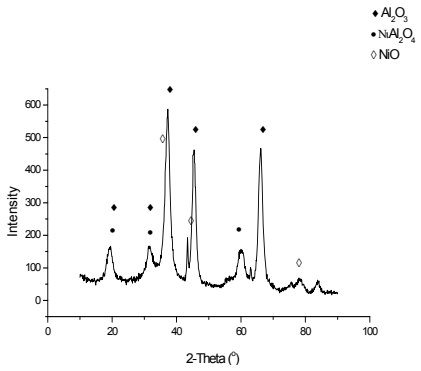

Fig. 1. XRD patterns of the Ni/ Al2O3

Catalyst	Surface Area(m^2/g)	Crystallite Size(nm)
Ni/Al_2O_3	138.5	7
Ni/ZrO_2	24.1	25.8
Ni/TiO_2	8.7	38.5
Ni/SiO_2	100.4	12.7
Ni/CeO_2	5.5	37
$Ni/MgAl_2O_4$	33.5	28.6
Ni/MgO	21.7	29.2

Catalyst	GHSV (l/kg h)	Conversion of CH_4	Conversion of CO_2	Selectivity of H_2	Selectivity of CO	H_2/CO
Ni/Al_2O_3	30000	92	89.6	95,8	99,2	1,48
Ni/MgO	30000	22.4	0	6.7	28.5	1.50

Table 2. Results and activity for Ni/Al_2O_3 and Ni/MgO

4 Conclusions

The combined air partial oxidation and CO_2 reforming of coal bed methane reaction results over impregnated Ni/Al_2O_3, Ni/MgO, Ni/ZrO_2, $Ni/MgAl_2O_4$, Ni/SiO_2, Ni/TiO_2 and Ni/CeO_2 catalysts. Ni/Al_2O_3 and Ni/MgO are presented in Table 2 for 10% Ni loading. The Ni/Al_2O_3 catalyst shows the conversions of CH_4 and CO_2 %92 and 89,6 respectively during the reaction. In the case of Ni/MgO catalyst, the initial conversions of CH_4 and CO_2 are %76 lower than those of Ni/Al_2O_3 catalyst. And the conversions of CH_4 and CO_2 decrease markedly in the reaction. The activity tests of different Ni loadings are still in progress.

Keywords: honeycomb-type catalyst, CO_2 methanation, wash-coat, CO_2 utilization

1 Introduction

The CO_2 methanation is a famous reaction that calls a familiar Sabatier reaction for the hydrogenation of CO_2. Recently, the CO_2 methanation has also come to be paid to attention as a reaction that converts the greenhouse gas into a useful resource gas and is one of the promising hydrogen careers, produced by renewable energy. Such attention has thus accelerated the research of the catalyst and system development for methanation more than before.

The important point in constructing the CO_2 methanation system is to develop the catalyst having a rapidly transforming ability of CO_2 and to eliminate the reactive exothermic energy to the reactive zone efficiently. Additionally, the processing of a large amount of raw material gas is requested from an industrial viewpoint. The structured reaction system that integrates a reactive zone and a heat-transferring zone is an effective reaction system to solve the problem of efficient elimination of thermal energy and the problem of the mass processing of CO_2.

For constructing the structured methanation system in this study, first, we investigated the performance of methanation of some nickel-based catalyst loaded on various support. Secondly, a structured catalyst with Ni/CeO_2 component having the highest methanation ability was prepared by wash-coating method on an aluminum honeycomb-fin and was measured its catalytic property and durability performances.

2 Experimental

The 10 wt% Ni-loaded granular catalyst was prepared by a wet impregnation method. The Al_2O_3 (ALO-8), TiO_2 (TIO-4), ZrO_2 (ZRO-3) and CeO_2 (CEO-2), which were provided by Catalysis Society of Japan, were used as the support materials. The support and $Ni(NO_3)_2 \cdot 6H_2O$ were added into a distilled water and well-stirred for 14 h at room temperature. After drying, the obtained powder was calcined at 500°C for 3 h so as to be a Ni-based granular-type catalyst.

Fig.1 Overview of the prepared honeycomb-type Ni-based catalyst.

The structured catalyst was prepared by a wash-coat method using an aluminium substrate with a honeycomb-fin configuration (18mmφ x 45mm-length, cell density 100cpsi, apparent surface area 183 cm^2). The granular Ni-based catalyst was first dispersed in distilled water to prepare the slurry. Then, the honeycomb-fin substrate was immersed in this slurry. By drying at 27°C for 24 h, the honeycomb-type catalyst as shown in Figure 1 was obtained.

The prepared catalyst was placed in the center of the reactor tube. The catalyst was reduced by H_2 at 500°C for 2 h before the reaction. After the reduction, reactants (CO_2/H_2/He =1/4/5 molar ratio, total gas volume=70 ml·min^{-1}) were supplied to the catalyst. The catalyst of 300 mg was loaded and GHSV based on the net volume of the catalyst layer was 14,000 h^{-1}. The reaction temperature range was from 200 to 500°C. Outlet gases were analysed by GC-TCD.

3 Results and discussion

Figure 2 shows the effect of reaction temperature on CO_2 conversion over the Ni/Al_2O_3, Ni/TiO_2, Ni/ZrO_2 and Ni/CeO_2 catalysts. Over 350°C, all catalysts showed high CO_2 conversion which is almost equilibrium value. In contrast, the significant difference in activity was observed below 350°C. The Ni/CeO_2 and Ni/ZrO_2 catalysts displayed a high activity of 84.7 % and 70.0 % conversion at 250°C, while the Ni/Al_2O_3 and Ni/TiO_2 catalysts showed a low CO_2 conversion. These results satisfied with the previous report [1]. The higher basic supports such as the CeO_2 and ZrO_2 would enhance the partial electron transfer from the supports to Ni element [2]. The increased basicity of the support might improve the ability of CO_2 activation on Ni-site, and in turn produced a higher activity.

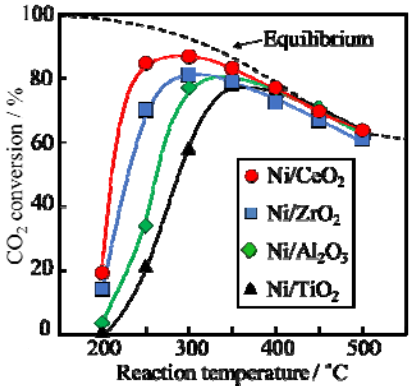

Fig.2 Methanation performance of various Ni-loaded catalysts.

By wash-coating Ni/CeO_2 component on the honeycomb-fin, the two types of the fin catalyst were prepared. One was the honeycomb-fin with straight flow channels (abbreviated as plain-type). Another was that with random flow channels, which was composed by connecting the plain-type fin with 1/4 length in series (abbreviated as stack-type). Figure 3 shows CO_2 conversion of the two types of the structured catalysts comparing with the granular-type catalyst. The prepared fin catalysts showed a high activity at 300°C or more. Then, the activity of the stack-type catalyst was higher than that of the plain-type catalyst. Such tendency might be caused from improving the mass transfer diffusion by stacking the substrate in series. A lower activity at 250°C or less compared with the granular catalyst might be mass transfer limitation. It was thought that the optimum temperature of methanation over the honeycomb-fin catalyst is 300°C as a result.

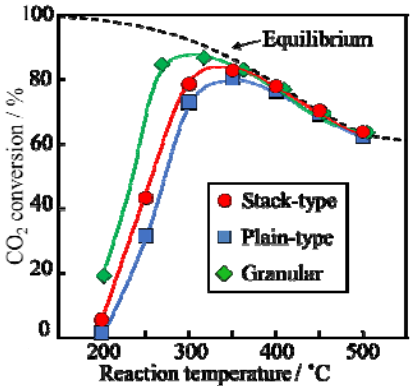

Fig.3 Methanation performance of the structured and granular catalysts.

Figure 4 shows the durability performance and the selectivity to CH_4 over the stack-type structured catalyst for about 120 h at 350°C. The catalytic performance did not deactivate at all. Additionally, the selectivity to CH_4 did not also decrease during the reaction. The developed catalyst has a high and practical potential to be used as a catalyst for the production of energy resource from CO_2.

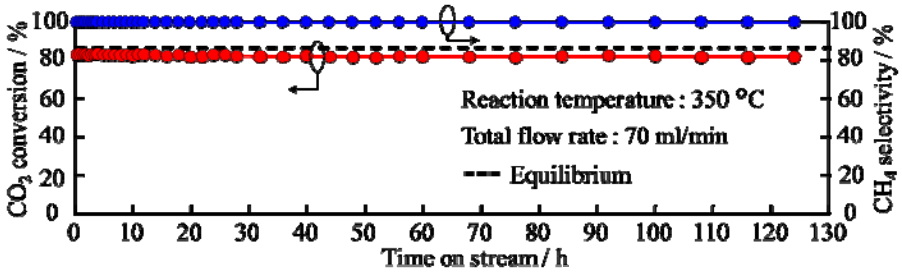

Fig.4 Durability performance of the stack-type structured catalyst.

4 Conclusions

The Ni/CeO_2 was selected as the suitable component of CO_2 methanation, comparing to the Ni/Al_2O_3, Ni/TiO_2 and Ni/ZrO_2. The honeycomb-fin type catalyst with Ni/CeO_2 prepared by the wash-coating showed a relatively high activity. The durability performance of the honeycomb-fin catalyst showed a high and stable performance for methanation.

CO_2 Capture by Hierarchical Mesoporous Chabazite Type Zeolites

Hillen L.*, Degirmenci V.

CenTACat, Department of Chemistry and Chemical Engineering, Queen's University, Belfast, Northern Ireland

* lhillen02@qub.ac.uk

Keywords: zeolite, SSZ-13, mesoporous, CO_2 capture

1 Introduction

Zeolites have numerous advantageous properties as an adsorbent for CO_2 capture when compared with their alternatives such as their high thermal stability and tuneable pore sizes [1]. In industrial gas separations, low silica zeolites such as faujasite (FAU) and LTA type zeolites (A, Y, 13X) are used extensively. On the other hand SSZ-13 with the chabazite (CHA) framework is a highly siliceous zeolite which has a less hydrophilic surface due to reduced Al content. Moreover, SSZ-13 differs from FAU and LTA type materials in that all of its cation sites are free to interact with adsorbed molecules. Many cation sites in FAU or LTA are located within hardly accessible sodalite cages [2]. While studies have been carried out to investigate SSZ-13 as a sorbent for CO_2 capture, these studies have been limited to microporous SSZ-13. The well-defined conventional microporous SSZ-13 zeolite crystal has pore size of 3.8 Angstrom which induces diffusion limitations. Introducing mesoporosity; i.e. pores larger than 2 nm, could provide fast adsorption/desorption kinetics alongside the desirable properties of zeolites such as the ability to work well at flue gas temperatures. In this study, we investigated the CO_2 adsorption efficiency of mesoporous SSZ-13 type zeolites.

2 Experimental/methodology

SSZ-13 was synthesised with the use of structure directing agent (SDA) trimethyl adamantyl ammonium hydroxide (TMAdOH). Mesoporous SSZ-13 type zeolites with different aluminium to silica ratios (20, 40) were synthesised by dual templating methods employing SDA and a mesopore generating template (octadecyl-(3-trimethoxysilylpropyl)-ammonium chloride - TPOAc) together [3]. Different template ratios were used to achieve varying degrees of mesoporosity throughout the material (mesoporogen/SDA: 4/20, 8/20 and 12/20). In addition, exchange of Na was performed to obtain Cu, Ca and K analogues along with the proton (H) form of the meso-SSZ-13 (TPOAc/TMAdOH: 8/20) zeolite. Materials were characterised for their structural and textural properties by XRD, N_2 physisorption, SEM and elemental compositions were determined by ICP-AES. CO_2 adsorption was carried out at ambient temperature and pressure by flowing CO_2 (4%) and N_2 (96%) through the adsorbent packed within a quartz tube. The inlet and the effluent CO_2 concentration were determined by a GC equipped with TCD. Adsorption/desorption cycles were carried out to investigate the regenerability of the sorbent.

3 Results and discussion

CO_2 adsorption experiments showed that the ratio of mesoporogen/SDA (TPOAC/TMAdOH) has a substantial effect on the CO_2 adsorption capacity. Na-meso-SSZ-13 prepared with 8/20 template ratio has 1.01 $mmol \cdot g^{-1}$ of adsorption capacity which is higher than that of meso-SSZ-13 (0.94 $mmol \cdot g^{-1}$) synthesized with 4/20 template ratio. Further increase in

mesopore generating template resulted in a higher still adsorption capacity (1.16 mmol·g^{-1} for 12/20 material). The trend in CO_2 adsorption capacity is in agreement with their mesoporous pore volumes and further increase in mesopore generating template results in more amorphous phase observed by XRD analysis suggests optimum synthesis conditions. Adsorption/desorption cycles have been carried out to investigate rate of sorption.

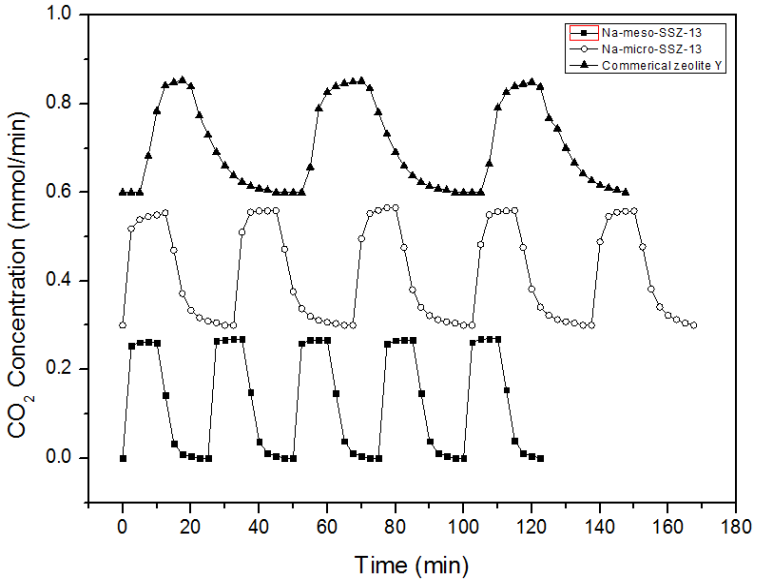

Figure 1. CO_2 breakthrough curves of microporous and mesoporous SSZ-13 compared with that of commercial zeolite Y

It has been observed that commercial zeolite Y has the highest CO_2 adsorption capacity which is 2.85 mmol·g^{-1}. This is substantially higher than the mesoporous SSZ-13 zeolites. However the benefit of introducing mesoporosity can be observed when the rate of adsorption is considered. Zeolite Y has a capture rate of 0.062 mmol·min^{-1}, on the other hand meso-SSZ-13 has 0.070 mmol·min^{-1}. CO_2 breakthrough curves of Na-micro-SSZ-13, Na-meso-SSZ-13 and zeolite Y are depicted in Figure 1. There was no loss of capacity or decrease in adsorption/desorption rate over longer period of time indicating the stability of the mesoporous materials. The faster adsorption/desorption is clearly the result of the introduction of mesopores, which allows fast diffusion of adsorbed gases. In the case of a large scale industrial operation, faster kinetics of mesoporous zeolites provide prospects of substantial savings by easing the requirements of high temperature (pressure) differences in TSA (PSA) cycles and thus decreasing the heating (pumping) costs for the same amount of CO_2 to be captured.

4 Conclusions

In this study we have successfully synthesized hierarchical mesoporous chabazite type zeolites and demonstrated their high potential as an adsorbent for CO_2 capture. The effect of degree of mesoporosity, Si/Al ratio, and the cation on the CO_2 adsorption will be presented.

Autocatalytic Fixation of Carbon Dioxide

Marakushev S.A.*, Belonogova O.V.

Institute of Problem of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Russia

* marak@cat.icp.ac.ru

Keywords: autocatalytic cycles, CO_2 fixation, organocatalysis, bifurcation points, reversibility

1 Introduction

Carbon dioxide conversion to organic chemical compounds is of great importance both in the chemical industry, and in carbon storage in ecosystems. This conversion requires activation of thermodynamically stable CO_2 by metal complexes in various redox states or by metalloenzymes. Recently, organocatalysts (containing no metals) have been intensely studied as coordination substrates for binding and activating CO_2. However, too little attention is paid to investigating chemical autocatalytic CO_2 fixation, a process occurring universally in chemosynthetic microorganisms. It is in autocatalytic cycles of CO_2 fixation that organocatalysis occurring really in nature can be observed.

2 Results and discussion

This paper deals with the origin and development of primitive ancient autocatalytic cycles of CO_2 fixation based on biomimetic combinatorial (modular) bicycles containing the general sequence of reactions intermediates (malate↔fumarate↔succinate) [1]. These three intermediate bicycle reactions are bifurcation points in the direction of specific cycles. The following reactions have succinate as a bifurcation point: (*a*) succinate → fumarate + H_2 ($f(\sigma_1)$ – 3-hydroxypropionate (3-HP) cycle) or (*b*) succinate + CO_2 + H_2 → 2-oxoglutarate + H_2O ($f(\sigma_1, \sigma_2)$ – reductive citrate (RC cycle), where σ_i are the homeostatic parameters of those transformations that may serve as a general characteristic for feedback systems, and $f(\sigma_i)$ is a homeostatic function that defines the reaction route. Here, the H_2 and CO_2 chemical potentials are homeostatic parameters σ_1 and σ_2, respectively. The decrease in H_2 chemical potential (reaction *a*) results in the formation of fumarate, which occurs independently of the CO_2 chemical potential, and the initiation of the 3-HP cycle ($f(\sigma_1)$). The increase in both H_2 and CO_2 chemical potentials (reaction *b*) forms 2-oxogutarate ($f(\sigma_1, \sigma_2)$) and initiates the RC cycle. This well-pronounced negative feedback of the autocatalytic bicycle causes its divergence into these two directions depending on the chemical potentials of the hydrothermal environment. These potentials are the driving forces for natural selection in autocatalytic proto-metabolic systems.

The kinetic irreversibility conditions (i.e., a large deviation from thermodynamic equilibrium used in self-reproduced chemical systems) cannot provide natural selection among autocatalysts [2, 3]. Natural selection only occurs if reaction reversibility and the autocatalyst A_i termination reaction are considered (Fig. 1):

$S + A_i \rightleftarrows 2A_i$ (k_i, k_{-i}) (1)

$A_i \rightarrow W$ (k_w) (2),

where S is a substrate, W is a waste product formed when autocatalyst A_i is irreversibly withdrawn from the autocatalytic cycle, and k_i, k_{-i} and k_w are the forward, reverse, and waste production rate constants, respectively, at the stages of autocatalyst amplification and autocatalyst termination.

A stationary state with positive A_i values is only possible if the reverse reaction (k_{-i}) is involved [4]. At the same time, kinetic irreversibility is necessary for autocatalyst termination (the formation of waste products). Several populations of autocatalysts can coexist at high stationary rate of substrate inflow, but a single population exists at a low rate and does not

disappear at any positive substrate flow [2]. It is considered that carbon fixation of CO_2 using the reducing power of hydrogen or that of less efficient reducing agents is not sufficient to bring about irreversibility [5], that clearly defines the need for the development of reversibility conditions (leading to competitiveness of different reactions of CO_2 fixation cycles).

The activation of thermodynamically stable CO_2 by organocatalysts (dicarboxylic, keto- and hydoxy acids, including phosphorylates compounds) and also metal organocomplexes in various redox states and the simultaneous development of theoretical concepts of autocatalytic coupled cycles of CO_2 fixation will make it possible to perform experimental chemical realization of such systems.

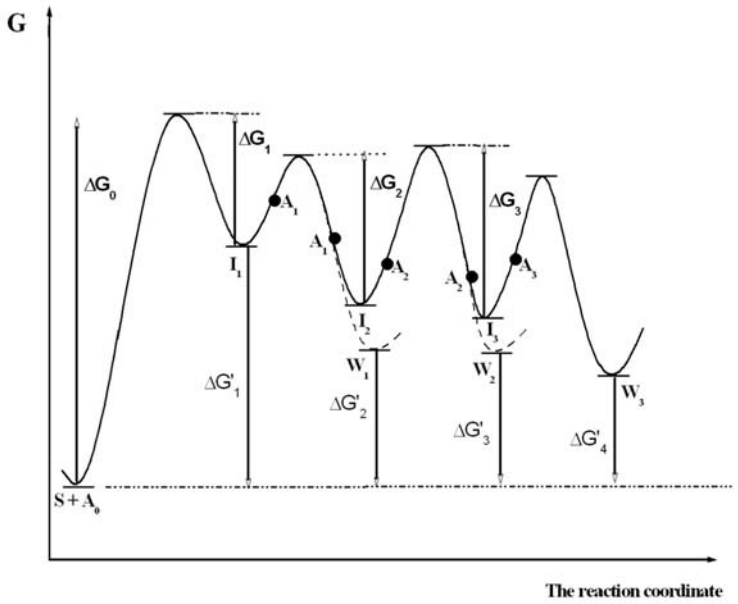

Fig. 1. The scheme of distribution of energy in the autocatalytic cycles. ΔG_0 - activation energy of the "initially" reaction; S – substrate, I_i – reactions intermediate, A_i – cycles autocatalyst, ΔG_1, ΔG_2, ΔG_3 – cost of reaction reversibility, $\Delta G'_1$, $\Delta G'_2$, $\Delta G'_3$, $\Delta G'_3$, $\Delta G'_4$ – cost of reaction irreversibility, W – waste product.

Surface Oxidation Mechanism of Pb-Based Materials by Utilization of CO_2 as an Oxidant

Calisan A., Uner D.*

Chemical Engineering Department, Middle East Technical University, Ankara, Turkey

* uner@metu.edu.tr

Keywords: Mars-Van Krevelen mechanism, shrinking core model, CO_2 reduction

1 Introduction

CO_2 sequestration is the key challenge of the 21st century chemical and energy production. Processes where CO_2 is used as a raw material for further chemical manufacture will probably be the ultimate goal of the carbon neutral technologies. The potential of CO as a syngas component increases the attention to chemical looping technologies where metal oxide is used as oxygen carrier. Mars and Van Krevelen (1954) described the principle of this mechanism as the vacancy created by the reaction is filled by a reactant atom from the bulk, rather than the gas phase [1]. Ceria fits Mars-Van Krevelen mechanism during dry reforming reactions since a series of surface reactions occur in the active sites. Ceria can supply oxygen from its lattice due to its high oxygen storage and transport capacity. The transported oxygen can be replaced by dissociation of CO_2. It is known that Ce^{3+} surface sites is active during the adsorption and activation of CO_2. [2]

2 Experimental/methodology

Technical grade metallic lead rods were used for the reaction tests. 495.9 gr metallic lead rods were put into reactor. The reactor and its oven was specially designed for the metal oxidation reactions. Oxidative gas was selected as CO_2 with a flow rated of 50ccpm. Reactor was heated with a rate of 8 ^oC/min. Product gas stream was sent to FT-IR's gas cell for continuous spectral measurement. A gas cell apparatus was installed to Perkin Elmer Spectrum 100 FT-IR Spectrometer for detection of change in product gas of the reactor output. CO formation rate was observed from change in molecular vibrational energy of product gas.

3 Results and discussion

The CO_2 was successfully reduced over Pb according to the reaction $Pb + CO_2 \rightleftharpoons PbO + CO$ as shown in Figure 1. The change in the wavelength 2000-2200cm^{-1} shows the evolved CO in the gas phase. The magnitude of the CO peaks increases as temperature increases. The first signals was observed after 100 ^oC. The magnitude of this signal is small and stays stable up to 400 ^oC. The CO formation increases between 400 and 800 ^oC. Reactor was kept isothermal when 800 ^oC was reached since previous experiments showed that the temperatures higher than 800 ^oC increases the possibility of thermal decomposition of formed lead oxide. After the experiment, samples were collected from the surface of oxidized lead. It was found that carbon deposits at the surface was detected from SEM/EDX analysis. The coke formation was believed to be the clue of Boudard reaction.

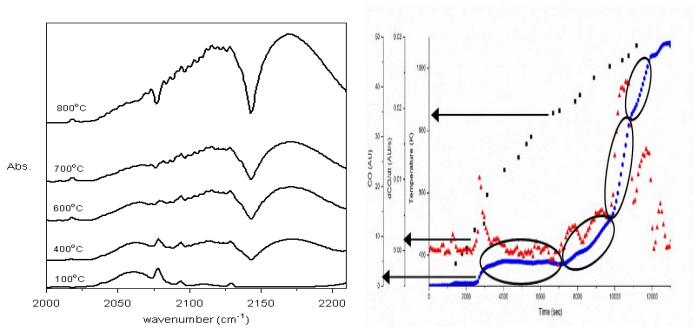

Figure 1: CO evolution band (left), CO formation as temperature increases (right)

Rate of the CO evolution was calculated in order to observe steps of CO_2 reduction steps. Mainly four periods were observed. 1st period was the longest stable period of the experiment. It was found that CO evolution rate was stable between 200 °C and 550°C. The periods 2nd to 4th shows the change in the rate of CO evolution period. Firstly, slow increase in the CO evolution was observed between 550 °C and 650°C. Then, CO formation increases rapidly up to 720 °C. The rate was getting slower up to 800 °C and became stable during the isothermal period.

It is assumed that shrinking core model fits the mechanism of Pb-based material oxidation. As the CO_2 is reduced by metallic lead, the thickness of the lead oxide layer increases. The thickness of the PbOx layer determines the magnitude of the diffusion resistance. In the mass transfer region, activation energy was estimated as $E_a = 120.9 kJ/mole$ as shown in Figure 2.

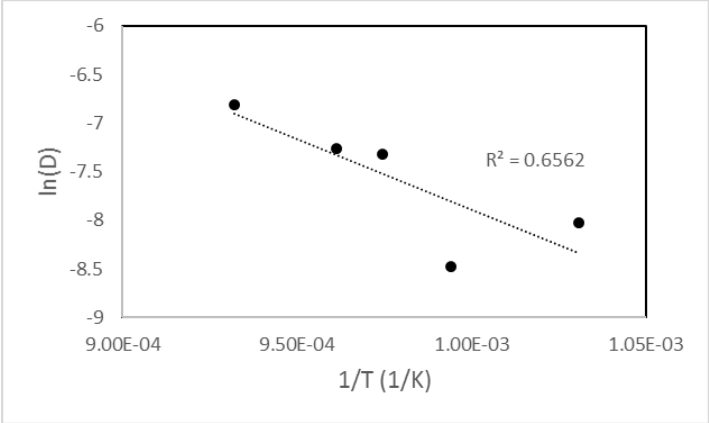

Figure 2: Activation energy estimation in mass transfer region

4 Conclusions

CO_2 reduction is increases considerably after 400°C. Formed CO was monitored by FTIR. Shrinking core model was applied to the FTIR data to find activation energy. By the assumption of mass transfer region, it is found that $E_a = 120.9 kJ/mole$ between 700 °C and 800 °C. Formed lead oxide was regenerated via thermal decomposition around 880°C. Mars and van Krevelen mechanism was proposed for the surface reaction between CO_2 and Pb. These studies encouraged that Mars and van Krevelen reaction rate can be applied for CO oxidation on PbO**.**

Keywords: supramolecular, catalysis, cationic, surfactant, micelle, microemulsion

1 Introduction

The catalysis of reactions in supramolecular systems based on surfactants is of current interest. The compartmentalization of reagents within nanosized micelles or microdrops results in a sharp increase in their local concentrations and affects their microenvironment thereby influencing their reactivity. This provides wide possibility for the control of the rate of ion-molecular reactions, namely hydrolytic cleavage of esters. These processes generally proceed in Stern layer of aggregates and dramatically depend on surfactant structure and charge, magnitude of the micellar surface potential.

In this work a comparative study of the aggregation behavior and catalytic effect on the rate of transfer of the phosphoryl and acyl group in different organized media based on cationic surfactant was carried out. To optimize the relationship between a structure and catalytic activity, it was investigated amphiphiles of varying nature, particularly mono- and dicationic surfactants with aromatic or heterocyclic moieties and different length of alkyl chain and spacer.

2 Experimental

The surface properties of the surfactants were studied on a K6 tensiometer (Kruss, Germany) using the Du Nouy ring detachment method at 25 ^{o}C. The bromide ion concentration in surfactant solution was determined using I-160MI ion meter equipped with a bromide-selective electrode. Average aggregate size and zeta potential were measured by dynamic and electrophoretic light scattering techniques (Malvern ZetaSizer Nano, Malvern Instruments, UK).

The surface potential was defined by the method of spectral probes. *p*-Nitrophenol was used as a probe. Acid-base properties of *p*-nitrophenol were studied by measuring the absorption of its ionized form at different pH values. The spectra were recorded on a Specord 250 Plus UV-VIS spectrophotometer in quartz cells

The reaction kinetics was studied spectrophotometrically on a Specord 250 Plus UV-VIS spectrophotometer in thermostated cuvettes. The reactions were monitored through changes of optical density of the solutions at the wavelength of 400 nm (formation of *p*-nitrophenolate anion).

3 Results and discussion

Aqueous micellar systems and oil-in-water microemulsions based on convenient and gemini cationic surfactants has been formed. Surfactant series with trialkylammonium, dimethylbenzilammonium and morpholinium head groups are involved in the study. Concentration boundaries of their existence and structural transitions of aggregates have been established. Quantitative parameters characterizing the aggregation behavior of the systems

(critical micelle concentrations, degree of counterion binding, aggregation numbers, the size and surface potentials) were obtained.

An important property of supramolecular systems determining their use in catalytic compositions is the ability to solubilize hydrophobic compounds. In this work, we studied the solubilization of nonpolar esters, dyes and spectral probes in the micellar solutions and microemulsions based on the cationic surfactants. Then we investigated their catalytic effect in the reaction of nucleophilic substitution. Micelles and microemulsions rate effect was studied toward to alkaline hydrolysis of *p*-nitrophenylic esters of carbonic acids (acetate, caprylate, caprinate, laurate, and myristate) and phosphorus acid esters. Changing the values of the observed rate constant of the esters hydrolysis were analyzed as a function of surfactants concentration, their structure and morphology of aggregates formed in the tested systems. Correlations between aggregation characteristics and reaction rate have been found. The most pronounced catalytic effect was observed for dicationic surfactants: maximal acceleration of *p*-nitrophenyl esters hydrolysis (up to 250 times) was observed at low concentration of surfactant within the area of existence of spheroid micelles. It was shown that surface potentials of the normal microemulsions are lower than those for the micellar solutions based on the same surfactant by ca. 100 mV. This is the main reason of the fact that rate constants of hydrolysis of esters are higher (by factor of 3–10) in micellar solutions as compared to microemulsions.

4 Conclusions

Supramolecular systems based on mono- and dicationic surfactants provide large opportunities for targeted design of systems with a high solubilizing capacity and controlling catalytic effect in ester bond cleavage. This makes it possible to recommend them for the wide application in chemical catalysis.

Keywords: triphenylphosphonium bromide, hydrolysis, phosphorus acid esters

1 Introduction

The biomimetic nature of micellar catalysis permits to achieve significant enhancement of reaction rate under mild conditions. The main factors determining the catalytic effect is a factor of the microenvironment change and increase the local concentration of reagents. The quantitative assessment of these parameters will shed light on the mechanism of the reaction. The most studied cationic surfactants in this context are alkyltrimethylammonium and alkylpyridinium halides. However, the change of the atom of the charged center and transition to surfactant with highly hindered head groups might have a significant impact on the catalytic effect. The aim of this work is the investigation of alkyltriphenylphosphonium bromides (TPPB) properties such as the solubilizing activity to the hydrophobic substrates and catalytic effect on the alkaline hydrolysis of phosphorus acid esters.

2 Experimental/methodology

The rate of substrate hydrolysis was monitored through changes in absorbance at 400 nm (the formation of p-nitrophenol anion) using the spectrophotometer Specord 250 Plus (Germany) in thermostated cuvettes with a pathway of 1.0 or 0.5 cm. The kinetic dependences processing was carried out using the Berezin equation and original computer programs. Aggregation numbers were calculated using pyrene (98%, Acros Organics) as a probe.

3 Results and discussion

It is well known that the transfer of a phosphoryl group is important in the processes taking part in an organism; therefore investigated phosphonium salts were tested as catalysts in the nucleophilic substitution reaction of p-nitrophenyl esters of alkylchloromethylphosphonic acid when the hydrophobicity of amphiphilic compound and substrate vary. A series of trimethylammonium bromides (TMAB) was studied under the same conditions for determining of head group role.

The kinetic curves of substrate hydrolysis have maximum that can be explained by the strong binding of the substrate with the micelles, which leads to transition of the substrate into aggregates at low concentrations of surfactant. Further increasing the concentration of the amphiphilic compound causes a growth in the number of micelles, and therefore the dilution of the reagents (decrease of the rate constant). The processing of kinetic dependence by Berezin equation allows to obtain rate constants in the micellar phase and the binding constants of the reactants.

4 Conclusions

The comparison of the results obtained for TPPB-series with the ammonium analogues was carried out. It was found that the higher the value of rate enhancement for TPPB achieved through concentration factor can be explained by the high aggregation activity.

Keywords: cerium, catalyst, bio-ethanol, ethylene

1 Introduction

Recently the attention of researchers is concentrated on bio-ethanol use, as the raw materials alternative to oil. From ethanol it is possible to receive by a catalytic method important chemical products as a divinyl, aromatic hydrocarbons, ethylene, hydrogen, etc. Large environmental friendliness, and also profitability of similar productions on condition of saturation of the industry products of biomass are caused by undoubted advantages in comparison with using as raw materials of an oil fraction, natural and casing-head gases.

Ethylene represents the considerable interest as raw materials for the production organic synthesis, from it receive more than 200 valuable connections the most important of which are ethyl chloride, ethylene dichloride-1,2, ethylene oxide, ethylene glycol and others.

Ethylene is received generally by a pyrolysis method as raw materials use the ethane, propane, butane containing in casing-head gases of oil production, gases of thermal and catalytic cracking, and also fluid hydrocarbons: natural gasoline and low-octane gasoline - naphthas fractions of straight distillation of oil. However this process endothermic also demands high temperatures of carrying out reaction. For ecological, and also economic reasons to use as a feed stock for receiving olefins of C_1-C_4 alcohols more actually [1,2].

Earlier the metal oxides (Cr, Cu and Ce) supported on various carriers (Al_2O_3, Al_2O_3HZS-5 and CaA) were investigated in the conversion of bio-ethanol to ethylene. The highest activity was exhibited by the catalyst Ce/γ-Al_2O_3. In this paper the influence of lanthanum oxide as modifying additives to structure Ce/γ-Al_2O_3 catalyst was investigated.

2 Experimental/methodology

The catalytic activity of the catalysts was studied in the flow regime using an inert gas medium in the 250–450°C range of temperatures with hourly space velocities (HSVs) of 1500–13000 h–1. The raw materials and the reaction products were determined using a gas chromatograph (GC-1000 LLC "Chromos"). The catalysts were prepared via incipient wetness impregnation of the support, followed by drying at room temperature and 300°C, with subsequent calcination at 500°C for 3 h. Before each experiment, the catalysts were reduced in a hydrogen flow for 1 h at 500°C and atmospheric pressure.

3 Results and discussion

The effect of lanthanum oxide on the catalyst activity Ce / γ-Al_2O_3 was investigated in the dehydration reaction of ethanol in the temperature range of 300 - 400C, at HSV = 6000 hr^{-1}. The results showed that at a reaction temperature of 350 °C a conversion of ethanol was 100%. The catalysts by activity in the dehydration of ethanol are located in a row: 3%Ce+1%La/γ-Al_2O_3 (C_{C2H4}= 96 vol.%) > 3%Ce+2%La/γ-Al_2O_3 > (C_{C2H4}= 93 vol.%) > 3%Ce+3%La/ɣAl_2O_3 (C_{C2H4}=

86 vol.%). The range activity of catalysts changes with increase of reaction temperature to 400°C: 3%Ce+3%La/γAl_2O_3 (C_{C2H4}= 98 vol.%) > 3%Ce+2%La/γ-Al_2O_3 (C_{C2H4}= 92 vol.%) > 3%Ce+1%La/γ-Al_2O_3 > (C_{C2H4}= 89 vol.%).

Textural characteristics of the developed catalysts were revealed by BET method. The results are presented in Table 1. The modifying of cerium catalyst by lanthanum (1 mass. % up to 3 mass. %) leads to increase of a specific surface area of the catalyst from 162 to 174 m^2/g. The phase composition of the catalysts was determined via electron microscopy. The results of electron microscopy showed that Ce/γ -Al_2O_3 catalyst characterized by formation a particles with 10 nm in size. Doping Ce/γ-Al_2O_3 with lanthanum increases the dispersion of the catalyst, but some aggregates of fine (2 nm) particles are observed in the aggregates, along with particles 10 nm in size.

Table 1. Textural characteristics of catalysts

Catalyst	Temperature of treatment	Surface Area /(m^2/g)	Pore volume /(cm^3/g)	Average pore size /nm
3% Ce/ Al_2O_3	500	133	0,079	2,36
3%Ce + 1%La /Al_2O_3	500	162	0,069	1,71
3%Ce+2%La /Al_2O_3	500	173	0,074	1,72
3%Ce+3%La /Al_2O_3	500	174	0,075	1,72

4 Conclusions

Thus doping Ce/γ-Al_2O_3 with lanthanum leads to formation of nanoparticles (2 nm) and to increase its surface area, thereby increasing the catalyst efficiency in the getting ethylene from bio-ethanol.

An *in-situ* FTIR-DRIFTS Study on Carbon Dioxide Reforming of Methane on Pt-Ni/Al_2O_3

Demirel S.E., Aksoylu A.E.*

Department of Chemical Engineering, Bogazici University, Istanbul, Turkey

* aksoylu@boun.edu.tr

Keywords: *in-situ* FTIR-DRIFTS, catalytic hydrogen production, dry reforming, heterogeneous catalysis

1 Introduction

Carbon dioxide reforming of methane (CDRM) is an important reaction for the utilization of the two major greenhouse gasses, namely methane and carbon dioxide [1].The aim of this work is to understand the routes and mechanistic steps of the CDRM reaction on the active sites of the Pt-Ni/Al_2O_3 bimetallic catalysts with different Ni:Pt ratios, which had been designed by our group and shown to have high activity and selectivity in CDRM reaction. The freshly reduced bimetallic catalysts with different Ni:Pt ratios, i.e. 0.2Pt-15Ni/Al_2O_3 and 0.3Pt-10Ni/Al_2O_3,were characterized by a detailed Fourier Transformed/Diffuse Reflectance Infrared (FTIR-DRIFT) analysis via using CO as a probe molecule in order to define the planes of the active phases present on the catalysts. In addition, FTIR-DRIFT analysis was performed under the flow of individual reactants (CO_2 and CH_4) and reactant mixtures, both at room temperature and at the highest possible temperatures which allow reliable operation of the FTIR-DRIFT cell, aiming to understand the adsorption properties of the reactants and to determine the species formed on the active sites during the CDRM reaction.

2 Experimental

The catalyst samples were firstly reduced *ex situ* at 773 K for 2 h under H_2 flow. The FTIR absorbance spectra were collected on a Bruker Vertex 70V equipped with a Mercury-Cadmium-Telluride (MCT) detector. The spectra were collected at a 4 cm^{-1} resolution in the 4000-600 cm^{-1} range. Ex situ reduced catalyst samples in a very fine powder form were diluted with dry KBr for improved S/N ratio. Prior to the tests, an *in-situ* catalyst pre-treatment was performed. First, sample was heated to 573 K under He flow. An *in-situ* reduction under a flow of %10 H_2/He at 573 K was performed for 1 hour followed by a He flush at 593 K for 1 h. The spectrum of the solid catalyst taken after the pre-treatment was subtracted from the spectrum of the catalyst obtained after exposure to the adsorption mixture. Individual adsorption and reaction experiments were conducted both at room temperature and at 573 K under 1% CO/He, 10% CH_4/He, 10% CO_2/He and 40%CO_2-40%CH_4-20%He mixtures.

3 Results and discussion

Investigation of the metal surface of both of the catalysts by CO adsorption at room temperature revealed that three bands, associated with CO interaction with alumina support, were observed over both catalysts (Fig.1 a-b). Those bands can be identified at around 2150, 1630 and 1360 cm^{-1}. Last two of those bands can be assigned to the carbonate species produced upon contact of CO with alumina support while the first one shows H-bonding of CO with surface hydroxyl groups of alumina on Al-ions [2-4]. As the Ni:Pt ratio decreased, bands around 2050 cm^{-1} became more prevalent, indicating that although it may be superimposed by the band of linear CO on Ni particles, there is also a band around 2050 cm^{-1} associated with the linear adsorption of CO on Pt sites. Peaks at 1850 cm^{-1} and 1929 cm^{-1} can be assigned to bridged CO

on Ni (111) and Ni (100) planes [4-5]. Those apparent peaks obtained at room temperature were diminished as the CO adsorption experiments were conducted at 573 K. The band around 2050 cm^{-1} was still observed on 0.3Pt-10Ni/Al_2O_3 indicating a significant interaction between CO and the catalytic surface, which is most probably strengthened by Pt via surface alloy formation.

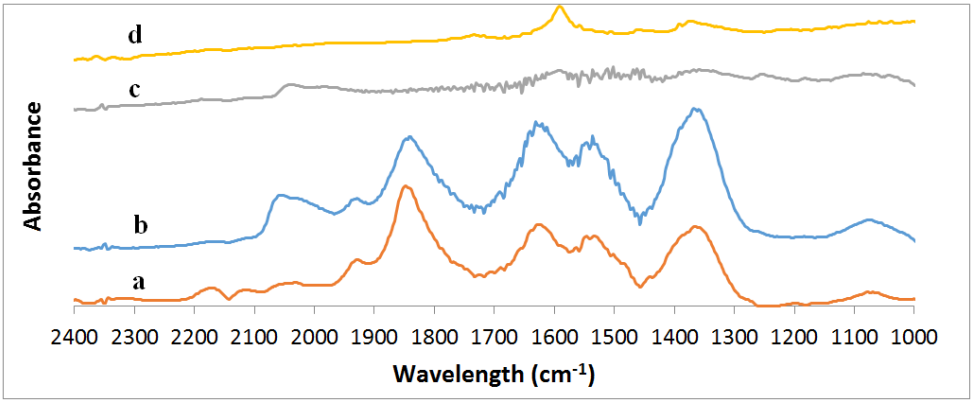

Fig. 1. Spectra obtained upon He flush following %1CO adsorption on: a) 0.2Pt15Ni at room temperature, b) 0.3Pt10Ni at room temperature, c) 0.3Pt10Ni at 573 K, d) 0.2Pt15Ni at 573 K.

In CO_2 and CH_4 adsorption experiments, bands around 1630, 1540 and 1360 cm^{-1} were still observed indicating that alumina support is an active support in dissociation of these reactants and in forming carbonate species (figures not shown). As the CO_2 adsorption test temperature was increased to 573 K, peak at 1540 cm^{-1}, associated with monodentate carbonate species, was strengthened. In CH_4 adsorption tests, C-H stretching band was observed at 3016 cm^{-1} both at room temperature and at 573 K. Although the bands related with carbonate species were weakened as the adsorption temperature was increased, bands were still significantly larger on the 0.3Pt-10Ni/Al_2O_3.

4 Conclusions

The results obtained from the in-situ FTIR-DRIFTS analysis revealed that Pt has a significant role on the structure of the active sites as well as on course of the reaction by both affecting the surface carbonate formation and CO adsorption mechanisms. FTIR-DRIFT results indicate that CO_2 activation/utilization is directly affected by the Ni:Pt ratio of the bimetallic catalysts.

Keywords: mixed reforming, catalytic syngas production, heterogeneous catalysis, CO_2 utilization

1 Introduction

Catalytic dry reforming of methane (CDRM) utilizes two major greenhouse gases (CO_2 and CH_4) in the process and produces syngas with more suitable H_2/CO ratio for further applications like Fischer-Tropsch synthesis, both of which have great importance for environmental and industrial aspects. There are two major drawbacks of CDRM process. CDRM is a highly endothermic reaction (800-900°C), which causes catalyst sintering. Additionally, methane cracking and Boudouard reactions creates carbon deposition which leads to catalyst deactivation. The drastic operating conditions impose the investigation on the development of new catalysts with improved stability and activity through preventing metal sintering and reducing coke formation. Stable CDRM activity is achieved when carbon formed at the methane dehydrogenation sites are cleaned by the surface oxygen formed from CO_2 disproportionation. Previous studies in our group have shown that Co-Ce/ZrO_2 has high activity with some activity loss due to coke formation [1, 2].CDRM catalysts that suffer from severe coke deposition may sustain stable and high activity when additional oxygen source other than CO_2 is present in the process [3].

The aim of this study was to investigate the mixed reforming performance of Co-Ce supported on ZrO_2 in a detailed fashion. In this context, CH_4:CO_2 ratio in the feed, the presence and amount of H_2O or O_2 in the feed stream and reaction temperature were considered as the experimental parameters. The effects of type and amount of additional oxygen source in mixed reforming on the oxidation states of the active phases, Co and Ce, were studied by XPS.

2 Experimental

Co-Ce catalyst was prepared by sequential impregnation. Co-Ce/ZrO_2 catalyst was calcined *in situ* in dry air (30 mL/min) for 4h at 773K and subsequently reduced *in situ* under H_2 flow (50 mL/min) for 2 h at 773 K as pre-treatment. CDRM + SR (Steam Reforming) mixed reforming performance tests were performed in a quartz down-flow micro-reactor at 873K, 923K and 973K with CH_4/CO_2 feed ratios of 2 and 1 and S/C ratios of 1 and 0.5. Feed and product streams were analysed by using an Agilent Technologies 6850 gas chromatograph (GC) equipped with a Thermal Conductivity Detector (TCD) and HayeSep D column. CDRM + POX (Partial Oxidation) mixed reforming performance tests were performed at 873K, 923K and 973K with CH_4/CO_2 feed ratios of 2 and 1, and for 4%, 7% and 10% O_2 concentrations in the feed. Feed and product streams were analysed by using an Agilent Technologies 6850 GC equipped with a TCD and Carboxen 1000 column. Freshly reduced and spent Co-Ce/ZrO_2 samples were characterized using X-Ray Photoelectron Spectroscopy (XPS), and the oxidation states of the metallic species present on the catalysts were analysed.

3 Results and discussion

The effects of temperature, CH_4/CO_2 feed ratio, additional oxygen source type and its

concentration in the feed were investigated; as an example, the effects of steam/carbon feed ratio and temperature on methane conversion in CDRM+SR is presented in Figure 1.

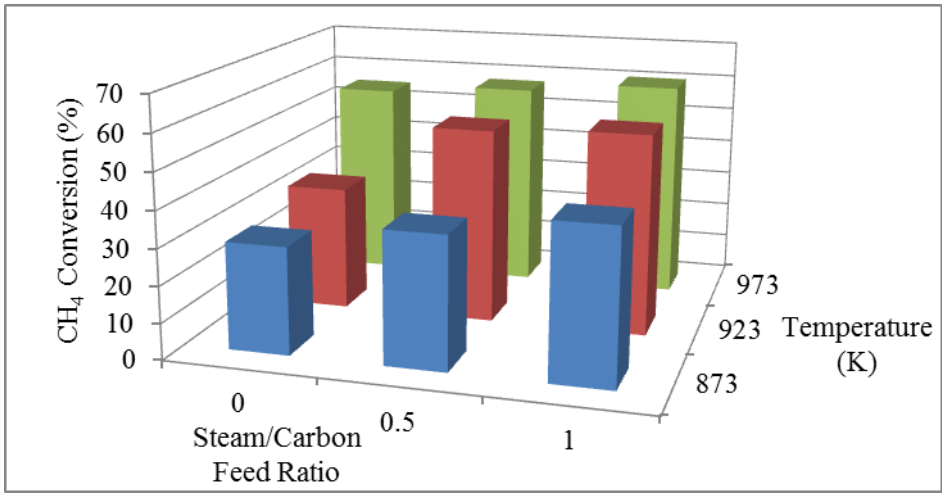

Fig. 1. CH_4 at the end of 6 h TOS conversion values obtained for CH_4/CO_2 feed ratio of 2.

As CDRM is favored at higher temperatures due to its extreme endothermicity, mixed reforming activity was increased with increasing temperature. Co-Ce catalyst has improved stability in mixed reforming compared to those in individual CDRM. The possibility of controlling the H_2/CO product ratio and reaching the same activity, i.e. methane conversion, at lower temperatures are the other advantages of mixed reforming over CDRM. The results showed that methane conversion increased with decreasing CH_4/CO_2 feed ratio indicating the additional methane was not fully utilized by the catalyst. Another advantage of using low CH_4/CO_2 ratio in mixed reforming was suppressing H_2/CO ratio close to unity. In CDRM + POX, the H_2/CO product ratio was constant and close to unity for the whole temperature range, whereas in CDRM+SR, the H_2/CO product ratio was pushed close to unity at high temperatures. The additional oxygen source, steam or oxygen, did not have a significant effect on activity, i.e. CH_4 and CO_2 conversion values. XPS analyses on spent samples showed that the presence and type of the additional oxygen source has a non-negligible effect on the oxidation states of the active phases.

4 Conclusions

The results showed that H_2/CO product ratio can be controlled, and the addition of steam or oxygen improved overall performance and stability in mixed reforming compared to those in individual CDRM. In CDRM + POX mixed reforming, the H_2/CO product selectivity was much closer to unity than that in CDRM + SR mixed reforming.

Keywords: Cu-ZSM-5 copper, peroxocomplex copper, oxocomplex, UV-Vis spectroscopy

1 Introduction

All methanotrops produce a copper-containing monooxygenase. There is a binuclear copper complex that is able to reversible oxidation/reduction cycle from Cu(I) to Cu(II) as well as to a oxygen activation. So, elucidation of the oxygen activation pathways are very important for the understanding the mechanism of oxidative action of monooxygenase type enzymes. The Cu-containing zeolites [1] are of interest for biomimetic approach due to the square-plain coordination of Cu(II) ions in copper oxide/hydroxide clusters and nanoparticles [2], easy transformation Cu(I) – Cu(II) [3], and formation of α–like site [1,4].

Here the DR UV-Vis spectroscopy was used to reveal condition where a peroxo/oxo complexes copper (II) are formed in CuZSM-5 catalysts.

2 Experimental

Two samples of Cu-ZSM-5 were prepared by ion-exchange of H-ZSM-5 with aqueous and ammonia solution of copper acetate, at room temperature. After 48 hours, the zeolite samples were filtered and washed with distilled water. The samples were dried and calcined in air at 500°C. The copper content was 1 and 2.8 wt.%, respectively.

Capacity of Cu-ZSM-5 to stabilize the oxo/peroxocomplexes was studied using activation in hydrogen peroxide (solid/solution) and in O_2 atmosphere (solid/gas).

For activation in H_2O_2, the Cu-ZSM-5 sample (pellets of 0.1-0.25 mm) was placed into the quartz cell and treated by 1M solution of H_2O_2 or solution containing 1M H_2O_2 with 0.01 or 0.02 M NaOH. The weight ratio of zeolite to solution was 1/3.

For activation in O_2, the Cu-ZSM-5 sample (pellets of 0.1-0.25 mm) was placed into the home-made UV-Vis DR quartz cell, evacuated into vacuum at 25°C and treated in 250 mbar of O_2 at 400°C.

For alternative pathway, the sample was evacuated into the UV-Vis DR cell at 400°C, after that 130 mbar of oxygen was added.

UV-Vis DR spectra of Cu-ZSM-5 were obtained at room temperature using a Shimadzu UV-2501 PC spectrophotometer equipped with a diffuse reflectance accessory (ISR-240 A).

3 Results and discussion

The square-plain copper-oxide structure is found to form peroxocomplexes at adding of hydrogen peroxide. This reaction takes place mainly in alkaline solution with pH 10 and above. The square-plain copper-oxide structure are present in the over-exchanged Cu-ZSM-5 and formed from isolated Cu(II) ions at treatment of the under-exchanged Cu-ZSM-5 by sodium hydroxide solution. Peroxocomplexes dicopper(II) over external surface and inside channels of Cu-ZSM-5 contain two Cu(II) ions bonding through terminal OOH-group and bridged OO-

group. They observed as ligand to metal charge transfer band (CTB L-M) at 21500 and 26500 cm^{-1} of DR UV-Vis spectra, respectively (Fig.1, C.3). They are similar to peroxocomplexes copper(II) in homogeneous copper nitrate solution and colloid solution of $Cu(OH)_2$ [2]. Over Cu-ZSM-5, they are gradual destroyed, and more stable terminal complex CuOOH (35500 cm^{-1}) is formed. The latter was observed by UV-Vis DR even after a drying of Cu-ZSM-5.

Unlike previously observed in [3], UV-Vis DR bands at 22000 and 28000 cm^{-1} attributed to Cu-dimers [3] were not observed in the our CuZSM-5 activated under 1st oxidizing conditions (Fig. 2, C.2). However, weakly intensive a.b. at 22500 and 27900 cm^{-1} appeared in UV-Vis DR spectra after activation of CuZSM-5 in vacuum at 400°C (Fig.2, C.3). The absorbance at 22500 cm^{-1} became stronger under subsequent high-temperature calcination of vacuum-dehydrated Cu-ZSM-5 in oxidizing atmosphere (2^d mode, Fig.2, C.4). Similar changes in the UV-Vis DR spectra of Cu-MFI were observed previously by Praliaud [5] and Teraoka [6]. They connected UV-Vis DR band at 22500 cm^{-1} with reoxidation of Cu^+ ions of nearby Cu^{2+}-Cu^+ or Cu^+-Cu^+ and attributed its to CTB L→M in copper dimer bridged by extra-lattice oxygen [5,6]. Such copper pairs have to be formed due to reduction by vacuum of Cu^{2+}-ions in structures with extra-lattice oxygen, for example in dimer, chain-like and square-planar copper-oxide structures.

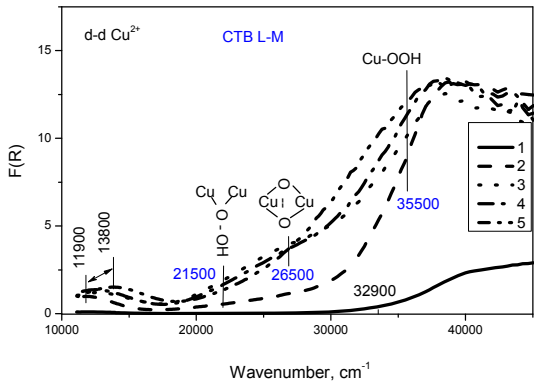

Fig. 1. UV-Vis DR spectra of 1%Cu-ZSM-5-30 before (1) and after adding 1M solution of H_2O_2 (2), 1M solution of H_2O_2 with 0.01 or 0.02 M NaOH (3 and 4) in 10 min and in 5 hrs (5).

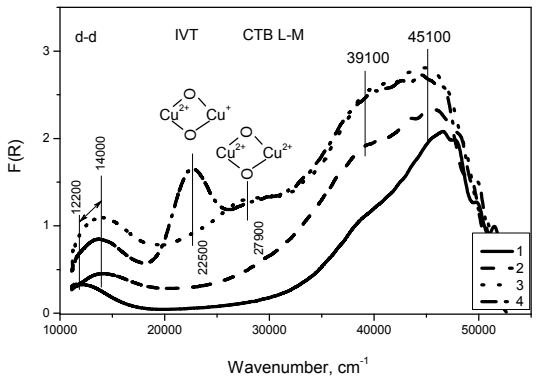

Fig. 2. UV-Vis DR spectra of 2.8%Cu-ZSM-5 before (1) and after dehydration at 400°C in O_2 (static condition, 2), in vacuum (3), and the latter after subsequent oxidizing treatment (4).

4 Conclusions

Cu-ZSM-5 possess the capability to stabilize copper(II) pero/oxocomplexes at treatment by hydrogen peroxide in alkaline solution as well as high-temperature calcination in O_2-containing atmosphere. Peroxocomplexes copper(II) characterized by CTB L-M 21500 and 35500 cm^{-1} could be considered as structural model of active site of hemocyanine and dopamine monooxygenase containing two copper ions located near and long distance, respectively.

Keywords: glass-fiber catalyst, hydrogen sulphide, selective oxidation, vanadia, iron, oxide

1 Introduction

Improvement of the sulfur recovery degree in Claus plants is a traditionally important environmental protection task in the processing of natural gas and oil. The optimization potential of existing Claus units in this respect is practically exhausted. Hence, the main tool for efficiency increase of sulfur recovery over the last few decades is the application of Claus tail gas clean-up processes [1]. Among these processes, the technologies based on selective catalytic oxidation of hydrogen sulfide into sulfur by oxygen are worthy mentioning [1,2] These processes use the catalysts on the base of iron oxides, which are characterized with high H_2S oxidation selectivity into sulfur. However, these catalysts have rather low activity, especially, at temperatures below 200ºC. Another important challenge in this area is development of the catalyst with enhanced mass transfer properties.

One of the promising directions of development in this area includes application of the catalysts on the base of the flexible micro-fibrous supports, e.g., glass fibers. Glass-fiber catalyst (GFC) is a relatively new type of catalytic systems, where the support represents itself the glass microfibers, structured in form of threads in the woven or knitted fabrics. The possible active components may include noble metals and/or oxides of transient metals, depending upon the requirements of the target catalytic process [3,4]. The glass-fiber catalysts (GFCs) may be structured in a form of cartridges, characterized with a low pressure drop [5] and extremely low mass transfer limitations [6]. In our recent study [3] we have demonstrated that GFCs, containing vanadia supported at glass-fiber fabric covered by an external layer of porous silica provide high activity in the low-temperature area and acceptable selectivity in H_2S oxidation reaction.

This study was dedicated to more wide screening of glass-fiber catalysts for this reaction.

2 GFC preparation and testing

The samples of glass-fiber catalysts were prepared by means of impulse surface thermo-synthesis IST method [7]. The preparation included the supporting of the thin layer of porous SiO_2 at the external surface of glass micro-fibers with following impregnation of this layer with solution of the active component precursor and fuel additive [4]. The list of active components included vanadia (4 and 8% mass V) and iron oxide (1 and 2% Fe), as the most active (V_2O_5) and most selective (Fe_2O_3) oxides in the target reaction, as well as copper chromite (2.5% Cu, 4.4% Cr), which was also considered earlier as an efficient catalyst for H_2S oxidation [8]. The value of the unit surface area in these samples varied in the range of 10-30 m^2/g. Commercial $FeOx/Al_2O_3$ (10% mass Fe, 110 m^2/g) catalyst was taken as the reference.

The samples were tested in H_2S oxidation reaction in the gas mixture, containing 1% vol. of

H_2S, 1% O_2 and helium as balance. Gas flow rate was equal to 1.5 ml/sec per g of catalyst. The temperature was varied in the range 175-250ºC. The results are given in the Fig.1

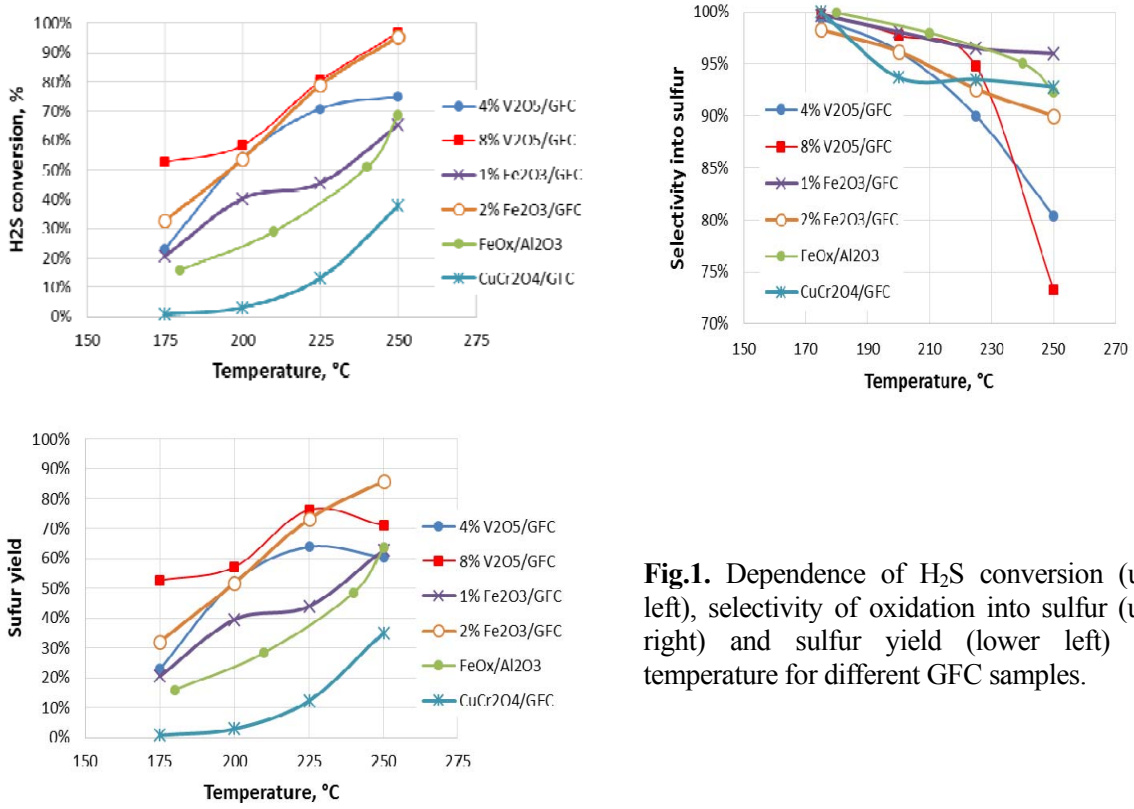

Fig.1. Dependence of H_2S conversion (upper left), selectivity of oxidation into sulfur (upper right) and sulfur yield (lower left) upon temperature for different GFC samples.

All vanadia and iron samples showed rather high oxidation activity, significantly exceeding that for conventional catalyst. Notably, Fe/GFC is much more active than conventional Fe/Al_2O_3 despite the much lower content of iron oxide. Cu-Cr catalyst has demonstrated much lower activity. The vanadia catalysts appeared to be more active, than iron ones, but less selective, especially at high temperatures. According to sulphur yield data (yield = H_2S conversion x selectivity) the most promising are the GFC containing V_2O_5 and Fe_2O_3. Vanadia provides better performance at lower temperatures while the iron oxide GFC is advantageous at higher temperatures. These catalysts may be recommended for practical application both separately and in combination.

Keywords: photocatalysis, titania, CO oxidation, Pt, Pd, Au nanoparticles

1 Introduction

Photocatalytic oxidation (PCO) processes have being intensively studied for the treatment of polluted water and air in recent decades. In particular, many types of volatile organic compounds (VOCs) could be completely decomposed over TiO_2-based photocatalysts under ambient conditions [1-3]. In addition to VOCs, carbon monoxide is one of the major air pollutants [4]. Also, CO can be produced as a final oxidation product together with CO_2 and water in the PCO of organic compounds.

The main drawback of unmodified TiO_2 photocatalyst is very low activity in the photocatalytic oxidation of carbon monoxide due to the low adsorption of CO on the TiO_2 surface. It is known that deposition of noble metals, such as Pt, Pd, Au, on the TiO_2 surface increases the CO chemisorption and thus can lead to increased activity of TiO_2 in the reaction of CO photocatalytic oxidation. Therefore, this work aims to synthesize TiO_2 photocatalysts modified by noble metals and to investigate their photocatalytic activity in the reaction of CO oxidation under UV irradiation.

2 Experimental/methodology

M/TiO_2 photocatalysts were prepared by deposition precipitation method. Typically, 2 g TiO_2 Hombifine N (100% anatase, S_{BET} ~ 350 m^2/g) were suspended in 30 ml distilled water and certain aliquot of aqueous solutions of metal precursor (H_2PtCl_6 or $HAuCl_4$ or $PdCl_2$) was added. To reduce metal precursor to metal, threefold excess of $NaBH_4$ was added into solution. The content of noble metal in M/TiO_2 samples was measured the X-ray fluorescence analysis using the ARL spectrometer with rhodium anode.

Kinetic experiments were carried out in a static reactor installed in the cell compartment of FT-IR spectrometer Vector 22 (Bruker, Germany). Typically, the samples were uniformly deposited onto the glass support to obtain layer with surface density equaled 1 mg/cm^2 and irradiated by high performance UV LED (Nichia, Japan) with λ_{max} ~373 nm. Concentrations of CO and CO_2 in the gas phase during the reaction were determined by FT-IR analysis using the Beer-Lambert law. Photocatalytic activity of samples synthesized was estimated as initial rate of CO_2 formation calculated by linearization of initial part of CO_2 accumulation kinetic curve.

3 Results and discussion

Three series of M/TiO_2 with M content varied from 0.01 to 4.0 wt. % were synthesized. The results of X-ray fluorescence analysis showed that the amount of M (Pt, Pd or Au) in the synthesized catalysts were close to calculated values.

Modified TiO_2 samples were tested in the reaction of CO oxidation at ambient conditions with or without UV irradiation. The rate of CO oxidation under UV irradiation was 1.5-5 times greater than the rate of oxidation without lighting if we compare the different metals used for

modification. It indicates that light energy can be used instead of thermal energy to increase the rate of CO oxidation over such type of catalyst.

Kinetic curves of CO removal in the case of TiO_2 samples modified by Pt, Pd or Au with 0.5 wt.% content are presented in the Fig. 1. The Pt/TiO_2 sample showed the best activity and fast conversion of 850 ppm CO to CO_2.

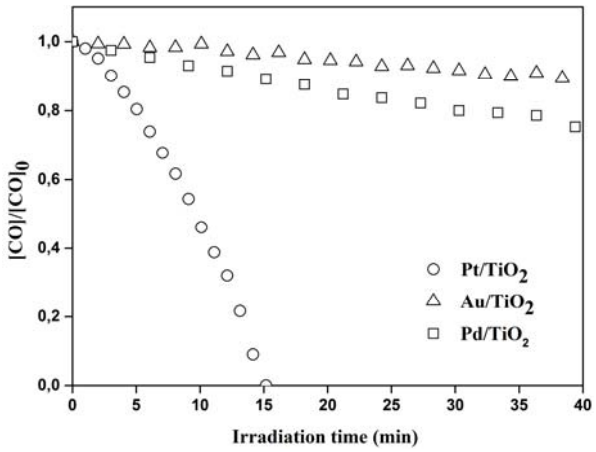

Fig. 1. Kinetic curves of CO removal during the PCO over TiO_2 catalyst modified by 0.5 wt.% Pt, Pd or Au.

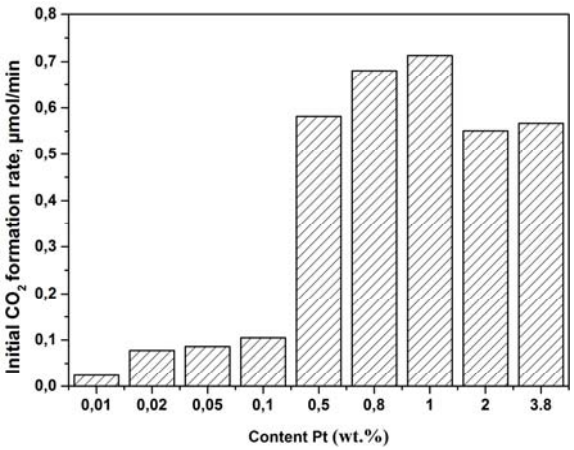

Fig. 2. Dependence of the initial rate of CO_2 formation during the PCO on the Pt content in Pt/TiO_2 photocatalysts.

The dependence of the CO oxidation rate on noble metal content in the catalysts was investigated. In the case of Pt/TiO_2 and Pd/TiO_2 samples activity increased with increase in the metal content up to an optimum level: 1 wt.% for Pt/TiO_2 and 0.05 wt.% for Pd/TiO_2 (Fig. 2). In contrast, Au/TiO_2 samples revealed lower activity and there was no clear dependency on the Au content. This seems to be due to the fact that the activity of Au-containing catalyst is highly dependent on the preparation technique.

4 Conclusions

The deposition of noble metals (Pt, Pd or Au) on TiO_2 by impregnation and subsequent chemical reduction of precursor compounds allows us to synthesize catalysts active in CO photooxidation.

The kinetics of the CO oxidation in the static reactor over synthesized catalysts with or without UV irradiation was investigated by IR spectroscopy. The rate of CO oxidation under UV irradiation 1.5-5 times greater than the rate of oxidation without irradiation depending on the metal used.

The optimum metal content in Pt/TiO_2 and Pd/TiO_2 samples corresponded to the highest photocatalytic activity in the CO oxidation was observed. In the case of Au/TiO_2 samples CO oxidation rate had no clearly defined by the Au content. The rate of CO oxidation for the most active sample in each series increases in the following sequence: $Au/TiO_2<Pd/TiO_2<Pt/TiO_2$, wherein Pt-containing sample in 6-fold more active compared to other samples.

Keywords: automotive catalyst, thermal stability, pulse, chemisorption, TPD, TPR, TPO

1 Introduction

Automotive exhaust catalysis is one of the most socially important technologies contributing on a global level to environmental protection. With tighter emissions standards, exhaust gas aftertreatment catalysts have to provide improved efficiency and robustness, including high resistance to thermal deactivation. It is important for engineers to be able to analyse catalysts failures etc. very efficiently in terms of time and resources spent. In this work, thermal stability of selected automotive exhaust catalysts (TWC, LNT, SCR) was characterized using laboratory flow reactor chemisorption methods. The work was performed at Ford Research Centre in Aachen (Germany).

2 Experimental

To prepare samples of the catalysts, pieces cut from the full-size catalysts were crashed and sieved; fraction of 0.25-0.50 mm (in some cases - > 0.5 mm) was used for experiments.

Experiments were performed with Autochem II 2920 machine (Micromeritics), using methods:

1. Pulse chemisorption of CO
2. Temperature-Programmed Reduction (H_2-TPR)
3. Temperature-Programmed Oxidation (O_2-TPO)
4. Temperature-Programmed Desorption of ammonia (NH_3 TPD)

Data were processed with standard routines, and using Matlab scripts developed by the authors.

To investigate thermal stability, samples of LNT or SCR catalysts were calcined at selected temperature, and then characterized with above mentioned methods. Then, the same procedure was repeated, but each time with increased calcination temperature. Calcination temperatures in a range of 600 to 900 (1000°C) were applied for LNT (SCR) catalysts characterization, correspondingly.

Pulse chemisorption was performed at 35°C using pulses of 10% CO in He for pre-reduced sample. Temperature-Programmed Reduction (TPR) was performed in 10% H_2-Ar, starting from 40°C and as a rule - up to calcination temperature. Temperature-Programmed Oxidation (TPO) was performed in 2% O_2-He for the sample that was reduced in the TPR run, after cooling it down to 40°C in He. To prepare samples for NH_3 TPD experiments, after calcination, they were cooled down to 120°C in He and treated 30 min in 15% NH_3-He flow. TPD run itself was then performed with rate of 10°C/min started from 120°C up to calcination temperature used on a given step.

In all experiments described above, response of the system was measured with TCD, and all following calculations were made based on the detector calibrations to corresponding components.

3 Results and discussion

Thermal aging of the LNT studied with CO pulse chemisorption and TPR/O. Evolution of the LNT (diesel prototype catalyst was used) properties after consecutive calcinations at 600, 700, 800 and 900°C displayed the following main TPR features:

- In the low-temperature region (<~250°C), H_2 consumption was very sensitive to the

calcination temperature, and correlated with the amount of chemisorbed CO at 35°C.

- In the mid-temperature region (~250-~600°C), H_2 consumption was also quite sensitive to the pretreatment temperature, being lower with increasing aging temperature.
- In the High-temperature region (above ca. 600°C), H_2 consumption in TPR run is nearly insensitive to calcination temperature (i.e., to aging/sintering).

Several surface and bulk species and corresponding processes for their reduction/oxidation were proposed while interpreting the results measured with pulse chemisorption, TPR and TPO. Tentative mechanism of thermal deactivation of the LNT was suggested.

Measured results clearly show that temperature limit for absolutely safe LNT operation is 700°C; excursions to 800°C result in slow deactivation; above 800°C sintering/active sites lost become faster; above 900°C deactivation is very fast. Corresponding recommendations for temperature regimes of the LNT were given.

Thermal Aging of the SCR catalyst studied with ammonia TPD. Efficiency of the SCR catalyst in NH_3-NO_x reaction measured in the laboratory flow reactor, as a function of the pretreatment temperature showed decrease after pretreatment of the catalyst at 900°C.

Catalytic activity of the Me-zeolite SCR catalysts is known to be strongly related to its adsorption capacity towards ammonia, and to its temperature dependence.

Investigating thermal deactivation of SCR catalyst consisted in pre-treatments of the SCR catalyst at 600…1000°C and recording of the NH_3 TPD profile after each pre-treatment.

It was found that critical temperature for keeping initial level of ammonia adsorption is ca. 900°C. Above 900°C, amount of the NH_3 adsorbed by the catalyst at 120°C decreased sharply. After 1000°C, NH_3 adsorption capacity dropped 10-fold versus fresh SCR catalyst.

The results of the TPD set were in reasonable agreement with catalytic performance results. Interpretation to the features observed in NH_3 TPD profiles were made, including discussing different adsorbed ammonia species.

Based on the results of the current study, corresponding recommendations for temperature regimes of the SCR catalyst were developed.

Analysis of the In-Field failed (IFF) Three-Way Catalyst (TWC). In-field failed three-way catalyst was investigated using pulse chemisorption and H_2 TPR technique. Fresh catalyst and oven-aged catalyst were also investigated in parallel.

Pulse chemisorption showed that IFF and oven-aged TWC have 2 orders of magnitude lower PGM dispersion compared to fresh sample.

At least 5 features were distinguished in measured TPR profiles. These features in H_2 TPR profiles were interpreted using results available in literature.

With ageing, PGM and support oxides were sintering thus drastically changing TPR profile, with appearance or disappearance of some TPR peaks. Key features in the TPR profile were distinguished that can be used as indicators for evaluating degree of ageing TWC.

4 Conclusions

In the presented work, applications of the chemisorption methods (pulse chemisorption, Temperature-programmed desorption (TPD), reduction (TPR) and oxidation (TPO)) to characterization of the thermal aging of the automotive exhaust catalysts, was described.

Pulse chemisorption and TPR were applied to study deactivation of the LNT catalyst. Relatively safe rich operation temperature for LNT was found to be ca. 800°C. Above this temperature, rapid irreversible deactivation due to PGM and support sintering were taking place.

For evaluated NH_3 SCR catalyst, ammonia TPD study helped to determine not-to-exceed temperature of ca. 900°C. Above this temperature, there is a high probability that zeolite will undergo destruction, so all NH_3 SCR reaction related properties will be irreversibly lost.

For the sample of the in-field failed three-way catalyst, temperature of the exposure was deducted based on the characterization of the catalyst with CO pulse chemisorption and TPR.

Keywords: mechanistics studies of dehydrogenation, propane, isobutane

1 Introduction

Non-oxidative dehydrogenation (DH) of propane and isobutane are established commercial processes for on-demand production of the corresponding olefins employing supported CrO_x or Pt-Sn catalysts. The active components have disadvantages of being toxic and expensive respectively. We have recently demonstrated that supported VO_x constitute a suitable alternative for propene DH catalysts . In the current study, we investigated their potential for isobutane DH and compare their performance to that in propane DH. In particularly, we focused on finding correlations between structural characteristics of VO_x species, acidic properties of supports and coke formation.

2 Experimental

The catalysts were prepared by grafting $VO(acac)_2$ onto silica (MCM-41), Siral® (Sasol) aluminosilicates with various SiO_2 content and alumina . They are further abbreviated as V/Si for VO_x/MCM-41, V/S1 for VO_x/Siral 1 with 1 wt.% SiO_2 and by analogy for other Sirals, V/Al-LS and V/Al-HS for VO_x/Al_2O_3-NorPro (low surface) and VO_x/Al_2O_3-Chempur (high surface) respectively. The index before the abbreviation stands for V content in wt.%.

For operando catalysts characterization, we used an in-house designed setup containing 5 continuous-flow fixed-bed reactors equipped with temperature-resistant UV-vis probes. Brønsted and Lewis acidity of the catalysts was determined by in situ IR pyridine adsorption. All catalytic tests were carried out at 550 °C in an in-house developed setup containing 15 continuous-flow fixed-bed reactors operating in parallel. The amount of coke on spent catalysts was determined in the temperature-programmed oxidation experiments performed in a setup containing 8 individually heated continuous-flow fixed-bed reactors . In situ thermogravimetric (TG) experiments were performed in SETSYS Evolution (Setaram) thermobalance. Rate constants of coke formation and catalyst deactivation were derived from evaluation of TG and catalytic tests with in-house developed software respectively.

3 Results and Discussion

The VO_x/SiO_2-Al_2O_3 catalysts showed different initial activity, propene selectivity and on-stream stability depending on SiO_2 content: 5V/Si was the most stable and selective while 3V/Al-LS was the fastest to deactivate . We also found that these catalyst characteristics are influenced by degree of polymerization of VO_x species. To understand the origins of different on-stream stability of the catalysts, the rate constants of catalyst deactivation (k_{deac}) and carbon deposition (k_{coke}) were obtained from kinetic evaluation of catalytic and in situ TG experiments . Unexpectedly, we did not observe any relation between catalysts acidity and k_{coke} or k_{deac}. Instead, these constants were found to correlate with VO_x polymerization degree. The latter was estimated from edge energy (E_{Edge}) of VO_x species derived from

UV-vis spectra: higher polymerized species have lower E_{Edge}. When k_{coke} and k_{deac} are plotted vs. E_{Edge} (Fig.1), it becomes evident that coke formation, and likewise catalyst deactivation, soars with rising degree of VO_x polymerization. This relation was verified in separate tests where conversion of propene (coke precursor) over 3V/Al-LS, 4V/S10 and 5V/Si was studied. The catalysts were selected as carrying large, medium and small VO_x species respectively and gave the initial rates of carbon formation [mg(C)g(V)$^{-1}$min^{-1}] of 1150, 800 and 650. Presumably, adsorbed C_3H_6 molecules have higher chances to react with each other and form surface carbonaceous species on larger VO_x particles.

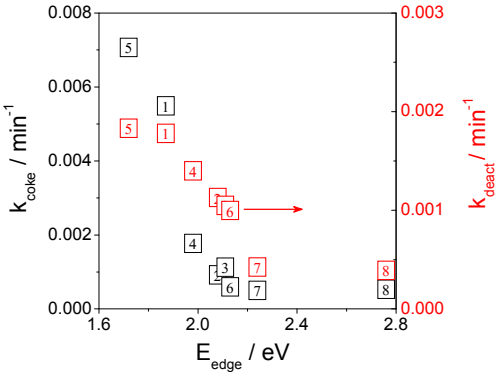

Fig. 1. Catalyst deactivation (k_{deact}) and coke deposition (k_{coke}) rate constants vs. edge energy. 1 - 3V/Al-LS, 2 - 4V/S1, 3 - 4V/S10, 4 - 6V/S10, 5 - 13V/S10, 6 - 5V/S40, 7 - 5V/S70, 8 - 5V/Si

Similarly to propane DH, 5V/Si was the most stable in isobutane DH, while 2V/Al-HS and 4V/S10 deactivated faster. However, 2V/Al-HS showed the lowest selectivity to carbon (S_C). Also, the selectivity to isobutene ($S_{isobutene}$) on 2V/Al-HS was always higher than on 4V/S10 and 4V/Si and was less sensitive to isobutane conversion ($X_{isobutane}$) than on 4V/S10 and 4V/Si (Fig. 2). Lower $S_{isobutene}$ on the two latter catalysts stems from their high activity for isobutene isomerization to n-butenes. To study pathways of coke formation, the coke precursors, isobutene and n-butene, were converted over the catalysts. 2V/Al-HS exhibited by far the highest selectivity to coke in these reactions. These results suggest that large VO_x species on Al_2O_3 are still very active in coke formation, but isobutene conversion to coke is suppressed under isobutane DH conditions, because the olefin and the alkane compete for the same sites. Conversion of n-butene into coke apparently proceeds faster than of isobutene. It involves DH of n-butene into butadiene and its further conversion into coke, possibly through Diels-Alder cyclization, on sites other than active in DH. Isomerization of isobutene into n-butene over 2V/Al-HS is slow compared to 4V/S10 and 4V/Si, thus carbon deposition through a faster route is suppressed over 2V/Al-HS for a shortage of coke precursor.

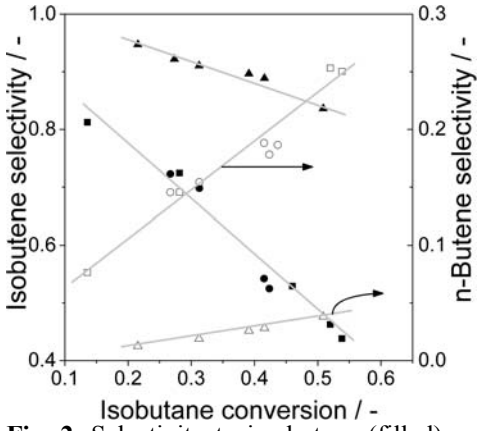

Fig. 2. Selectivity to iso-butene (filled) and to n-butenes (plain) vs. conversion of isobutane. ▲ - 2V/Al-HS, ● - 4V/S10, ■ - 4V/Si.

In summary, the results obtained so far indicate that higher degree of polymerization of supported VO_x species promotes consecutive reactions of C_3-C_4 olefins resulting in carbon deposits. Yet, ability of isobutene to transform into n-butenes opens new and swift path to higher byproducts and eventually coke. Hence, optimization of VO_x-based DH catalysts should encompass higher dispersion of VO_x phase and suppression of isomerization activity.

Keywords: block, catalysts, emission, motor, transport

1 Introduction

Problem of cleaning of exhaust gases of motor transport and departing gases of the industry - one of essential problems of the mankind, drawing attention of the public and the scientific leading countries of the world. Preservation of the environment from industrial and transport pollution constantly makes increasing demands to improvement of ways of preparation of catalysts of neutralization and cleaning of gas emissions of harmful impurity. Modern environmental problems of the Republic of Kazakhstan are difficult, diverse and territorially differentiated. On emissions of harmful substances from stationary sources in atmosphere the country is in the lead three, conceding to Russia and Ukraine.

In Kazakhstan daily throw out about 3 million tons of harmful substances, such as carbon oxide, nitrogen oxides, hydrocarbons, etc. Level of air pollution of many industrial cities of Kazakhstan exceeds more than 6-10 times existing standard limits because of emissions of motor transport, boiler-houses and plants. In Kazakhstan, in country scales, the share total emissions of polluting substances in atmosphere all technogenic sources reaches on the average 60 %. In the industry traditionally degree of recycling of toxic substances on an average level and, as consequence, regions of its disposition are a source of emissions of the most toxic substances. Among known ways of recycling and neutralization of harmful emissions of the industry and motor transport the most effective is deep catalytic oxidation of organic substances to carbon dioxide and water.

2 Experimental/methodology

The block catalysts on the metal carrier with the honey comb structure of channels were developed and prepared for 8 furnaces of heating of oil and carried out the skilled - industrial tests of catalysts with the joint-stock company "Embamunai-gas" on real waste gases of furnaces of heating of oil for the purpose of decrease in toxic emissions. 17 samples of block catalysts for 8 furnaces of heating of oil have been prepared. Catalysts were made from a heat resisting foil by winding of the smooth and goffered foil in the metal block of the cylindrical form, with the subsequent drawing of active components. Diameter of the block filter for furnace PTB-10/64 is equal 410 mm, height 400 mm. For furnace PT-16/150 diameter of catalytic filter - 500mm, height 400мм, catalyst dimensions on the furnace PT-3,5 were 900 mm on 400 mm. Catalytic filters were established directly on pipes of departing gases of furnaces of heating of oil after samplers to the catalyst. For the purpose of decrease heat emission the catalyst was wrapped by heat-insulating mineral cotton wool with a reflecting foil. In the course of work of the furnace temperature of gases was defined before and after the catalyst by means of the mercury thermometer and a gas analyzer temperature-sensitive element. Concentration of toxic gases before and after catalytic filters measured by means of gas analyzer MCI-150 (firm "Bosh").

3 Results and discussion

Block catalysts have the cylindrical form and are convenient in placing directly at a source of toxic emissions. The developed catalysts possess high degree of cleaning of departing gases of the industry from carbon oxide - 90-100 %, at temperatures from 90°C and above, from various hydrocarbons on 80-100 %. In a complex with carbon oxide, or with hydrocarbons catalysts will neutralize nitrogen oxide on 40-100 %, depending on their ratio. For example, at use of the block catalysts containing a mix of cobalt and manganese oxides the greatest degree of transformation CO in CO_2 (to 100 %) it is reached for one pass at volume speeds of a gas mix from 10 000 h^{-1} to 100 000 h^{-1} and temperature 110°C.

The developed effective catalysts of cleaning of exhaust gases of motor transport and waste gases of the industrial enterprises from toxic impurity on the metal carrier correspond under characteristics to standard EURO-3.

The party of catalytic filters - 4 samples has been established on the furnace with compulsory giving of air PTB-10/64 on "S.Balgimbaevo's" deposit. The temperature of departing gases to the catalyst was equal to 350°C, concentration of toxic gases to the catalyst by carbon oxide (CO) - 1280 ppм, on nitrogen oxide (NO) – 49 ppм, on sum by nitrogen oxides (NO_x) - 51ppм. After catalyst the indication was equal on CO – 5 ppм, on NO-39 ppm, on (NO_x) - 41ppм. Efficiency of neutralization of toxic emissions was equal on CO - 99.6 %, on NO - 20.4 %, on NO_x 19,6 %.

Other party of the catalytic filters has been established on 5 furnaces of heating of oil and water on a deposit "Southwest Camyshitovoye". On the furnace PT-3,5 with compulsory giving of air and on 4 furnaces PT-16/150 with the own draught of air. Efficiency of decrease in toxic emissions on furnace PT-3,5 with the catalytic filter was equal on CO - 66.8 %, on NO - 20.6 %, NO_x - 20 %, and on SO_2-100 %. Decrease in toxic emissions on furnace PT-16/150 after the catalyst was on CO - 100 %, on NO - 7,7 %, NO_x - 7.7 %, on SO_2 - 57.1 %.

During carrying out of trial tests it is revealed, that catalytic filters work effectively and decreased contents of the toxic gases from 7.7 % on nitrogen oxides to 100 % on carbon oxide.

4 Conclusions

Catalytic filters on metal blocks are developed for furnaces for heating of oil which work effectively and reduce the content of poisonous gases: CO - 100 %, NO - 7,7 %, NO_x - 7.7 %, on SO_2 - 57.1 %.

Keywords: chloroform, hydrodechlorination, palladium, platinum, rhodium, ruthenium

1 Introduction

Chloroform (TCM) plays an important role in the chemical and pharmaceutical industry, where it is used as solvent and reactant. However, because of its high toxicity and carcinogenic character, TCM is classified nowadays among the most hazardous gas pollutants. Catalytic hydrodechlorination (HDC) becomes one of the most promising emerging technologies for removing this compound. Noble metals supported on activated carbon (Pd/C, Pt/C, Rh/C and Ru/C) were shown to be fairly active in the HDC of TCM (1), with notable differences in stability and products distribution depending on the predominant metal species.

For a better knowledge of reaction mechanisms, catalysts of Pd, Pt, Rh and Ru were prepared using CeO_2-Sm_2O_3 as support in order to obtain high proportions of zero-valent metallic species, and those catalysts were tested in the HDC of TCM. The catalysts were characterized by XPS, and a density functional theory (DFT) analysis was conducted to study the activation of hydrogen and TCM by metal clusters (2).

2 Experimental/methodology

The catalysts, based on noble metals (palladium, platinum, rhodium and ruthenium) supported on ceria-samaria (CeO_2=80% w/w; Sm_2O_3=20% w/w) with metal contents of 1 wt%, were prepared by incipient wetness impregnation (Pd/CS, Pt/CS, Rh/CS and Ru/CS). The support was previously calcined at 300 ºC in airstream for 2 hours (flow rate = 100 ºC·hour^{-1}). The HDC experiments were conducted in a continuous flow reaction system, consisting of a quartz fixed bed reactor coupled to a gas-chromatograph with a FID detector to analyze the reaction products. The catalysts were reduced previously at 300 ºC using 50 Ncm^3·min^{-1} of hydrogen for 2 hours. The operating conditions used were: Atmospheric pressure, total flow rate of 100 Ncm^3·min^{-1}, an initial concentration of TCM of 1000 ppm, a space-time of 0.4-1.73 kg·h·mol^{-1}, H_2/TCM molar ratio of 100 and a reaction temperature of 250 ºC. All computational studies were performed with the Gaussian 09 program with density functional methods, as implemented in the computational package.

3 Results and discussion

The proportion of zero-valent species (Me^0) in the catalysts was measured by XPS was 78.8 %, 80.4 % and 86.8 % for Pd/CS, Pt/CS and Rh/CS respectively. Figure 1 shows the TCM conversion obtained with all the catalysts along 15 hours. Pt/CS and Pd/CS are more active than Rh/CS and Ru/CS as similar conversions values were obtained at lower space-time values. This can be attributed to their higher hydrogenation capability as suggested by the selectivity patterns (higher hydrocarbons and DCM were favoured for the latter in detriment of methane) and the dissociative adsorption energies of H_2 on the different metals (Table 1). A pronounced decrease

of activity with Rh/CS and Ru/CS is observed, and also for Pt/CS though in a lower extent, while Pd/CS showed very stable activity. The extent of deactivation followed a similar trend that the increase of the dissociative adsorption energy (Table 1) were Ru ≈ Rh > Pt > Pd. DFT results showed that total dissociation of TCM is favoured in the zero-valent species of Pt, Rh and Ru. This implies a higher amount of chloromethanes derived radicals for the available H_2, leading to the formation of a higher amount of hydrocarbons of more than one carbon atom, that can be adsorbed on the catalyst surface.

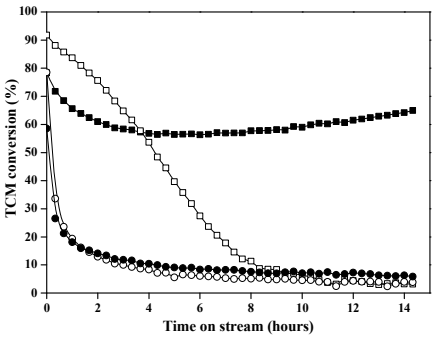

Fig. 1. Evolution of TCM conversion with time on stream at a H_2/TCM molar ratio of 100 and a reaction temperature of 250 ºC using:

(■) Pd/CS (τ = 0.4 kg·h·mol^{-1});
(□) Pt/CS (τ = 0.4 kg·h·mol^{-1});
(○) Rh/CS (τ = 0.8 kg·h·mol^{-1});
(●) Ru/CS (τ = 1.73 kg·h·mol^{-1})

Furthermore, the higher stability of Pd/CS catalyst compared to that supported on activated carbon (1) is ascribed to its significant lower amount of Pd^{2+}, species which promotes the associative adsorption of the chloromethane and therefore the poisoning of the active sites of the catalyst.

Table 1. Calculated enthalpy of dissociative adsorption of TCM and hydrogen on metal clusters.

Atomic species	ΔH_d TCM (kcal/mol)	ΔH_d H_2 (kcal/mol)
Pd^0	-64.3	-14.5
Pd^{2+}	-67.8	-37.1
Pt^0	-109.0	-17.2
Pt^{2+}	-53.8	-19.3
Rh^0	-134.1	-12.9
Rh^{2+}	-58.5	-12.2
Ru^0	-161.0	-13.7
Ru^{2+}	-75.5	-2.5

4 Conclusions

Pd/CS catalyst shows the best performance in the HDC of TCM, showing a high activity and good stability. The latter can be related to the lower strength of adsorption of chloroform on zero-valent Pd clusters, which prevent coke formation and the low amount of electro-deficient species which avoids the non-dissociative adsorption of the chloromethane.

Keywords: aniline, reactive dye, TiO_2, photocatalytic ozonation, mineralization, water

1 Introduction

Photocatalysis has shown to be adequate for the degradation of a wide range of pollutants, but in some cases the complete mineralization is slowly attained; therefore, it is mainly economically advantageous for diluted streams . In addition to photocatalysis, ozonation is able to selectively convert recalcitrant organic compounds and can be used with superior performances in some high strength waste waters . Molecular ozone can oxidise water impurities via direct selective reactions between ozone (O_3) and other chemical species, or via indirect O_3 reactions, which involve the formation of hydroxyl radicals (HO•) . The disadvantage of this process is the limited mineralization of the organic compounds. Therefore, it is necessary to modify the method when the definite removal of the pollutant and its degradation intermediates is required . Generally, a combination of several methods improves the removal of pollutants from the wastewater compared with the individual treatments . Irradiation of O_3 in aqueous solutions by UV light produces additional $HO^{\bullet}$ radicals, and consequently, the efficiency of contaminants removal should increase. The present targets at the photocatalytic ozonation of aniline (ANL) and C. I. Reactive Dye Blue 5 (RDB) in the presence of P25. In order to verify the presence of synergetic effects, photocatalysis (Light/P25) and catalytic ozonation (O_3/P25) were also carried out, as well as, photo-ozonation (O_3/Light).

2 Experimental

The removal of pollutants was carried out in a glass immersion photochemical reactor loaded with 250 mL of ANL (C_0 = 1 mM) or RDB (C_0 = 200 ppm) and 125 mg of photocatalyst. The reactor was equipped with a Heraeus TQ 150 medium-pressure mercury vapour lamp located axially and a DURAN 50® glass cooling jacket was placed around the lamp (main resulting emission lines at λ_{exc} = 365, 405, 436, 546 and 578 nm). The experiments were performed at 150 cm^3 min^{-1} and with an inlet ozone concentration of 50 g m^{-3}. The catalyst selected was commercial TiO_2 from Evonik Degussa Corporation, sample P25. ANL concentration was analysed by HPLC with Lichrocart Purospher Star column. For RDB, solution decolourisation was followed by UV/Vis spectrophotometry at the maximum absorption wavelength, previously determined (λ = 603 nm) with a JASCO V-560 UV/Vis spectrophotometer. The degree of mineralisation was followed by TOC analysis in a Shimadzu TOC-5000A Analyzer.

3 Results and discussion

The conversion of ANL and RDB as function of time under the selected experimental conditions is described in Figure 1. Except for photocatalysis (Light/P25), ANL was completely removed in all tested oxidative processes at early times with no significant differences observed for the remaining systems. Similar performance was observed during RDB degradation. These results were expected since O_3 by itself is an extremely powerful oxidant

capable of reacting with a vast range of compounds, and it attacks selectively aromatic moieties and unsaturated bonds, such as ANL and RDB.

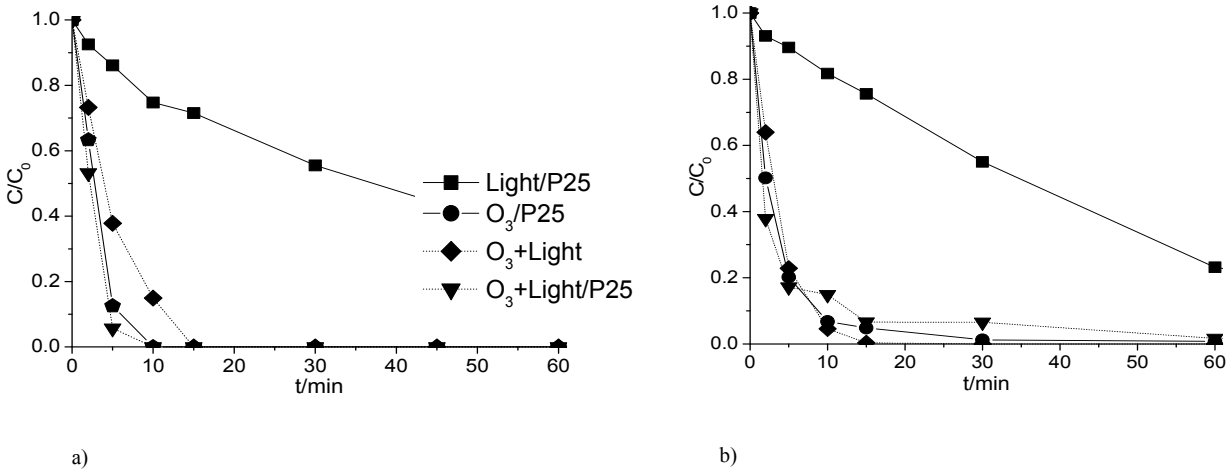

Fig. 1. Degradation of ANL a) and RDB b) by tested oxidation processes.

The degradation of these molecules resulted in the formation of several intermediates further transformed into saturated compounds, which are not significantly mineralized by O_3 alone. Therefore, it is expected that the advantage of combining O_3 with light and/or catalyst will be noticed in terms of TOC removal (Fig. 2). The best TOC removal was achieved by photocatalytic ozonation, which means that in addition to parent compounds, a considerable amount of oxidation by-products were also degraded. Photo-ozonation also presented a good performance during RDB degradation, leading to mineralization level of 65%. Although photocatalysis presented worse performance than catalytic ozonation in degradation of ANL and RDB, in terms of TOC removal this did not happen.

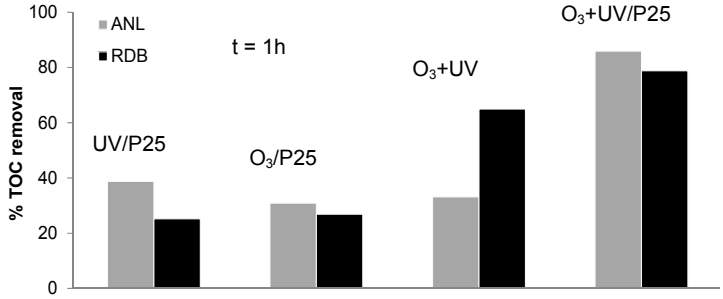

Fig. 2. Percentage of TOC removal during ANL and RDB degradation.

4 Conclusions

All tested oxidation processes completely removed ANL and RDB in a short reaction time, with the exception of photocatalysis. The combination of ozone, light and P25 lead to maximum mineralization.

Mixed MoTi-Pillared Clay as a Catalyst for Selective Catalytic Reduction of NO by NH_3

Rejeb R.[1*], Kalfallah B.L.[1], Delahay G.[2]

1 - Laboratoire de Chimie des Matériaux et Catalyse, Département de Chimie, Faculté des Sciences de Tunis, Tunis, Tunisie

* rejebranda@gmail.com

Keywords: molybdenum, titanium, sulphate, pillared clay, SCR, nitrogen oxides

1 Introduction

Selective catalytic reduction (SCR) of nitrogen oxide (NO) by ammonia is the most universal method used for the removal of this pollutant from industrial flue gases. The SCR-NO process is currently performed with TiO_2 carrier that supports the active components, i.e., V_2O_5 and WO_3 or MoO_3 [1]. It is well known that V_2O_5-MoO_3 supported on TiO_2 is one of the industrial SCR-NO catalysts. However, the use of TiO_2 as a catalyst support is limited by its low specific surface area, porosity and resistance to sintering compared to Ti-pillared clay (Ti-PILC) that offer a better surface area, porosity, thermal stability and sufficient acidic functions.

In order to develop efficient catalyst for SCR-NO, considerable efforts have been made to investigate Ti-pillared clay (Ti-PILC) and their SCR behaviour to substitute the conventional TiO_2 [2-5]. So far, there has not been any published work describing a method for the preparation of molybdenum supported on Ti-PILC or studying the effect of molybdenum amounts on the physico-chemical properties of Ti-PILC nor discussing the catalytic activity of the mixed MoTi-pillared clays. For this reason, it has been interesting to investigate SCR-NO by ammonia over mixed MoTi-Pillared clay prepared in presence and absence of sulfate.

2 Experimental/methodology

The starting material was commercial clay mineral provided by Sigma Aldrich. The intercalating Ti-solution was prepared by slowly adding $TiCl_4$ into HCl (6M) or H_2SO_4 (3M) under vigorous stirring. The Mo-solution was also prepared at room temperature by dissolving ammonium heptamolybdate ($(NH_4)_6Mo_7O_{24}$, $4H_2O$) in distilled water. For mixed intercalation, both intercalating Ti-solution and Mo-solution were simultaneously added to the suspension of the initial clay under vigorous stirring. After 24h, the solid fraction was separated by centrifugation, dried at room temperature and finally calcined at 400 °C.

3 Results and discussion

The SCR activities of the investigated samples are shown in Fig. 1. The Ti-PILC exhibits smaller activity in SCR-NO reaction. After molybdenum addition to Ti-pillared clay (MoTi-PILC), the total acidity and the NO conversion increased significantly. This result indicates that molybdenum contribute to the improvement of the surface acidity and the SCR-activity.

The NO conversion over sulphated Ti-pillared clay (STi-PILC) is mainly related to the surface acidity and especially to Bronsted acid sites enhanced after sulphate addition [3, 4]. The catalytic behaviour of the sulphated MoTi-pillared clay (SMoTi-PILC) is largely related to total acidity of the catalyst. The addition of molybdenum onto sulfated Ti-PILC increased slightly the Bronsted acidity and considerably the Lewis acidity. These results demonstrate the beneficial role of molybdenum in the mixed MoTi-PILC catalyst. Furthermore, the best efficiency was

obtained with mixed MoTi-PILC having the highest acidity.

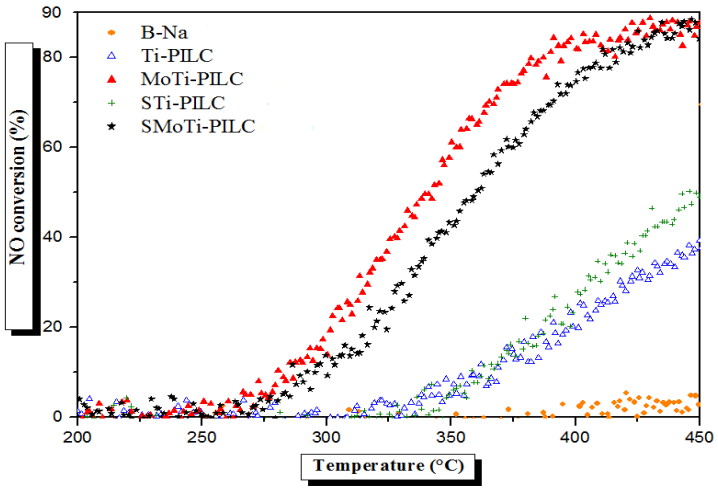

Fig.1: NO conversion as a function of temperature.

4 Conclusions

The addition of molybdenum to Ti-pillared clay, prepared in absence or in presence of sulphate, enhanced the total acidity and the NO removal activity. Furthermore, the promoting effect of sulfate was not found in presence of molybdenum. The best catalyst for SCR-NO reaction is mixed MoTi-PILC, having the highest acidity. It could be envisaged as a support for transition metals, such as vanadium, for the catalysis of SCR-NO or other chemical reactions.

Preferential Oxidation of Carbon Monoxide over NiO/CeO_2 and $NiO\text{-}CuO/CeO_2$ in Hydrogen-Rich Streams: Effect of Copper

Chagas C.A.*, Schmal M.

Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

* chagas@peq.coppe.ufrj.br

Keywords: hydrogen, preferential oxidation, carbon monoxide, copper nickel, selectivity to CO_2

1 Introduction

Preferential oxidation of CO (CO-PROX) with an appropriate catalyst is one of the most economically and technologically promising methods for remove CO from H_2-rich gas streams, as compared to other processes [1]. The crucial requirements for the PROX reaction are high CO oxidation rate and high selectivity to CO_2. Selectivity is crucial considering the competing H_2 oxidation that may lead to a decrease in the overall fuel cell efficiency. Besides oxidation of both CO and H_2, methanation and WGS reactions can also take place simultaneously [2]. Several catalyst formulations have been reported in open literature and tested for this purpose. Particularly, copper-containing catalysts have been the object of numerous publications in the environmental catalysis field, due to their catalytic properties for CO oxidation applications [3]. Some works reported in literature suggesting that copper oxide catalysts are actives and selective as the platinum-group catalysts when operating at a lower reaction temperature [4]. However, the debate about what copper species are most beneficial in the preferential oxidation of CO is still open in literature and not well understood. In the present study, we investigated the effect of addition of CuO oxides species on supported NiO. We have prepared and characterized monometallic (NiO/CeO_2) and bimetallic ($NiO\text{-}CuO/CeO_2$) system and tested for CO-PROX reaction.

2 Experimental/methodology

NiO/CeO_2 and $NiO\text{-}CuO/CeO_2$ supports were prepared by incipient wet impregnation method [5]. The nominal loading amount of NiO and CuO were 20 and 5 wt. %, respectively. The catalysts were characterized by X-ray diffraction measurements and fluorescence (XDR, XFR), reduction in thermal programmed reduction (TPR), high-resolution transmission electron microscopy (HRTEM) and textural analysis. The catalytic tests were carried out in a continuous-flow and fixe-bed microreactor, using 150 mg of catalyst and operating at atmospheric pressure. The reaction was performed at different temperatures from 50 to 200 °C, in steps of 25 °C and kept for 30 minutes at each temperature. The feed composition consisted in 1 vol.% CO, 1 vol.% O_2, 60 vol.% H_2 and He balance at a flow rate of 150 $cm^3\ min^{-1}$.

3 Results and discussion

The physicochemical properties of the catalysts are listed in Table 1. It shows that the chemical analysis for all the samples closer to the nominal values.

Table 1. Physical and Chemical properties of the samples.

Catalyst	Chemical composition (wt%)			S_{BET}	Vp	R_m
	NiO	CuO	CeO_2	($m^2\ g^{-1}$)	($m^2\ g^{-1}$)	(nm)
CeO_2 (support)	-	-	100	48	0.205	11.2
$20NiO/CeO_2$	18.9	-	81.1	33	0.154	11.05

20NiO-5CuO/CeO_2	22.2	6.2	71.6	39	0.116	8.76

As expected, the insertion of NiO led to a decrease in the specific surface area (from 48 to 33 m^2 g^{-1}) and pore volume (from 0.205 to 0.154 cm^3 g^{-1}) of ceria. On the other hand, the addition of CuO on NiO/CeO_2 increased the specific surface area (from 33 to 39 m^2 g^{-1}) and a decreased the pore volumes (from 0.154 to 0.116 cm^3 g^{-1}), as shown in Table 1. The CO and O_2 conversion and selectivity to CO_2 for the samples are shown in Fig. 1. Note that all samples exhibited CO conversion increases with temperature, with a maximum at 125 °C for the promoted Cu sample and at 170 °C for the unpromoted sample. For higher temperature, the conversion decreases competing with the oxidation of H_2 affecting the CO_2 selectivity. The CO_2 selectivity of the NiO-CuO/CeO_2 catalyst was 100% up to 150 °C. Then, the CO_2 selectivity decreased significantly (T = 200 °C, S_{CO2} = 53%).

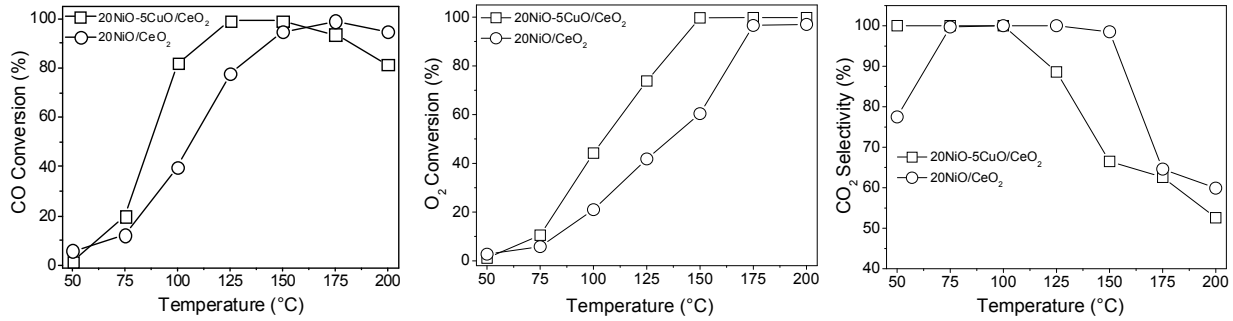

Fig. 1. CO and O_2 conversion and selectivity to CO_2 as a function of reaction temperature.

The stability of the catalysts for CO-PROX were tested with time on stream at 200 °C for 30 h and the results are shown in Fig. 2.

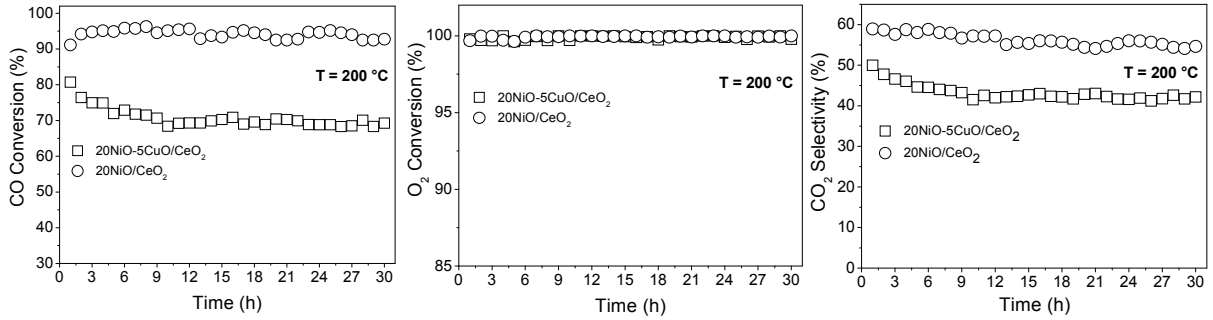

Fig. 2. CO and O_2 conversion and CO_2 selectivity under isothermal conditions at 200 °C.

4 Conclusions

The NiO/CeO_2 and NiO-CuO/CeO_2 were active and selective to CO-PROX reaction until 200 °C and also showed good stability during time on stream. These materials are promising catalysts for CO-PROX reaction presenting more resistant to methanation than platinum-group catalysts reported in the literature.

Photocatalytic Reduction of Nitrate to Nitrogen in Water under Visible Light Irradiation in the Presence of $Pt/SrTiO_3$: Rh Photocatalyst and $SnPd/Al_2O_3$ Non-Photocatalyst

Hirayama J.[1], Kamiya Y.[2*]

Keywords: nitrate reduction, photocatalysis, visible light, groundwater purification, Tin-palladium

1 Introduction

Pollution of groundwater with nitrate (NO_3^-) is a serious problem in the world. Drinking water with high NO_3^- concentrations causes various diseases, including blue baby syndrome. Thus, NO_3^- in groundwater must be decomposed for drinking water. Photocatalytic reduction of NO_3^- has attracted much attention as a method for the decomposition of NO_3^-. We have proposed a photocatalytic reaction system combining a semiconductor photocatalyst (Pt/TiO_2) and a supported bimetallic non-photocatalyst ($SnPd/Al_2O_3$) dispersed in water [1], but this system can work only under UV irradiation because Pt/TiO_2 is a UV light active photocatalyst. In the present study, we expand the photocatalytic system to NO_3^- reduction driven by visible light by using $Pt/SrTiO_3$:Rh instead of Pt/TiO_2 [2].

2 Experimental

$SrTiO_3$:Rh was prepared by calcining a mixture of $SrCO_3$, TiO_2, and Rh_2O_3 at 1373 K. Modification of $SrTiO_3$:Rh with Pt was conducted by a photodeposition method with $H_2PtCl_6 \cdot 6H_2O$ in aqueous methanol solution. Loading amount of Pt was fixed to 0.1 wt%. $SnPd/Al_2O_3$ was prepared by an incipient wetness method using Al_2O_3 (Aerosil Alu C), aqueous $PdCl_2$ solution, and aqueous $SnCl_2$ solution. Loading amount of Sn and Pd were fixed to 2.3 wt% and 4.2 wt%, respectively. Just before the reaction, $SnPd/Al_2O_3$ was reduced with $NaBH_4$.

Photocatalytic reduction of NO_3^- in water was carried out in a Pyrex reaction vessel connected to a closed gas circulation system at 298 K. The catalyst powder of $Pt/SrTiO_3$:Rh (500 mg) and $SnPd/Al_2O_3$ (150 mg) were dispersed in 250 mL KNO_3 solution (0.8 mM) with 10 vol% CH_3OH and then the suspension was irradiated with a 300 W Xe lamp with cutoff filter ($\lambda > 420$ nm). The products were analyzed by using two ion chromatographs and a gas chromatograph, and by the iodometric titration.

3 Results and discussion

Table 1 summarizes the data of the photocatalytic reduction of NO_3^- in water under visible light irradiation for 6 h. $Pt/SrTiO_3$:Rh alone (Entry 1) showed negligible activity, while is a visible light-active photocatalyst. This is because $SrTiO_3$:Rh itself and Pt metal are incapable of activating NO_3^-. $SnPd/Al_2O_3$ also showed only low catalytic activity (Entry 2). The conversion (3%) in Entry 2 was due to non-photocatalytic reduction of NO_3^- with methanol over SnPd bimetal. In contrast to these, the high conversion was obtained, if both $Pt/SrTiO_3$:Rh and $SnPd/Al_2O_3$ were present in the reaction solution (Entry 3). In addition, formation of undesirable NH_4^+ was suppressed with low level (6% selectivity). When the reaction was conducted under dark conditions, the conversion was low even in the co-presence of both catalysts (Entry 4). Thus, the enhanced activity show in Entry 3 was strongly related to the photocatalytic reaction.

The catalyst that $SrTiO_3$:Rh modified directly with SnPd bimetal was much less active than Pt/$SrTiO_3$:Rh–SnPd/Al_2O_3 system (Entry 5). SnPd/$SrTiO_3$:Rh did not produce H_2 at all in the absence of NO_3^- in water even though visible light was irradiated, indicating that this did not act as a photocatalyst probably due to shielding effect of incident light by, and formation of a number of recombination sites on the SnPd bimetal.

Next, we investigated a reaction mechanism over the Pt/$SrTiO_3$:Rh–SnPd/Al_2O_3 reaction system. The amount of H_2 needed to the reduction of NO_3^- was calculated from the converted NO_3^-, and producted NH_4^+ and N_2, and it was found that this was three times larger than the amount of H_2 evolved by the photocatalytic reaction over Pt/$SrTiO_3$:Rh in the absence of NO_3^-. This result suggested that methanol as well as the products includingH_2CO and HCO_2H, which were formed by photo-oxidation of methanol, other than H_2 must act as reductants for NO_3^- over$SnPd/Al_2O_3$ (Fig. 1).

Thus we further investigated non-photocatalytic reduction of NO_3^- with CH_3OH, H_2CO, and HCO_2H in the presence of SnPd/Al_2O_3 under the dark conditions. In the reaction where CH_3OH, H_2CO, and HCO_2H was added simultaneously, the conversion was 17% at 6 h, which was almost the same as the conversion for the photocatalytic reduction of NO_3^- in the Pt/$SrTiO_3$:Rh–SnPd/Al_2O_3 system. By comparison of the decomposition rate of NO_3^- with each compound, it was found that mainly H_2CO and HCO_2H, in addition to H_2, acted as reductants for NO_3^- reduction, but CH_3OH was almost completely ineffective although it was abundantly present in the reaction solution.

Table 1 Photocatalytic reduction of nitrate in water under visible light irradiation.

Entry	Catalyst	Conversion	Selectivity/%	
		/%	NH_4^+	N_2
1	Pt/$SrTiO_3$:Rh	< 1	---	---
2	SnPd/Al_2O_3	3	35	65
3	Pt/$SrTiO_3$:Rh+ SnPd/Al_2O_3	16	6	94
4[a]	Pt/$SrTiO_3$:Rh+ SnPd/Al_2O_3	5	9	91
5	SnPd/$SrTiO_3$:Rh	8	16	84

[a]Under dark conditions.

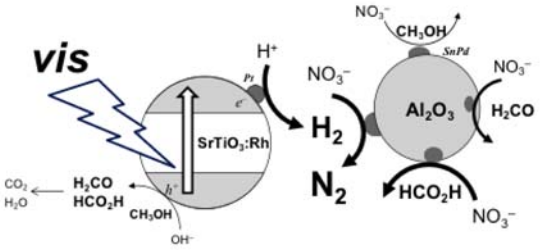

Fig. 1 Schematic illustrations of the reaction mechanism of photocatalytic reduction of NO_3^- in water in the co-presence of Pt/$SrTiO_3$:Rh and SnPd/Al_2O_3 under visible light irradiation.

4 Conclusions

The photocatalytic reaction system comprising Pt/$SrTiO_3$:Rh and SnPd/Al_2O_3, which were dispersed in water, efficiently and selectively promoted the photocatalytic reduction of NO_3^- in the presence of methanol under visible light irradiation. Products including H_2CO and HCO_2H, which were formed by photo-oxidation of methanol over Pt/$SrTiO_3$:Rh, other than H_2 acted as reductants for NO_3^- over SnPd/Al_2O_3.

Keywords: methane combustion, Pd-Co/Al_2O_3 catalysts, Pd-Co-La/Al_2O_3 catalysts, Pd-Co-La-Ce/Al_2O_3 catalysts

1 Introduction

Methane, being a greenhouse gas, plays a significant role in the global warming. Most of the catalysts, designed for methane combustion, are based on palladium – separately or in combination with different metals or metal oxides, supported on alumina. The main problem in the practice is the deactivation of the Pd-based catalysts. An alternative for the stabilization of the support and the catalytic active phase could be found in the introduction of rare earth oxides into the existing catalytic systems. La_2O_3 is an excellent stabilizer of the specific surface area of supports like Al_2O_3 and ZrO_2. CeO_2 is also well known as an alternative for stabilization of PdO since it hinders the PdO reduction and promotes Pd re-oxidation when PdO–CeOx contact is available.

2 Experimental

The single-component (Pd/Al_2O_3 and Co/Al_2O_3) and multi-component (Pd+Co/Al_2O_3, Pd+Co/$LaAl_2O_3$, Pd+Co/$LaCeAl_2O_3$) samples were prepared by impregnation of γ-Al_2O_3 with aqueous solutions of $Co(NO_3)_2.6H_2O$, $Pd(NO_3)_2.2H_2O$, $Ce(NO_3)_2.4H_2O$ and $La(NO_3)_3.2H_2O$. The palladium and cobalt contents in each one of the prepared samples were approximately 0.03 wt % and 0.3 wt%, respectively. The catalysts were characterized by X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), electron paramagnetic resonance (EPR), transmission electron microscopy (TEM) and reaction kinetics measurements.

4 Results and discussion

Finely dispersed palladium particles were formed on the surface of all samples. According to the XPS data Pd^{2+} and Pd^{4+} present on the surface of the fresh catalysts modified with Co only, while the major part of the surface palladium in the La and Ce containing samples is in the form of Pd^0.

The following order of activity is observed: Pd+Co/Al_2O_3>Pd+CoLaCe/Al_2O_3>Pd+CoLa/ Al_2O_3>Pd/ Al_2O_3. The modification of Pd/Al_2O_3 with Co significantly improves its catalytical activity. This effect is explained by the stabilization of palladium as PdO on the support due to strong interaction between Pd particles and the surface cobalt oxide phase. It is very likely that, when La and Ce are deposited before the Co deposition, the formation of cobalt surface phase is hindered as well as the further stabilization of PdO phase. The Pd+Co/Al_2O_3 sample demonstrates remarkable stability after ageing. However, the activities of the catalysts, modified with La and Ce drop after ageing, most probably due to sintering of palladium.

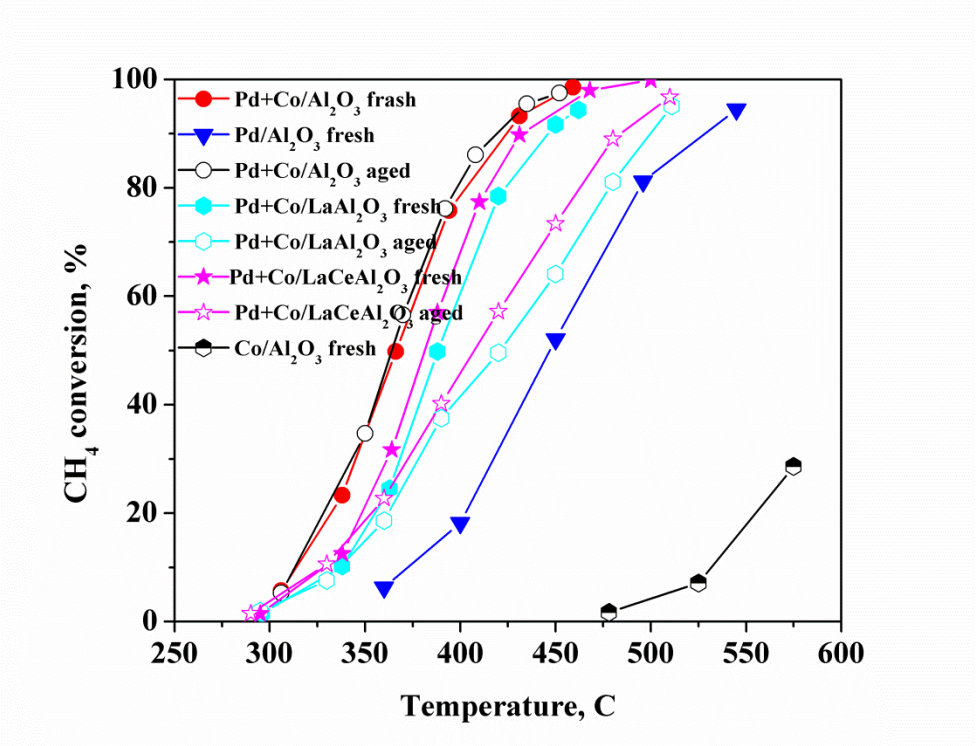

Fig. 1. Temperature dependencies of the methane conversion

4 Conclusions

The alumina-supported palladium catalysts, modified with cobalt demonstrate high activity and stability in the reaction of complete methane oxidation. The active species in the methane oxidation over Co-modified palladium catalyst are PdO clusters. The role of the surface cobalt oxide phase is to stabilize the palladium in its oxidized state and to serve as reservoir of the oxygen species. The modification with La and Ce prevent Co-Al phase formation and as result the stabilization of palladium in form of PdO.

Keywords: ethanol, deep oxidation, catalysts, cobalt-manganese, mixed oxides, magnesia-alumina

1 Introduction

Volatile organic compounds (VOC) emitted in industrial gases can be eliminated applying the catalytic total oxidation. We found high catalytic activity of the Co-Mn-Al mixed oxides, obtained by heating of the coprecipitated layered double hydroxide (LDH) precursor, in the ethanol total oxidation [1]. Activity of this catalyst was remarkably increased by addition of small amount of the potassium promoter. The catalysts prepared by pelletizing the powdered material contained high amounts of expensive cobalt, which was not fully utilized in the catalytic reaction. Therefore, we focused on preparation of supported catalysts with lower concentration of active components placed exclusively in the outer shell of the support pellets. In the present study, we applied the method of impregnation using acidic solution of metal salts in combination with a support having basic properties that could limit penetration of active components into the support pellets.

2 Experimental

The catalysts were prepared by impregnation of magnesia-alumina pellets (5x5 mm, Sasol) with aqueous solutions containing Co, Mn and Al nitrates (molar ratio of Co:Mn:Al=4:1:1) and subsequent heating at 500 °C in air. The prepared samples were characterized by chemical analysis, powder XRD, measurement of nitrogen adsorption at -196°C, TPD of CO_2, and TPR. Distribution of active metals in the catalyst pellets was determined by SEM. Catalytic activity in the total oxidation of ethanol, which was chosen as a model VOC, was measured under unsteady-state conditions with heating rate of 2.27 °C min^{-1} (100–400 °C), at ethanol concentration in air of 1.5 g m^{-3} and GHSV 20 000 ml g_{cat}^{-1} h^{-1}. Temperatures T_{50}, at which 50% conversion of ethanol was observed, were chosen as a measure of the catalysts activity. For comparison, the pellets (5x5 mm) of commercial Co-Mn-Al mixed oxide catalyst (ASTIN 2-100) were also examined.

3 Results and discussion

Results of chemical analysis, amounts of reducible components, and amounts of CO_2 desorbed from the catalysts are summarized in Table 1.The sum of Co and Mn in the supported catalysts varied from 4 to 15 wt. % (commercial catalyst with about 55 wt. % of Co+Mn exhibited uniform distribution). The magnesia-alumina support contained, apart from 30 wt. % of Al_2O_3, about 1 wt. % of Na. Basic properties of the support as well as surface area of the samples were decreasing with gradual adding the active metal oxides. The SEM imaging confirmed limited penetration of active metals into support pellets (Fig. 1a). Powder XRD patterns of all samples showed diffraction lines corresponding to spinel-like phases.

Table 1. Chemical analysis, redox and basic properties of the catalysts, depth of Co, Mn penetration in the pellets, and temperatures T_{50} of ethanol oxidation

Sample	Cat-0	Cat-5	Cat-10	Cat-10[a]	Cat-15[a]	Cat-20[a]	ASTIN 2-100
Co, wt. %	0	3.33	4.75	6.55	9.35	11.82	45
Mn, wt. %	0	0.82	1.22	1.62	2.31	2.94	9.8
Na, wt. %	0.8	0.59	0.67	-	0.67	0.64	2.6[b]
Surface area, m^2/g	130	105	59	87	68	55	87
H_2-TPR, mmol/g[c]	0	0.46	0.70	0.67	1.28	1.63	5.74

[a]twofold impregnation, [b] potassium,[c] temperature range 25-500 °C, [d]depth of (Co+Mn) penetration L=layer/pellet radius

Ethanol conversion over the examined catalysts is demonstrated in Fig. 1b. The most active sample, even more active than the commercial Co-Mn-Al mixed oxide catalyst with almost 55 wt.% of (Co+Mn), was the catalyst with much lower content (only about 12 wt.%) and non-uniform distribution of Co and Mn in the pellets. The main reaction byproduct, acetaldehyde, was completely transformed into CO_2 at temperatures lower than 300 °C (Fig. 1c). Formation of the other reaction byproduct, CO, was not detected.

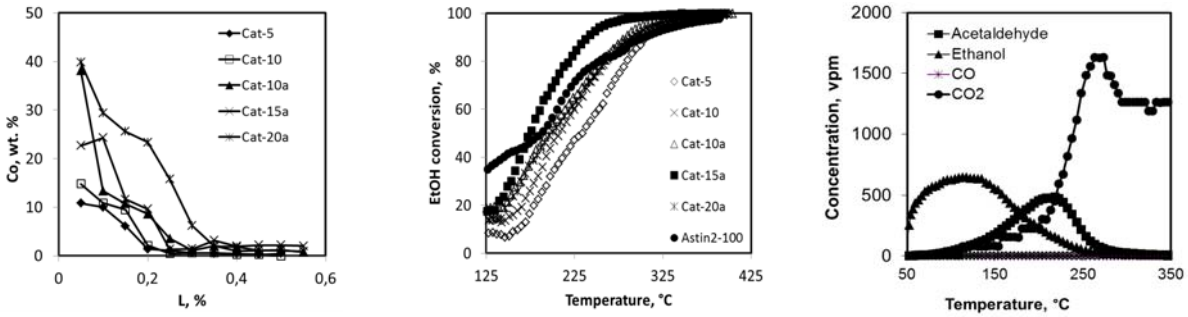

Fig. 1.a) Distribution of cobalt in the supported Co-Mn-Alcatalysts, b) conversion curves of ethanol, c) reaction components as a function of reaction temperature for the most active catalyst Cat-15[a]

4 Conclusions

Impregnation of the magnesia-alumina pellets having basic properties with acidic solution of Co, Mn and Al nitrates led to limited penetration of metal cations into the support and formation of catalysts with non-uniform distribution and reduced content of active components. The formed active layer in the support resisted to attrition during the catalytic reaction. The activity of the supported catalysts slightly differed from that of the commercial catalyst with uniform distribution of Co and Mn and (Co+Mn) about 55 %. Supported catalyst with optimum concentration (ca. 12 wt. %) showed better catalytic properties than the commercial one.

Keywords: macro-porous, PMMA, coal gasification process

1 Introduction

In coal gasification process, sulfur compounds such as H_2S and COS can be contained in synthetic gas, due to the sulfur component in coal, and the sulfur compounds contained in synthetic gas can be selectively removed with a desulfurization sorbents on the hot gas desulfurization process. SO_2 is produced in the regeneration process of the sulfide sorbent. SO_2 can be conversed to elemental sulfur by catalytic reduction process using a reducing agent.

2 Experimental/methodology

In this study, the macro-porous Cu-Sn-Zr catalyst was prepared in order to SO_2 decomposition. The catalytic activity of Cu-Sn-Zr catalyst for SO_2 reduction was confirmed in our previous study. Thus, the porous materials were synthesized in order to enhance the catalytic activity. The template was used for the formation of macro-pores and the nano-spherical beads of poly-methyl-methacrylate (PMMA) were used as a template. Therefore, PMMA colloidal nano-beads were synthesized with MMA by the suspension polymerization method in this study. Tin chloride, copper nitrate, zirconium oxy nitrate were used as a precursor for a synthesis of Cu-Sn-Zr Catalyst, and was impregnated over PMMA beads by rotary vacuum evaporator. The solid material of Cu-Sn-Zr/PMMA was thermal treated for 4 h at 600 ^oC.

3 Results and discussion

The porous morphology of Cu-Sn-Zr catalyst prepared in this study was observed by SEM analysis, as shown in Fig.1. The surface area of this material measured by nitrogen adsorption method was approximately 80 m^2/g and non-porous Cu-Sn-Zr catalyst surface area was 40 m^2/g. In reaction test, the activity macro-porous Cu-Sn-Zr catalyst was tested under regenerator-off gas contained with steam(20 mol%), oxygen(4 vol%). Reaction temperatures(300~500 ^oC) was regulated by a temperature controller. In activity test, the conversion of SO_2 was approximately 95 %, sulfur yield was 93 % at 400 ^oC. On the other hand, the SO2 conversion of non-porous Cu-Sn-Zr catalyst was 78 %, sulfur yield was 75 % at 400 ^oC.

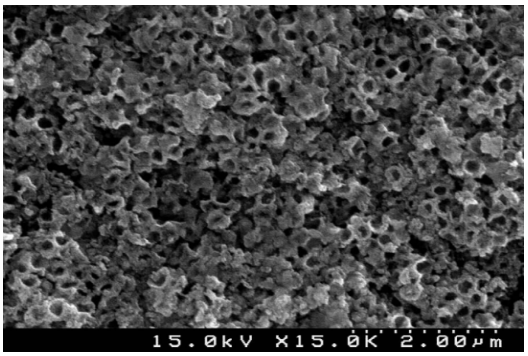

Fig. 1. SEM image of macro-porous Cu-Sn-Zr catalyst

4 Conclusions

Macro-porous Cu-Sn-Zr catalyst has a larger surface area than non-porous Cu-Sn-Zr catalyst. So, macro-porous Cu-Sn-Zr catalyst has a higher catalytic activity than the non-porous Cu-Sn-Zr catalyst. Thus, the use of a macro-porous Cu-Sn-Zr catalyst can be obtained a high catalytic reactivity.

Keywords: homogeneous catalysis, photo-fenton, open channel reactor, paracetamol

1 Introduction

The conventional wastewater treatment plants do not warranty the degradation of emergent persistent organic pollutants (POPs), among them the pharmaceuticals. Advanced Oxidation Processes, like photodegradation using artificial ultraviolet radiation or solar radiation, are proposed as an alternative for the treatment of contaminated water with POPs. These processes were defined as those that involve the in situ formation of highly reactive radicals, especially hydroxyl radicals, in sufficient quantities to produce the water purification [1]. In the present work, the hydrodynamic characterization and evaluation of an open channel reactor for ultraviolet degradation of paracetamol by homogeneous catalytic photo-Fenton are presented.

2 Results & discussion

Hydrodynamic characterization of the open channel reactor

The hydrodynamic characterization of the reactor (Fig. 1) was performed through the analysis of the residence time distribution (RTD) using a radioactive ^{99m}Tc tracer. This process was done in two steps. First, the open channel reactor was evaluated in continuous mode operation. To evaluate the influence of the volume of fluid in the reactor and the diameter of the flow distributor's orifices on the flow pattern, an experimental 3^2 design was used. The dependent variables were the mean residence time (Trm), the number of perfectly mixed tanks and the mean residence time of the model in the main flow. Several hydrodynamic models, using the software DTSPro v.4.2, were evaluated. The best hydrodynamic model was the model of perfectly mixed tanks in series exchanging with stagnant zones. The average relative error of estimation was 8.7 %. Then, the mixing time in the overall reacting system operating in close loop mode was determined, been of 34 minutes.

Photodegradation of paracetamol

In all experiments, the volume in the reactor was 5 L and the initial concentration of paracetamol was 100 mg/L, taking into account the results of previous studies [2]. All experiments were carried out with pH control, using technical water. The samples (10 mL) for analysis were taken at regular time intervals (30 min, 1h, 2h, 4h and 6h in photolysis and photolysis with H_2O_2 experiments and 15 min, 30 min, 1h, 2h, 4h and 6h in photo-Fenton experiments). The monitoring of the paracetamol concentration was done by HPLC.

In photolysis experiments, the pH was equal to 7. The intensification of photolysis with H_2O_2 was studied at two values of pH (3 and 7) and different concentrations of oxidant (6.9, 13.9, 27.8, 41.7, 55.6, and 69.5 mmol/L) were employed corresponding to the half, one, two, three, four and five times the stoichiometry of the oxidation reaction. In the photo-Fenton experiments various concentrations of Fe^{2+} ($FeSO_4 \cdot 7H_2O$) (0.48 and 1.39 mmol/L) and H_2O_2

(13.90 and 55.56 mmol/L) at pH = 3 were used according to a factorial design 2^2.

Figure 2 shows the results of the degradation of paracetamol by photolysis and photolysis with H_2O_2 at different values of pH and different concentration of H_2O_2. The best results were obtained for photo-Fenton process, when the pharmaceutical was completed destroyed at 15 minutes with mineralization of 85 % at 6 hours.

1 Introduction

PAHs show adverse health effects. For instance, benzo(a)pyrene is classified as carcinogenic by IARC. Therefore, at the international level, many countries have committed themselves to minimizing air emissions through the Aarhus Protocol on POPs which was signed in 1998 under the Geneva Long Range Transboundary Air Pollution Convention. At the French level, emission limit values for PAHs have been introduced in a recent regulation on combustion plants with a thermal input higher than 20 MWth (Ministerial Decree of 26 August 2013).

Catalytic oxidation is one of the most promising technologies to reduce the emissions of air pollutants [1]. Metal oxides or supported noble metals methods are the most investigated catalysts for the destruction of organic pollutants.

Acid zeolites (protonic forms) have been considered as effective cheap alternative catalysts to metal oxides for hydrocarbons oxidation [2]. Catalytic performances of these zeolites were associated with the presence of Bronsted acide sites.

In this work, the removal of 1-methylnaphtalene (1-MN), a model compound representative of PAH, by catalytic combustion in the presence of steam is investigated.

The behavior of various acidic zeolites towards the gas-phase catalytic oxidation of 1-MN is investigated. The effect of some parameters on 1-MN oxidation is studied: the structure of the zeolite, Lewis and Bronsted acidity and Si/Al ratio. The performance of these zeolites is compared to 0.97 wt% Pt/Al2O3 which is one of the most active catalysts in complete oxidation of naphthalene [3].

2 Experimental/methodology

Catalytic activity experiments were carried out in a vertical stainless steel tube reactor, which in turn is placed in a tube furnace. Catalytic activity is measured over the temperature range 150°C-400°C and the temperature is measured by thermocouple axially placed in the catalyst bed. Catalysts are packed to a constant volume to give a gas hourly space velocity of 20000 h-1 for all studies. The two liquids (1-MN and water) are injected with syringe pumps. Prior to the catalytic tests, the samples (100mg) are treated in air (10 L/h/g) at 500°C for one hour. The reaction feed is 9% of oxygen, 10% of water and 500 ppm of 1-MN in nitrogen. The gases (1-MN, CO, CO2) at the reactor outlet are analysed on-line by a gas chromatograph.

In this work, we study the oxidation activity which is expressed as 1-MN conversion (X) and carbon dioxide selectivity (Y). There are determined as follows:

$$X = \frac{A_{blank} - A_{out}}{A_{blank}}$$

With Ablank: Area of 1-MN peak before the reaction; Aout : Area of 1-MN peak at the reactor outlet during the reaction.

$$Y = \frac{Ac_{out}}{A_{max}}$$

With Acout: Area of carbon dioxide peak during the reaction; Amax: Theoretical area of carbon dioxide peak when the 1-MN is totally converted to CO2.

3 Results and discussion

The zeolite catalysts (HFAU, HZSM-5, BETA, mordenite) are compared to the 0.97 wt% Pt/Al2O3 catalyst. One of the methods to compare catalysts is to plot light-off curves with 1°C/min decreased oven program temperature from 350°C to 150°C. Figure 1 shows the 1-MN conversion as a function of the reaction temperature under 0.97 wt% Pt/Al2O3 catalyst. 100% conversion of 1-MN is obtained around 320°C. With the same catalyst, second method consists in measuring the conversion during one hour and a half of temperature steps. No difference between conversions measured with the two methods is observed. Thus, no deactivation on this catalyst is occurred.

Regarding zeolite catalysts, conversion measurement with step program temperature is required due to the deactivation induced by the formation of coke under acid sites[2].The acidity of the zeolite is characterized, after and before catalytic test, with pyridine/CO adsorption followed by FTIR. The correlation between acid properties, structure and Si/Al ratio and catalytic activity is discussed.

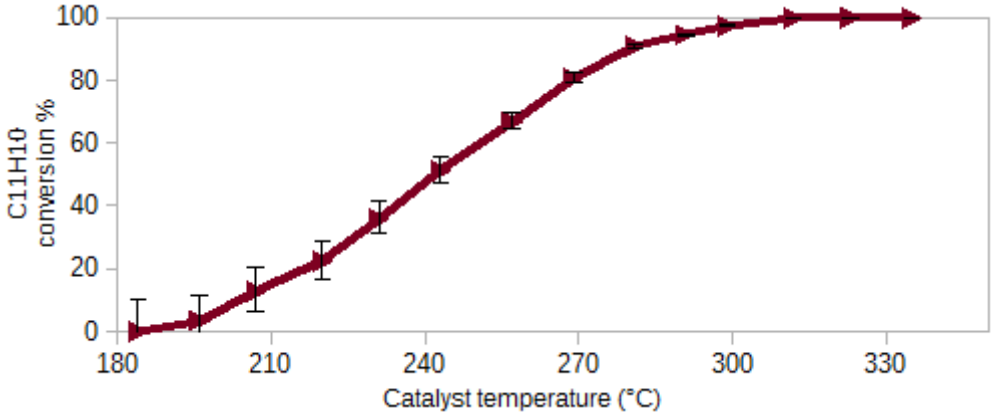

Fig. 1. Light-off curve over 0.97 wt %Pt/Al_2O_3. Feed composition: 460 ppm 1-MN, 9% O_2 in N_2 VVH=20000h^{-1}

Keywords: perovskite films, nanowires catalysts, thin films, sputtering, Diesel oxidation catalyst

1 Introduction

Reduction of pollutants emissions contained in vehicles exhaust gas are among the main priorities of future European standards. A way to meet those standards requirements is to equip vehicles with a catalytic post-treatment able to minimise the rejection of pollutants in the atmosphere. Nowadays, noble metals, such as platinum and palladium, are used because of their high catalytic performances. However, those metals are quite expensive and their sintering at rather low temperature decreases their catalytic performances. These observations had encouraged the development of new free noble metal catalysts. In that case, perovskite ceramics seem promising since these compounds are cheaper than noble metals and could be implemented as Diesel oxidation catalysts. However, the main drawback of perovskites are their rather low specific surface areas. In this present study, we propose to use the reactive magnetron sputtering technique to produce nanostructured thin films of perovskites. Coatings of silver and strontium double substituted lanthanum cobaltite perovskite have been deposited on dense alumina and YSZ (Yttria-Stabilized Zirconia) substrates by reactive magnetron sputtering. Deposition parameters such as the current applied to the metallic targets and the oxygen partial pressure have been optimized to generate nanowires. Catalytic performances of the perovskite layers have been carried out for CO oxidation.

2 Experimental/methodology

Thin films of $La_{1-x-y}Sr_xAg_yCoO_3$ (x=0,1, y=0,48 for LSACO-8; x=0,2, y=0,48 for LSACO-7; and x=0,23, y=0,21 for LSACO-5) perovskites have been prepared by using reactive magnetron sputtering at room temperature from a La (thickness : 3 mm, diameter : 200 mm, purity : 99,9 %), Ag, Sr and Co targets (thickness : 6 mm, diameter : 200 mm, purity : 99,9 %). The applied current on targets was in the range 0.35-0.4 A, 1.1-1.2 A, 8-12 mA and 0.6-1.2 A for Co, Sr, Ag and La, respectively. The pressure inside the sputtering chamber was 1.5 Pa. Depositions were performed in reactive conditions with a flow of oxygen and argon of 20 and 50 sccm, respectively. The draw distance between targets and substrates was 50 mm. Films were deposited on commercial dense disks (diameter: 16 mm, thickness: 0.6 mm) of alumina (KERAFOL 95) and Yttria-Stabilized Zirconia (YSZ, LEPMI). All of as-deposited coatings were found to be amorphous. After a calcination at 773K for 2 hours, XRD have shown that they have crystallized into the required perovskite structure. SEM, EDX and XPS analysis have been performed to determine the chemical composition of the films after calcination as well as their microstructure.

A continuous flow quartz reactor was used for the catalytic performance measurements. The overall flow rate, 4.5 L h^{-1}, was monitored with mass flow controllers (Brooks). The CO

concentration (CCO) was 3000 ppmv (Air Liquide, CO 1 ± 0.002 % in He); oxygen concentration (Air Liquide, O_2 99.95 %) was 3%, helium was used as carrier gas. CO, CO_2 and O_2 were analyzed by using an on-line micro gas-chromatograph (R3000 SRA Instruments). CO_2 was detected with a CO_2 IR analyzer (Horiba VA 3000).

3 Results and discussion

The microstructure of lanthanum cobaltite thin films after calcination at 773K strongly depends on the silver loading in the perovskite (Fig. 1). For low Ag level, such as LSCO-5, films are rather dense with cracks whereas for high loadings, such as LSACO-7 and LSACO-8, layers presents a nanowire type morphology. The thickness of the perovskites films is around 1.5 µm.

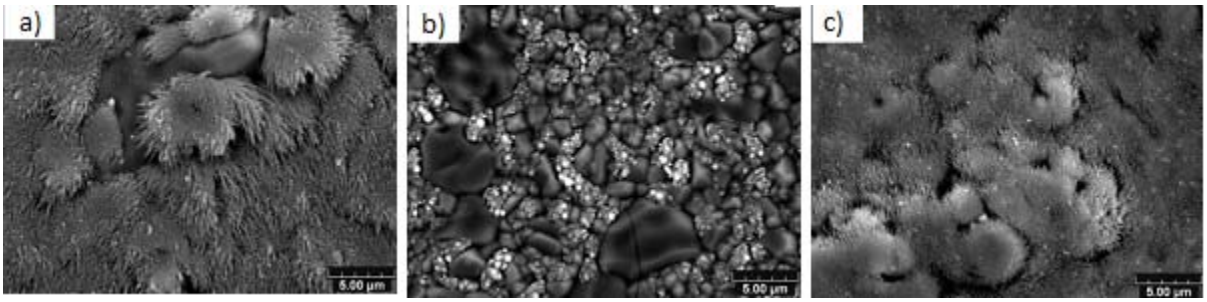

Fig.1: SEM images of perovskite films surfaces: LSACO-8 a), LSACO-5 b), LSACO-7 c).

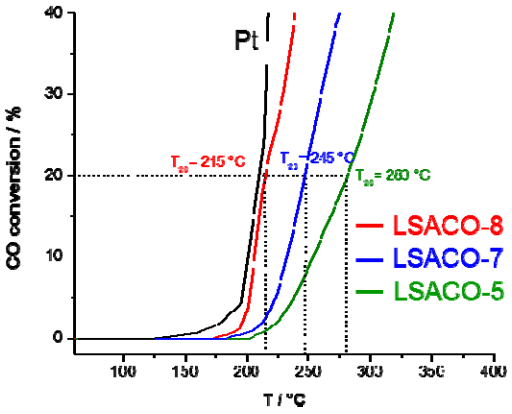

Fig.2: CO conversion as a function of temperature of lanthanum cobaltite thin films interfaced on YSZ. Comparison with a Pt film prepared by PVD (thickness = 80 nm).

Catalytic performances for CO oxidation (Fig. 2) increase with the Ag loading inside the perovskite and therefore with the film porosity induced by nanowires. Values of T20, temperature at 20% of CO conversion, decreases from 280°C down to 215°C between LSACO-5 and LSACO-8. In addition, catalytic properties of LSACO-8 are similar to those a Pt thin film interfaced on the same substrate. XPS analysis have evidenced a surface segregation of Ag as well as the presence of Ag oxide. Thermal stability of these catalytic perovskites films have also been tested.

4 Conclusions

Nanostructured silver and strontium double substituted lanthanum cobaltite perovskite thin films have been synthetized by reactive magnetron sputtering. A nanowire type morphology has been achieved for high Ag loadings. These nanowires, thermally stable at 500°C, increase the porosity of the catalytic films and then their catalytic properties.

Keywords: photocatalyst, VOCs, UV, air, ozone

1 Introduction

The use of UV light in combination of other oxidation agents (ozone, hydrogen peroxide, photocatalyst) for water purification has proved a high efficacy for both water purification and disinfection [1], [2].

Many air emissions also need a purification stage to abate toxic VOCs and a similar system may be a valid alternative to the current incineration technologies because it saves a high amount of fuel and it reduces dramatically the CO_2 emissions. This research area is quite innovative and it requires a further investigation to match the performances of an incinerator.

The aim of this work is the study of the efficiency of a treatment with UV and photocatalyst to degrade trace concentrations of VOCs with a low UV power. The catalysts will be both commercial and specifically prepared and the UV-catalyst system will be combined with ozone to study the synergic effect of all the possible oxidants.

2 Experimental/methodology

The experimental set up is composed by a reactor with a cylindrical body, a length of 320 mm and a diameter of 180 mm. At the center of the reactor, different UV-C lamps can be placed axially. The lamps investigated in this work are low-pressure Hg lamps and the power varies between 14 and 42W. The walls of the reactor can be coated by the photocatalyst and this study investigates commercial catalysts as. Aeroxide P-25, Aeroxide P-90, and Cristal PC-105 as well as catalysts specifically synthesized.

The liquid pollutant is fed in an evaporator with a syringe pump and the vapor is then mixed with the main air stream. The air flow rate is adjusted by flow meters and external ozone may be added to the stream. The external ozone is generated by the *A2Z Ozone Systems S-3G Lab* generator and the ozone output can be adjusted up to 3 g/hr.

After the reactor, the organic products are analyzed with a GC Agilent 7890B coupled with a MS 5977A. The ozone concentration is monitored with an ozone analyzer, *2B Technologies UV-106L*, and the temperature and humidity are also monitored and controlled.

The aim of the first tests is the investigation of the VOC degradation due to the UV + ozone only. The main investigated variables are temperature, humidity and flow rate. The study is going to be extended by including the catalysts coated on the reactor inner walls and by study the performances of a UV+catalyst system and of a combined UV+ozone+catalyst system.

3 Results and discussion

Figure 1 shows the results of the first tests with the UV+ozone system. The VOC degradation is studied at different inlet concentrations and residence times inside the reactor.

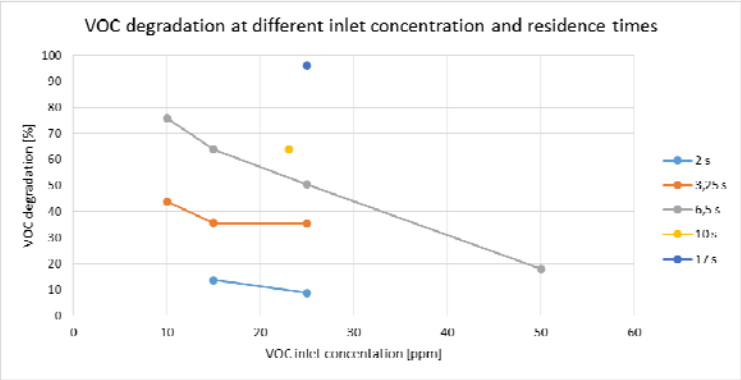

Fig. 1. VOC degradation at different inlet concentrations and reaction residence time.

First, the Figure shows that this system has a great potential for the VOC abatement because high values of conversion can be achieved with a very high residence time. However, such a high residence time is not affordable in many applications, therefore the maximization of the degradation will be sought with other media. Another result is the linear decrease of the VOC degradation with the inlet concentration suggesting a simple first-order correlation.

This study will be completed by testing the whole range of inlet concentrations, residence times and ozone concentrations. Then, the catalyst will be implemented in the system to investigate its potential application.

Among commercial catalysts, Aeroxide P-25, Aeroxide P-90, and Cristal PC-105, other catalysts will be synthesized with different techniques (e.g. sol-gel [3] or microemulsion) and different dopants. The use of dopants is mainly aimed to increase the affinity towards organic compounds or prolong the reactive time [4].

After the screening of the catalyst, the most promising ones will be combined with ozone to study the synergic potential of both the oxidants.

4 Conclusions

This work investigates the use of a combined system made by UV-C lamps, ozone and photocatalysts to abate the VOCs present in air emissions. The study is focused on trace concentration and the current investigation involves the influence of VOC, ozone concentration and residence time in the final conversion.

The results show a good potential of the current system for the designed application and they suggest a correlation between the VOC initial concentration and the conversion.

This preliminary study will be extended and different photocatalysts will be implemented to improve the global conversion and evaluate the efficiency of the catalysts compared to ozone as oxidation agent.

Keywords: carbon dioxide, cyclic carbonates, heterogeneous catalysis, mesoporous, titanium-silicates, MIL-125, oxidative carboxylation

1 Introduction

Utilization of CO_2 and its transformation into useful organic chemicals has become an increasingly popular research topic. In particular, the synthesis of cyclic carbonates via cycloaddition of CO_2 to epoxides is one of the promising technologies for chemical fixation of carbon dioxide. On the other hand, the direct synthesis of cyclic carbonates from olefins, an environmentally benign oxidant and CO_2 might become a more economically viable process due to the use of low-cost and easily available raw materials, viz., olefins, and avoidance of the separation of epoxides after their synthesis. In this work, we explored the catalytic performance of a mesoporous mesophase titanium-silicate, Ti-MMM-E, prepared by a simple and versatile evaporation-induced self-assembly (EISA) technique [1] in the oxidative carboxylation of styrenes using two environmentally friendly oxidants, H_2O_2 and *tert*-butylhydroperoxide (TBHP). For the sake of comparison, other types of Ti-containing catalysts, specifically, mesoporous titanium-silicate Ti-MMM-2 and metal-organic framework MIL-125, were also examined. The effects of reaction conditions on the olefin conversion and carbonate yield have been studied. Special attention was drawn to the crucial issues of the catalyst stability and recyclability as well as employment of solvent-free conditions.

2 Experimental/methodology

The Ti-MMM-E catalyst was prepared through EISA in ethanol/H_2O/HCl solution using tetraethoxy titanium (IV) modified with acetylacetone (1:1 mol/mol) as titanium precursor, tetraethylorthosilicate as silica precursor, and cetyltrimethylammonium bromide as template as described previously [1]. Ti-MMM-2 [2] and Ti-MIL-125 [3] were prepared by hydrothermal synthesis according to the literature protocols.

Catalytic experiments were carried out in thermostated stainless steel Parr-4792 reactor with PTFE insert under 8 bar CO_2. Typical reaction conditions were as follows: styrene/TBHP(H_2O_2)/TBABr/Ti molar ratio = 1/1.5/0.1/0.06, MeCN (if any), biphenyl (internal standard for GC). The mixture was stirred continuously while the pressure (8 bar) and temperature (30-90 °C) were kept constant during the reaction. After specified reaction time (24 or 48 h), the reactor was cooled down by ice water and depressed before opening The reaction products were identified by GC-MS and quantified by GC. After the catalytic run, catalyst was separated by filtration, washed with solvent, dried in air at room temperature overnight, calcined in air at 350 ^oC for 2 h and at 550 ^oC for 4 h, and then reused. The catalyst was characterized by DR UV–vis spectroscopy, N_2 adsorption measurements, and elemental analysis before and after reuse.

3 Results and discussion

Among the catalysts studied, the mesoporous titanium-silicate Ti-MMM-E prepared by the simple and affordable EISA methodology demonstrated superior catalytic performance in terms

of substrate conversion and carbonate selectivity in the oxidative carboxylation of styrenes using TBHP as oxidant and tetrabutylammonium bromide (TBABr) as cocatalyst at mild reaction conditions (Figure 1). We evaluated the impact of the reaction conditions (solvent nature, temperature and reactant concentrations) on the styrene conversion and carbonate selectivity using Ti-MMM-E as the most prospective catalyst. Rise of the temperature from 30 to 70 ^{o}C increased both substrate conversion and carbonate selectivity. A multiplication of the reactant loading in the reactor revealed that increase in the initial concentration of styrene while keeping constant the molar ratio of all the reactants improved carbonate selectivity and conversion. Under green solvent-free conditions, the selectivity towards styrene carbonates reached 69-70 % at 92-98.5 % substrate conversion at 70 ^{o}C and 8 bar CO_2 (Fig. 1). Thus the volume yield of styrene carbonates as high as 0.3 kg per L of the reaction mixture could be achieved.

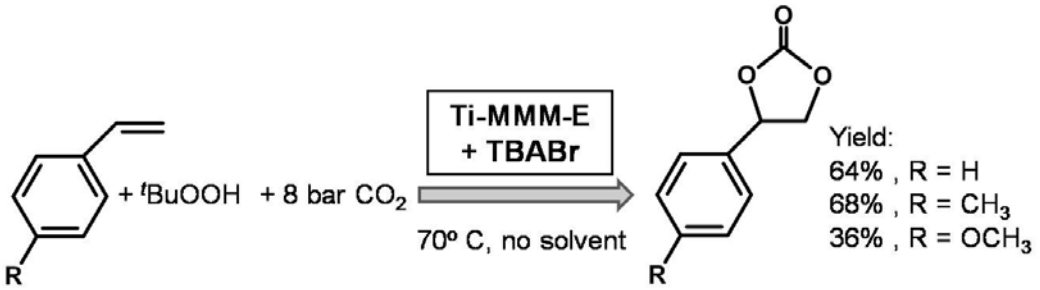

Fig. 1. Oxidative carboxylation of styrenes by Ti-MMM-E/TBABr/TBHP/CO_2 system.

Importantly, no titanium leaching into solution occurred and the Ti-MMM-E catalyst could be easily recovered by simple filtration and used repeatedly without a significant deterioration of the catalytic performance. Studies by DRS-UV, and N_2 adsorption confirmed the retention of the catalyst structure.

4 Conclusions

The mesoporous titanium-silicate Ti-MMM-E prepared by evaporation-induced self-assembly is an efficient heterogeneous catalyst for the oxidative carboxylation of styrenes with *tert*-butyl hydroperoxide and carbon dioxide in the presence of tetrabutylammonium bromide as cocatalyst under mild solvent-free conditions (50-70 ^{o}C, 8 bar CO_2).

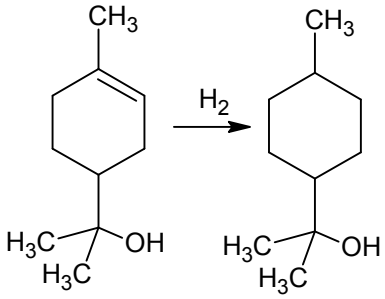
Keywords: terpineol hydrogenation, Raney, nickel, palladium catalysts

1 Introduction

Natural or synthetic α-terpineol is one of the most important and demanded substances, utilized in perfumery and cosmetics to give to remedies the smell of lilac. Dihydro-α-terpineol is also actively used as component of fragrances, perfume compositions and odorants. However, there were discovered only *trans*-form in nature (in American turpentine and pine oil), while *cis*-modification is just obtained synthetically. Dihydro-α-terpineol is commercially demanded in the world. The direct way to produce it is hydrogenation of synthetic terpineol. Synthetic α-terpineol represents a liquid mixture of terpineol isomers: α-terpineol (90-94%), β-terpineol (3-5%), γ-terpineol (2-4%) and terpinene-1-ol (1-2%).

2 Experimental

In presented work the technique of dihydro-α-terpineol obtaining was enclosed in heterogeneous catalytic hydrogenation of terpineol by the reaction below:



Experiments of terpineol hydrogenation to dihydroterpineol were carried out in laboratory reactor over powder and cellular catalysts in ethylacetate solution under pressure of hydrogen 0.7-1.1 MPa and temperature 70°C.

Powdered Raney nickel and palladium-covered γ-Al_2O_3, as well as block-structured α-Al_2O_3 catalysts, covered by γ-Al_2O_3 and pyrocarbon as substrates for palladium coatings, were investigated.

The hydrogenation process was controlled by decrease of hydrogen pressure. All products were analyzed by gas chromatography method.

3 Results and discussions

As shown in Table 1, conversion of α-terpineol significantly depends on the catalyst structure. Thus, the hydrogenation process over skeletal Raney nickel and powdered palladium catalyst lasts for 3 hours, while the same yield of dihydro-α-terpineol over block-structured palladium catalyst is achieved for 1 hour. In addition, the process is suspended with decreasing of hydrogen pressure in the system.

Hydrogenation over catalyst with pyrocarbon substrate requires separate words. The 90% yield of dihydro-α-terpineol reaches under lower pressure and for shorter time. This can be explained by more developed surface area of carbon.

Table 1. α-Terpineol hydrogenation with various catalysts of various structure

№	Structure	Substrate	Active metal and its content, % wg	Pressure of H_2, MPa	Time, hour	Yield, %
1	Skeletal	-	Raney Ni	1.1	3	94
2	Powder	γ-Al_2O_3	0.6% Pd	1.1	3	94
3	Block	γ-Al_2O_3	0.5% Pd	1.1	1	93
4	Block	γ-Al_2O_3	0.5% Pd	0.9	2	89
5	Block	γ-Al_2O_3	0.5% Pd	0.7	2	84
6	Block	Pyrocarbon	0.5% Pd	0.7	1	90

4 Conclusions

As a result of terpineol hydrogenation data analysis in all of the investigated reactions dihydro-α-terpineol was obtained with high yield (84-94%) for 1-3 hours at 70°C. There were shown that the most active catalysts are block-structured palladium catalysts.

Keywords: catalyst nitrogen oxidation, catalytic combustion, Al_2O_3, CuO, CeO_2

1 Introduction

High temperature catalytic oxidation of nitrogen contaiining compounds has great importance for the analysis of environmental and industrial samples and the control of emissions of waste incineration facilities. The complete oxidation of nitrogen in different functional groups, ammonia and nitrates to NO and NO_2 is a crucial step for the determination of nitrogen in samples and NO_x abatement [1,2]. Altough platinum group metals have excellent oxidation activity, they are expensive and easily poisoned by the presence of S, Cl and P containing organic substances. Therefore, there is a great interest to develop new active, selective and resistant catalyst to treat waste oxidation gases. In this study, the catalytic activities of CuO and CuO-CeO catalysts for the complete oxidation of various nitrogen containing functional group are investigated at different temperatures and the results are compared with platinum catalyst.

2 Experimental Method

The catalyst samples were prepared to obtain a loading of 10% Cu, 3%Cu-7%Ce, 1% Pt over the Al_2O_3 as a suppport by incipient wetness method. After impregnation, the catalyst samples dried at 110 ^oC for 24 hours and calcined at 500 ^oC for 5 h in a furnace. Characterization of the catalyst samples was performed by X-ray powder diffraction (XRD) and BET. EDTA, urea, potassium nitrate, ammonium chloride, thiourea, pyridine, glycine, yeast extract, and metylamine were selected as model components representing various nitrogen containing functional groups. The experiments were performed in a quartz tubular reactor in two zone furnace and the sample first oxidized at 700-850 ^oC under air flow of 50 ml/min and the waste gases treated in second zone at 500^oC over catalyst bed. The catalytic activities of the samples were investigated by mass spectrometry by analyzing combustion products.

3 Results and Discussion

BET surface area values of the catalysts samples are given in Table 1. It is seen that the surface area changes significantly when impregnating cerium and copper on Al_2O_3.

Table 1. BET Surface area of the catalyst

Sample	BET Surface Area (m^2/g)
Al_2O_3	314.8
1%Pt/Al_2O_3	309.6
10%Cu/Al_2O_3	244.3
3%Cu- 7%Ce/Al_2O_3	261.0

In Figure 1, the diffraction peaks of Cu/Al2O3, Cu-Ce/Al_2O_3 and Pt/Al_2O_3 samples are shown. Results show that CuO is highly dispersed over the Al_2O_3 support in all the catalysts.

The low amount of CuO over the Al_2O_3 support does not allow to form bulk CuO so this XRD result is expected[3]. In the samples containing cerium oxide, characteristic peaks of crystalline CeO_2 are clearly seen which is in agreement with literature [3].

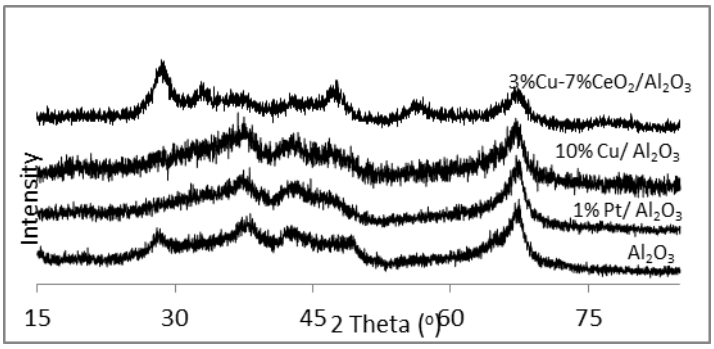

Figure 1. XRD patterns of catalyst samples and support

NO (m/z=30) signals observed in mass spectrometry for urea and EDTA samples having equivalent mass of nitrogen (7.52 mg), over 10%Cu/Al_2O_3 catalyst sample are shown in figure 2. As it is seen from the figure, EDTA oxidation follows at least two step mechanism compared with the simple structure of urea.

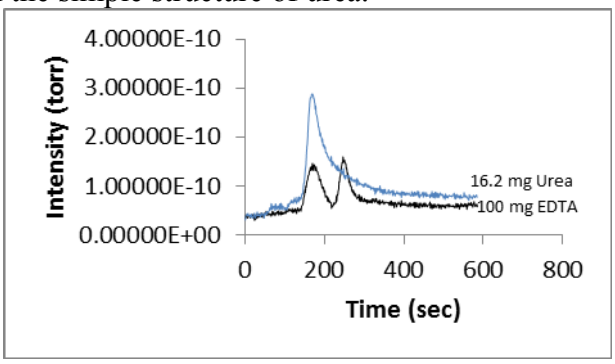

Figure 2. Change in amount of NO in the combustion gases

4 Conclusions

In this study Cu/Al_2O_3, Cu-Ce/ Al_2O_3 and Pt/Al_2O_3 catalyst samples are tested for the complete oxidation of various nitrogen containing functional groups at different temperatures. The characterization of physical properties of catalyst samples was performed by XRD and BET. The catalytic activities of the samples were investigated by analysing of combustion products of model components with mass spectrometry.

Keywords: oxidation, ozone, sulfur, desulfurization

1 Introduction

Tightening environmental regulations on sulfur content in motor fuels requires improvement of existing and development of new technologies for the removal of sulfur compounds. Existing large-hydrotreating process requires high financial and energy costs, which makes it's introduction on mini-refineries unprofitable. Among the alternative methods with low cost the most promising process is oxidative desulfurization [1]. The aim of our work is developing new oxidative desulfurization technology using ozone as an oxidant.

2 Results and discussion

In this work the oxidant was used with catalytic system, which contains a transition metal salt with an organic ligand capable of forming under the influence of ozone oxidative active complex and further oxidize the fuel present in the sulfur-containing compounds, followed by adsorption of oxidation products on silica gel. In this method, the ozone is prevented from direct contact with the fuel, making the process not only cheap and accessible, but also safer. The results are shown in the table.

Fuel type	Salt/ligand	Initial sulfur content, ppm	Residual sulfur content, ppm
Gasoline	$CuSO_4$/ sodium gluconate	700	180
Gasoline	$CuSO_4$/ EDTA	700	330
Gasoline	$VOSO_4$/ sodium gluconate	700	195
Diesel	$CuSO_4$/ sodium gluconate	3500	2090
Diesel	$CuSO_4$/ EDTA	3500	2355

3 Conclusions

This process allows to achieve the degree of desulfurization of gasoline and diesel fractions 74 and 60%, respectively.

Investigation of Commercial Catalyst for Methane Oxidation after Real Operation Condition

Alikin E.A.*

Ecoaliance Ltd, Novouralsk, Russia

* alikin@eco-nu.ru

Keywords: methane oxidation, palladium, sulphur, carbon, layer, catalyst reduction

1 Introduction

CNG transport is actively developed throughout the world. In spite of essential increase of ecological parameters of such vehicles, the problem of neutralization of unburned methane, which is greenhouse gas, arises. Palladium catalysts with high metal surface concentration (3-6%) are still irreplaceable for methane oxidation in commercial application. However such catalysts are quickly deactivated during operation in lean fuel-air mixtures. The target of this study is a search of causes of palladium catalysts deactivation under life tests.

2 Experimental

The object of research is an active layer of monolith catalyst after 13000 km run (3 months of operation) within a bus. The active layer Pd(2.5%)-Pt(0.6%)/(Al_2O_3+$Ce_{0.5}Zr_{0.5}O_2$) was separated from ceramic carrier. Physical-chemical characteristics of the powder was investigated by BET, XRD, TEM-EDX and other methods. Desulfatation test of catalyst powder was performed by TGA equipped with MS. Catalytic activity tests of monoliths was performed in flow reactor system (MEXA-9500 HORIBA).

3 Results and discussion

The catalyst layer researched by TEM-EDX shows that there is an accumulation of essential amount of sulfur in the alumina structure (Figure 1a). Sulfur concentration are vary 1,5-4% against areas of oxide carrier. Besides, essential part of carbonic deposits that covers palladium particles (Figure 1b), they are also present separately in the form of filamentous particles.

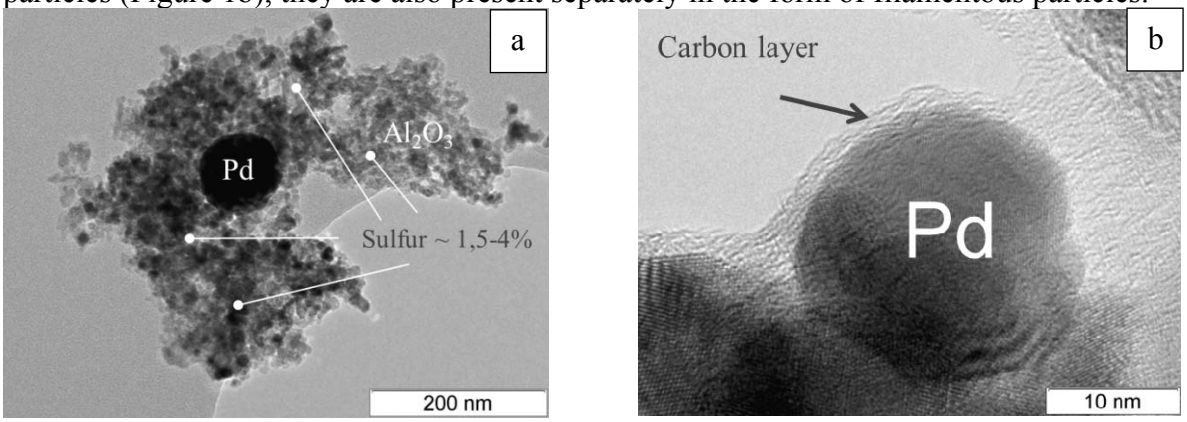

Fig. 1. Microstructure of catalyst layer after 13000 km run

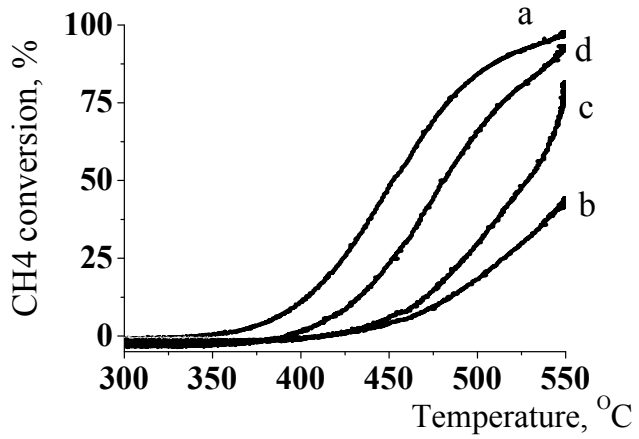
As a result of sulfur poisoning this catalyst sample loses its activity, methane oxidation temperature rises more than 100 °C, oxidation efficiency reduces for 50% (Figure 2b). Low efficiency was unchangeable during prolonged holding in lean reaction gas mixture.

Next step we tried to select the conditions (temperature, gas media) for desorbing of sulfur compounds using TGA with MS. During heating in air desorbing of sulfur takes place in the wide temperature range 550-1030 °C with maximum of 780 °C. Catalyst activity after this

procedure rises insignificantly (Figure 2c). However rich methane media passes through the catalyst during a few minutes the sulfur desorption is more intensive even at 580-600°C temperature. After this procedure methane conversion in 550 ^{O}C almost completely recovers to the previous level (Figure 2d).



a – fresh sample

b – sample after run 13000 km

c – sample «b» after annealing 1000 ^{O}C/1h in muffle

c – sample «b» after treatment in CH_4-rich media in 570 °C/5 min

Fig. 2. – Methane oxidation light-off curves

4 Conclusions

Commercial catalyst loses its activity due to sulfur poisoning of Al_2O_3 with subsequent covering of palladium particles with carbonic deposits. Catalyst activity may be partially recovered by treatment in the medium enriched by methane. During the process sulfur compounds desorbing takes place.

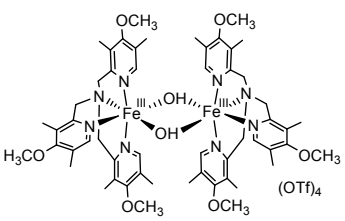
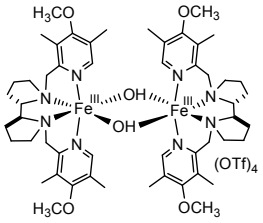
Keywords: biomimetic, enantioselective, epoxidation, EPR, iron, mechanism

1 Introduction

In Nature, metalloenzyme-catalyzed oxidations often exhibit exquisite substrate specificity as well as regioselectivity and/or stereoselectivity. This stimulates chemists to develop synthetic bioinspired systems that may have broader substrate scope and tunable selectivity, which makes them challenging protagonists of environmentally friendly catalytic chemistry of the near future.[1a] Catalyst systems based on iron complexes with tetradentate N_4-donor, mainly, aminopyridine ligands, H_2O_2, and carboxylic acid as an additive have attracted particular attention in the last decade due to high efficiency and selectivity in the preparative oxidations of C–H and C=C groups of various organic molecules.[1b] Although the mechanistic landscape of aminopyridine iron catalysts has been discussed in a series of elegant experimental works, the problem of direct experimental detection and identification of the elusive oxygen-transferring species in these catalysts is far from being solved.[1c]



1



2

In the present study we have undertaken an EPR spectroscopic study of the active species of the highly effective and enantioselective catalyst systems (epoxidizing olefins with up to 99% *ee*)[2] based on aminopyridine iron complexes **1** and **2** with electron-donating substituents at the pyridine rings.

2 Experimental/methodology

Complexes **1** and **2** were synthesized by mixing appropriate amounts of the corresponding ligand (1 equiv), iron(II) triflate (1.05 equiv) and H_2O_2 solution (0.5 equiv) in CH_3CN followed by slow diethyl ether diffusion into the resultant solution at 5 °C. For complex **2**, the X-ray structure was obtained. EPR spectra (−196 °C) were measured on a Bruker ER-200D spectrometer at 9.3–9.4 GHz, modulation frequency 100 kHz, modulation amplitude 5 G. Measurements were conducted in a quartz finger Dewar filled with liquid nitrogen. Samples were prepared by mixing the reagents directly in a quartz EPR tube (d = 3 mm) in a 1.8:1 CH_2Cl_2/CH_3CN mixture at −90…−75 °C. To measure the reactivity of intermediates **1b** and **2b** towards alkene oxidation, the appropriate amount of a frozen alkene solution was rapidly placed into the EPR tube containing frozen solution of preliminary generated intermediates **1b** or **2b**. After the solution melting at −85 °C, the decay rates of **1b** and **2b** were monitored at this temperature.

3 Results and discussion

The starting dinuclear complexes **1** and **2** were EPR silent. The addition of the excess of CH_3COOH (10-50 equiv) to these complexes at room temperature resulted in the formation of the low-spin (S = 1/2) acetoxo-iron(III) complexes $[(L)Fe^{III}(OC(O)CH_3)]^{2+}$ **1a** (g_1 = 2.58, g_2 =

2.38, g_3 = 1.72) and **2a** (g_1 = 2.54, g_2 = 2.41, g_3 = 1.79) displaying different stability at room temperature ($\tau_{1/2}$(**1a**) = 2 min, $\tau_{1/2}$(**2a**) = 1 h). The addition of 3 equiv of H_2O_2 to just prepared samples **1**(**2**)/CH_3COOH at −80…−75 °C led to the formation of new low-spin (S = 1/2) iron-oxygen intermediates **1b** (g_1 = 2.070, g_2 = 2.005, g_3 = 1.956) and **2b** (g_1 = 2.071, g_2 = 2.008, g_3 = 1.960) extremely unstable even at −85 °C ($\tau_{1/2}$(**1b**) = 5 min, $\tau_{1/2}$(**2b**) = 4 min). The evaluated maximum concentration of **1b** and **2b** did not exceed 1-2% of the total iron concentration. It should be noted that the samples **1**(**2**)/H_2O_2 containing no acetic acid displayed no EPR signals in the range g = 1.5–3.

To directly assess the reactivity of **1b** and **2b** towards alkene epoxidation, the rates of decay of **1b** and **2b** in the absence and in the presence of various alkenes were compared. It was found that the addition of relatively small amounts of cyclohexene or *cis*-*β*-methylstyrene ([alkene]/[Fe] = 0.5) to the samples containing **1b** or **2b** results in the decrease of the half-life time of **1b** and **2b** from $\tau_{1/2}$ = 4-5 min to $\tau_{1/2}$ < 0.5 min at −85 °C, whereas electron-deficient alkenes (1-acetyl-1-cyclohexene and cyclohexene-1-carbonitrile with an [alkene]/[Fe] ratio up to 10) do not visibly affect the decay rates of **1b** and **2b**. Hence, **1b** and **2b** are highly reactive towards electron-rich alkenes even at −85 °C. To quantify the products of interaction of **1b** and **2b** with cyclohexene, catalytic oxidation experiments at −85 °C were performed. 4.5 and 5.3 TN cyclohexene oxide were obtained 15 min after the reaction onset with catalysts **1** and **2**, respectively (TN = moles of product per mole of Fe, [Fe]:[H_2O_2]:[CH_3COOH]:[C_6H_{10}] = 1:10:20:30, [Fe] = 0.02 M). The total amount of other cyclohexene oxidation products was <1% with respect to the epoxide. Thus, the active species **1b** and **2b** oxidize cyclohexene at −85 °C with >99% selectivity towards the epoxide.

The g-values and line widths of intermediates **1b** and **2b** are very similar to those of spectroscopically well characterized model oxoiron complex $[(TMC)Fe^{V}{=}O(NC(O)CH_3)]^{+}$ (TMC = tetramethylcyclam).[3] On the basis of this similarity and reactivity data, we have assigned intermediates **1b** and **2b** to the oxoiron(V) $[(L)Fe^{V}{=}O(OC(O)CH_3)]^{2+}$ active species of selective alkene epoxidation by the catalyst systems studied herein.

4 Conclusions

In summary, the extremely unstable iron-oxygen intermediates formed in bioinspired catalyst systems based on dinuclear ferric complexes with aminopyridine ligands containing electron-donating substituents, H_2O_2 and acetic acid have been detected by EPR spectroscopy for the first time. The detected intermediates **1b** and **2b** are highly reactive and selective towards electron-rich alkene epoxidation even at −85 °C. They exhibit rhombic EPR spectra with the main values of g-tensor close to those of known oxoiron(V) complexes. Presumably, the observed small g-tensor anisotropy is due to the delocalization of unpaired electron over the organic ligand.

Keywords: Cu-CHA, NSR-SCR, double, bed, zero emission

1 Introduction

The reduction of NO_x emission in diesel vehicles and new biofueled engines below the limits imposed by regulations is an important environmental problem. In recent times, the combination of after-treatment systems (NSR-SCR) emerges as a promising solution [1,2]. NSR (NO_x Storage and Reduction) technology operates alternatively under lean and rich conditions and conventional Lean NO_x Traps (LNTs) are formulated with a high surface area support (Al_2O_3), incorporating platinum and alkaline/alkaline earth spread as monolayer oxides. However, a drawback of these catalysts is the NH_3 slip produced during the regeneration step [1-3]. SCR (Selective Catalytic Reduction) process is based on the reaction between the ammonia and NO_x and it is developed for stationary emission sources or heavy-duty vehicles with NH_3 as supplied reducer (urea tank).To achieve zero emission in light diesel vehicles, hybrid systems NSR-SCR have been proposed [1,2]. The most studied catalysts for SCR catalyst are exchanged zeolites, such as ZSM5, or BETA, with iron or copper as metals, despite of presenting low hydrothermal stability. Actually, small pores zeolites as chabazite have proposed. Nevertheless, some studies indicate that a bimodal distribution could be more adequate. This contribution is focused on the DeNOx of a combined system NSR-SCR, over Pt-Ba-K/Al_2O_3 and Cu-chabazite catalysts, with a bimodal porous distribution and synthesized in one step; and the decoupling of the performance of individually catalytic bed.

2 Experimental

NSR (Pt-Ba-K/Al_2O_3) and SCR (Cu-CHA) homemade catalysts have been prepared and well-characterized by DRX, XPS, N_2 adsorption-desorption, TEM, SEM and Raman. The experiments were performed in a down flow stainless steel reactor, with 1 g of 0.03-0.05 mm pelletized sample. SCR feed conditions consist of 750 ppm NO, 750 ppm NH_3 and 6% O_2 in Ar for different GSHV and the presence of water was also studied. LNT catalyst and double configuration (NSR-SCR dual system) were run under NSR conditions between long lean (150s) and short rich (20s) periods. The composition of the lean gas mixture was 750 ppm NO and 6% O_2 using Ar as balance gas; this oxygen was replaced by 4% H_2 during the rich period. All the experiments were carried out in the temperature range between 150-450 ºC, analyzing the outlet gases concentration by online FTIR multigas analyzer (MKS 2030).

3 Results and discussion

The Pt-Ba-K/Al_2O_3 formulation presents a high adsorbed NO_x conversion and almost complete N_2 selectivity values [3] and the Ba/K combination hinder practically the NH_3 slip even at lower temperatures. However, it has been subjected to extreme conditions, such as a high hydrogen concentration in short periods to increase undesirable products to value the

performance of dual system. In the Cu-CHA with a bimodal porous distribution synthesized in one step, the Cu is incorporated as Cu +1/Cu +2 oxide forms. In Figure 1 are represented the NO conversion values as a function of temperature in the standard SCR conditions. Complete NO-conversion values are registered in the SCR whole range, being mainly Cu^{2+} species that are involved in the DeNOx-SCR process. It was checked the NO conversion increase at lower space velocity, otherwise, N_2O production is higher due to ammonia nitrates decomposition. Nevertheless, in all cases the selectivity to nitrogen is almost 100%. The presence of water in the feed stream improves SCR efficiency, showing lower N_2O values and a higher N_2-selectivity.

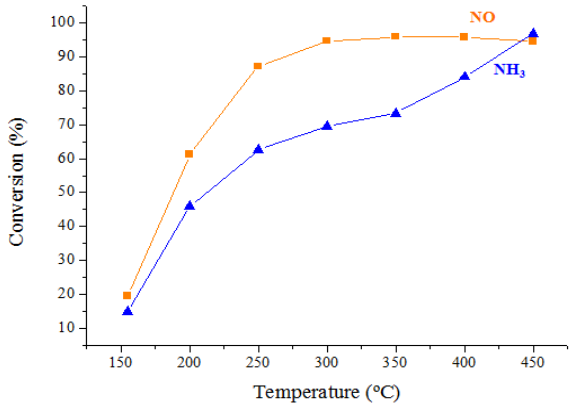

Fig. 1. NO (■) and NH_3 (▲) conversion profiles over Cu-CHA for standard SCR conditions

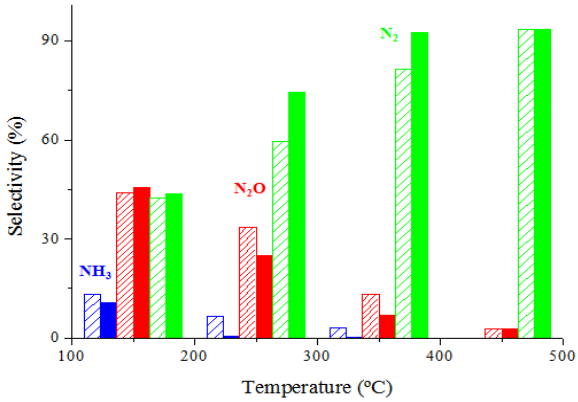

Fig. 2. NH_3, N_2O and N_2 selectivity in NSR conditions for Pt-Ba-K/Al_2O_3 catalyst (striped) and NSR-SCR coupled system (plain)

Decoupled fixed-bed catalysts have been studied individually to confirm that exist an improvement in the NOx elimination with these catalyst formulations. In fact, the combination of double-bed of NSR-SCR catalysts provokes a sensible increase of the nitrogen production and a reduction of N_2O and NH_3; that it can be observed from data represented in Figure 2. Cu-CHA as SCR coupled system is acting as a NH_3 trap and even in extreme conditions during the short rich-periods. It is possible to couple with others LNT_catalysts that produce more ammonia and during much longer in rich periods with low H_2 concentration supplied.

4 Conclusions

This combination of after-treatment systems consisting of a LNT catalyst with minimum NH_3 emission and a copper-chabazite, highly selective to N_2, acts as an effective NO_x removal process.

Keywords: carbon dioxide, methane reforming, ferrites, perovskite

1 Introduction

Catalysts based on perovskite-type layered structures are alternative catalysts based on noble metals in a variety of high temperature catalytic processes of the industrial synthesis and gas purification as they are able to maintain their catalytic and mechanical properties under the severe reaction medium.

Synthesis gas (a mixture of H_2 and CO) is an input material for many chemical and petrochemical products. Carbon dioxide (dry) reforming of methane is a perspective way to produce synthesis gas to existing. Derived synthesis gas has a low H_2/CO ratio close to unity, it can be used in the Fischer-Tropsch process, two greenhouse gases (CO_2 and CH_4) are utilized in this process and natural gas can be used as a feedstock.

2 Experimental/methodology

The perovskite-type ferrites $GdSrFeO_4$, $Gd_2SrFe_2O_7$, $GdFeO_3$ and solid solutions $Gd_{2-x}Sr_{1+x}Fe_2O_7$ (x = 0,1 - 0,6) were synthesized by the high temperature solid state reactions and by sol-gel technology.

Characterization by powder X-ray diffraction (XRD) and scanning electron microscopy (SEM), has been performed for the determination of the structure and morphology of synthesized samples. XRD was performed on a Thermo ARL X'TRA diffractometer using CuKα radiation. The SEM images of synthesized samples were obtained on Carl Zeiss EVO 40EP and Zeiss Supra 40VP scanning electron microscopes.

Mössbauer spectra have been recorded at room temperature by using spectrometer Wissel (^{57}Co in a rhodium matrix with activity 10 mKu), the isomeric shifts were calculated with respect to α-Fe. In order to evaluate the part of paramagnetic species the intensity of the signals was determined precisely up to the factor of resonance absorption.

Analysis of acid-base properties of the samples surface was performed by adsorption of pyridine (Py). Their concentration in solutions were determined by UV - spectroscopy on single-beam scanning spectrophotometer SF-103.

The catalytic activity were studied in a flow apparatus at atmospheric pressure in the temperature range of 773-1223 K and flow rates of 0.5-1.0 l/h. Experiments were carried out with feeding a mixture of gases in a ratio of components CH_4:CO_2 = 1: 1,1: 2 and 2:1. Analyses of the products were performed by chromatography (Crystal 2000M) in a column of stainless steel filled with Porapack Q at 393K.

3 Results and discussion

The complex physico-chemical methods of investigation showed that synthesized catalysts

are well-crystalline homogenous perovskite-type ferrites with different number of perovskite layers $GdSrFeO_4$ (n=1), $Gd_2SrFe_2O_7$ (n=2), $GdFeO_3$ (n=∞) and solid solutions $Gd_{2-x}Sr_{1+x}Fe_2O_7$. Samples obtained by ceramic technology are in microcrystalline state and the iron atoms are found in one state - Fe^{3+}, which is magnetically ordered; oxides prepared by sol-gel technology are in nanocrystalline state and iron atom is in a heterovalent state (Fe^{3+} coexists with Fe^{+4}) in three different symmetry fields. A lowering of the symmetry of the surrounding of Fe^{+3} atoms is attributable to the presence of oxygen vacancies. Found that the adsorption of CH_4 and CO_2 occurs at different centers. Suggested that the Fe^{3+} ions are responsible for the formation of atomic hydrogen and carbonate complexes occur at ions Gd^{3+} and Sr^{2+}.

The maximum conversion (α_{CH4} = 37%, α_{CO2} = 57%) and products formation rate (W_{H2} = 0,07 mol/(h∗g), W_{CO}= 0,16 mol/(h∗g)) were achieved by performing the reaction at an equimolar ratio of CH_4 and CO_2.

On almost all investigated ferrites among the reaction products was detected water, the quantity of generated carbon monoxide was 2-4 times greater than the quantity of hydrogen and carbon dioxide conversion was almost two times higher methane conversion. Activation energies of CO formation and the corresponding values of lnk_0 were less than the similar values of E_a and lnk_0 for hydrogen. Based on these data suggested that the DRM reaction is complicated by the reverse steam reforming of CO.

It is shown that an increase in the number of perovskite layers (n) in the complex oxides structure leads to an increase in the catalytic activity. And a partial substituted or complete replacement of ions Gd^{3+} by ions Sr^{2+} leads to some reduction of activity. Among the systems of variable composition $Gd_{2-x}Sr_{1+x}Fe_2O_7$ obtained by the sol-gel technology samples with x = 0.3 had the highest activity. Increase of strontium content led to lowering of the symmetry of the surrounding of Fe^{+3} atoms, occurrence of heterovalent state of iron atoms (Fe^{3+}, Fe^{4+}) with oxygen vacancies. It influenced increase in the total surface acidity and catalytic activity in terms of CO_2 conversion. The catalytic activity was increased in the row $SrFeO_{3-x}$ (n=∞) ≈ $GdSrFeO_4$ (n=1) ≈ $Gd_{2-x}Sr_{1+x}Fe_2O_7$ (n=2) < *$GdFeO_3$ (ceramic)* (n=∞) < *$GdFeO_3$ (sol-gel)* (n=∞). Higher catalytic properties of perovskite-type ferrites synthesized by sol-gel technology can be associated with their nanocrystalline state, a porous structure, as well as with heterovalent iron state and oxygen vacancies, which probably are favorable for the surface oxidation-reduction reactions and the process of CO_2 activation.

4 Conclusions

The perovskite-type ferrites $(Gd,Sr)_{n+1}Fe_nO_{3n+1}$ (n=1, 2, ∞) were studied. Obtained catalytic properties in carbon dioxide methane reforming. It is shown that samples synthesized by ceramic technology are present in microcrystalline state and oxides prepared by sol-gel technology are in nanodispersed state. Heterovalent state of iron atoms (Fe^{3+}, Fe^{4+}) with oxygen vacancies has been found in perovskite-type ferrites prepared using sol-gel technology. It is reflected in the increase in the total number of electron-seeking surface centers and activity of CH_4 and CO_2 conversion.

Was shown the role of the structure of perovskite-type ferrites in the catalytic methane conversion.

Mechanistic Kinetic Modeling of NO Oxidation over a Commercial Cu-Zeolite Catalyst for Diesel Exhaust Aftertreatment

Fahami A.R., Nova I., Tronconi E.*

Dip.Energia, Politecnico di Milano, Milano, Italy

* enrico.tronconi@polimi.it

Keywords: Cu-zeolite, NO oxidation, reaction, modeling, Redox mechanism

1 Introduction

The Standard SCR reaction has been recently studied over Cu and Fe–zeolites by many research groups in order to establish a mechanism consistent with kinetic evidence [1]. A detailed understanding of NO oxidation to NO_2 over SCR catalysts is believed to be crucial to describe the mechanism of Standard NH_3-SCR [2]. A key point in fact is to clarify whether formation of NO_2 generates an active intermediate on the surface of SCR catalysts [3], or just leads to a terminal product in the gas phase [4].

In this work we aim at developing and validating a mechanistic kinetic model for NO oxidation to NO_2 over Cu–zeolite catalysts. Firstly, a Redox mechanism is proposed in line with previous research [4,5], and consequently a rate equation is derived from the steps of the mechanism. Then, a systematic set of steady state kinetic runs is carried out over a commercial state-of-the-art Cu-zeolite SCR catalyst to cover the effects of several operating variables. The results of such experiments are eventually used to estimate the intrinsic rate parameters of the proposed kinetic mechanism.

2 Experimental/methodology

A commercial Cu-zeolite originally in the form of wash-coated cordierite honeycomb monolith (400 cpsi–5 mils) was crushed to particles and sieved (140–200 mesh) in order to prevent mass transfer limitations. A quartz tubular microreactor (ID = 6 mm) was loaded with 60 mg of the catalyst powder. The species concentrations at the reactor outlet were continuously measured by a quadrupole mass spectrometer and a UV analyzer in parallel.

3 Results and discussion

In the assumed mechanism, copper dimers $(Cu\text{-}O\text{-}Cu)^{+2}$ are regarded as the active sites for the NO oxidation reaction, consistently with recent literature [6]. The first step is the oxidative activation of NO on the Cu sites, forming nitrites as surface intermediates (Cu^{+2}-ONO). In the next step, nitrites decompose and result in the evolution of gaseous NO_2, leaving reduced Cu sites (Cu^{+1}). This step is believed to be the Rate Determining Step (RDS) of the NO oxidation mechanism at low temperature. Finally, the reduced sites are reoxidized by oxygen to form copper dimers again. Blockage of the active sites by water as well as by nitrate buildup via the reaction between nitrites and NO_2 are taken also into account as inhibitory steps.

The effect of several operating variables on NO oxidation was investigated in the kinetic runs, including temperature, NO, O_2, H_2O and NO_2 concentrations (Figure 1), and space velocity. Since at higher temperatures NO oxidation approached thermodynamic equilibrium, only the results in the 150 to 350°C T-range are shown. The rate parameters of the individual steps in the kinetic mechanism were estimated by multi-response non-linear regression based on the least squares method, using the temporal evolutions of the relevant gaseous species

concentrations (NO, NO_2) as experimental responses. The model responses were generated by integrating in time a transient isothermal pseudo-homogeneous plug-flow model of the test microreactor. The experimental (symbols) and fitted (solid lines) NO conversions are compared in Figure 1. According to both the experimental and the fit results, NO has a kinetic order close to one (Fig.1A), oxygen has a positive fractional reaction order (Fig.1B), while H_2O is associated with a strong inhibition effect on NO oxidation (Fig.1C), which is well predicted by the model thanks to the assumption of water blocking the active sites. NO_2 also exhibits a strong negative effect on the rate of NO oxidation (Fig.1D), in line with other reports [1,3]. Again, the coverage of the Cu-sites by nitrates invoked in the proposed mechanism does a good job in describing such an inhibitory effect.

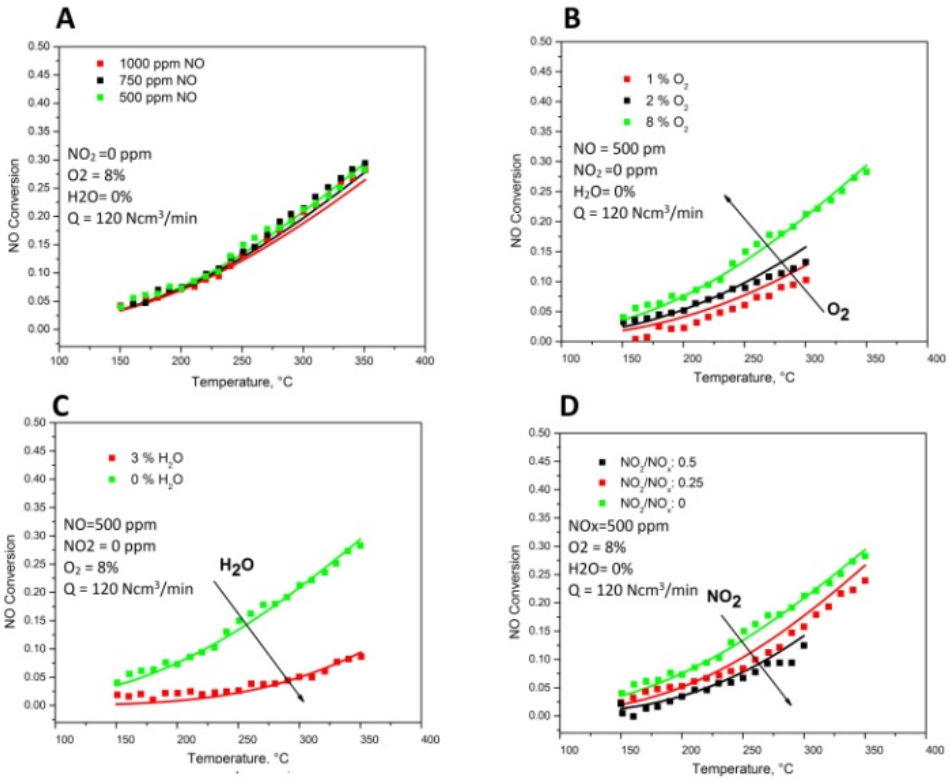

Fig. 1. NO oxidation over Cu-zeolite, GHSV= 120,000 [Ncc/h/$g_{catalyst}$] A) NO effect, B) Oxygen effect, C) H_2O effect, D) N_2O effect. Helium is used as the carrier gas.

4 Conclusions

We show that the predictions of a kinetic model based on our proposed redox mechanism for NO oxidation to NO_2 are quantitatively in accordance with the experimental data for a variety of conditions. This mechanistic model seems therefore a step forward towards a better understanding of the SCR-deNO_x activity of Cu-zeolites.

Modelling Hydrocarbon Deactivation of SCR Zeolite Catalysts

Selleri T.[1], Nova I.[1], Tronconi E.[1*], Weibel M.[2], Schmeißer V.[2]

1 - Dip.Energia, Politecnico di Milano, Milano, Italy
2 - Daimler AG, Germany

* enrico.tronconi@polimi.it

Keywords: NH3-SCR, Cu, zeolites, poisoning, hydrocarbons modelling

1 Introduction

NH_3-SCR currently represents the leading technology for the NOx abatement from lean burn Diesel engines. However, in the upcoming years, due to the enforcement of stricter emissions regulations, demanding challenges awaits. In particular, the low temperature and cold start performances of the deNOx systems are of major concern. In these conditions, the catalytic devices upstream of the SCR converter in the after-treatment train (such as the Diesel Oxidation Catalyst) are not operative, leading to a significant hydrocarbon (HC) slip that impacts negatively on the activity of the SCR catalyst. Furthermore, medium- and long-term performances are decreased by coking and by strong T-gradients occurring during catalyst regeneration.

The aim of this contribution is to develop a reliable numerical simulation tool of the HC poisoning process, useful for the design of effective SCR systems.

2 Experimental/methodology

In the present work, an extension of the 1D+1D model of SCR monolith converters developed by Tronconi et al. [1] is proposed. In particular, a kinetic scheme accounting for different HC poisoning effects has been implemented and validated. Experimental data for model calibration were collected at Daimler labs over a commercial Cu zeolite monolith sample exposed to different types of HCs such as C_2H_2, C_3H_6 and $C_{10}H_{22}$. Fitting procedure of kinetics parameters was performed through a genetic algorithm optimization routine written in MATLAB.

3 Results and discussion

According to previous literature indications [2], a preliminary kinetic model of the HC deactivation process was developed according to a dual site approach, which includes: i) a redox site (S1), where NO is oxidatively activated and HC poisoning occurs due to partial oxidation, intermediate adsorption and coke formation; ii) an acid site (S2), responsible for ammonia and HC adsorption. In order to keep the model complexity as low as possible, only two lumped HC molecules were considered as representative of broad classes of compounds: light HC (C_2H_2, C_3H_6 …) and heavy HC ($C_{10}H_{22}$, $C_{12}H_{24}$, …).

Hydrocarbon poisoning is a complex phenomenon that involves different processes, depending on the nature of the HC considered as well as the type of zeolite structure. Light HC compounds are known not to compete significantly with NH_3 for adsorption on acid sites. It has been reported [3] that oxygenated compounds generated during partial oxidation of small hydrocarbons are responsible for catalyst deactivation due to active site blocking. On the contrary, heavy HC are adsorbed unconverted on the catalyst surface, leading to pore blocking and to a strong decrease in performances [4].

In order to reproduce as many as possible of such effects, both lumped light and heavy HC molecules were adsorbed on S2 sites. Then, for light HCs, a spillover mechanism from acid to redox metal sites, similar to the one reported in [2], was introduced in the kinetic scheme. Here,

the HC compound undergoes an oxidative activation step on the catalyst leading to the formation of oxygenated intermediates and poisoning of redox metal sites. Increasing the temperature, complete oxidation may occur and activity is recovered. In this way, effects on the ammonia storage and desorption dynamics, normally limited, but also effects on the catalytic activity were described correctly. Moreover HC oxidation by NO_2 was accounted for in the model, a crucial step to accurately describe the HC effects in SCR reactions with NO_2 such as the Fast SCR. Figure 1A shows e.g. the HC promoting effect on NO_2 conversion for NO_2 SCR.

The model was initially validated against experimental and literature data, showing good agreement. In particular lab scale transient and stationary tests on monolith samples of a commercial Cu zeolite catalyst, addressing the combined effects of propene poisoning and temperature increase [4], were correctly predicted. Moreover the model was able to properly represent the NO conversion dynamics when propylene pulses were fed to the SCR reactor in isothermal experiments [5] over both Fe and Cu zeolite catalysts.

The model has been then fitted to dedicated experimental data collected at DAIMLER on a commercial Cu zeolite. For this purpose, a specific routine written in MATLAB, based on the genetic algorithm toolbox, was developed. Figure 1A shows the fit of the promoting effect of HC on NO_2 conversion in a NO_2 SCR run. In Figure 1B, the fit of NH_3 oxidation in presence of acetylene is presented: the model is able to correctly account for both NH_3 and C_2H_2 concentration profiles as well as for the outlet CO production. In all the considered cases, model simulations were found to be in good agreement with the experimental results.

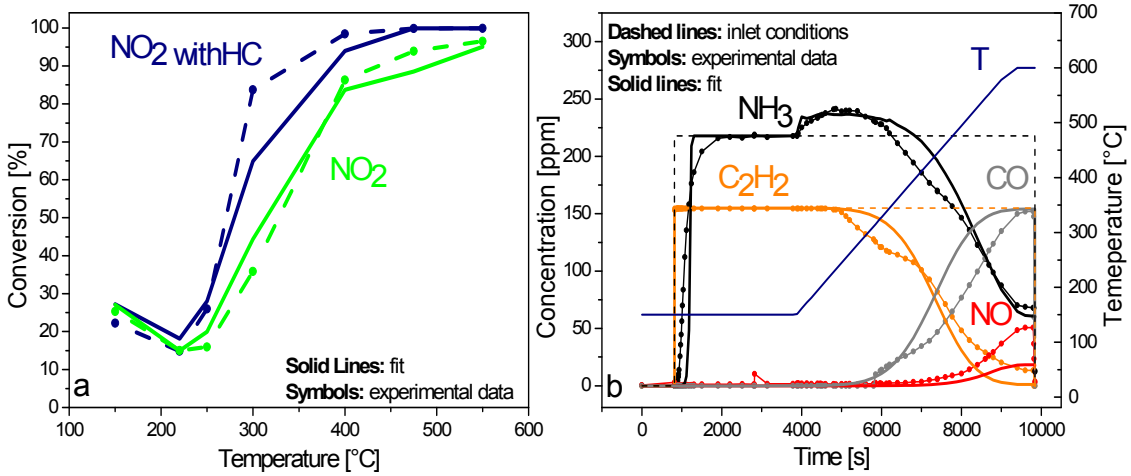

Fig. 1. Fit results. A) NO_2 SCR with and without C_2H_2: SV=66000 h^{-1}; NH_3 = 223 ppm; C_2H_2=170 ppm; NO_2=165 ppm O_2=10%; H_2O=10%. B) NH_3 oxidation with C_2H_2: SV=66000 h^{-1}; NH_3=218 ppm; C_2H_2=155 ppm; O_2=10%; H_2O=10%; T=150 °C-550 °C; heating rate=5°C/min.

4 Conclusions

HC poisoning is one of the most relevant issues for the operation of NH_3-SCR converters at low temperature. Its inclusion in numerical simulation tools is crucial for time and cost effective development and optimization of advanced catalysts and systems.

Keywords: magnetic carbon nanostructure, nanocatalysts, green chemistry, ruthenium nanoparticles, hydrogenation

1 Introduction

Carbon nanostructures finds a wide range of applications in different industrial and technological fields. In particular their promising electrical, chemical and physical properties could improve the catalytic activity of metal nanoparticles attached on their surface. [1] However an essential aspect for practical application of these nanomaterials in catalytic industrial processes is their recoverability and recycling. For this reason anchoring magnetic nanoparticles on the surface of carbon nanosupports could be a strategic choice able to guarantee their efficient magnetic separation from the reaction media. [2]

There are several protocols to support metal species over carbon nanostructures: deposition from solution; self-assembly methods; electro- and electrophoretic deposition and deposition from gas phase. The aim of this work is to propose a new sustainable and eco-friendly procedure to anchor ruthenium or/and magnetite nanoparticles on the surface of multiwalled carbon nanotube (CNT) and graphene oxide (GO). This green method is based on the use of: an alcohol as a solvent and reducing agent, monomode microwave as heating source, short reaction time, in the absence of hazardous reducing and stabilizing agents.

Finally the new monometallic and bimetallic catalysts are employed in the selective hydrogenation of p-chloronitrobenzene (p-CNB) to p-chloroaniline (p-CAN) under mild reaction conditions.

2 Experimental/methodology

The microwave syntheses of monometallic and bimetallic nanocatalysts were performed in a CEM Discover S-class system. The instrument consisted of a single-mode cavity. It works with a continuous power generation and control of power supply and it is capable of supplying power with 1W increments from 0 to 300 W. The system is equipped with a vertically focused IR temperature sensor.

For the preparation of monometallic systems (ruthenium or magnetite nanoparticles over carbon nanostructures) 1g of support (CNT, GO) and the iron or ruthenium precursors ($[Fe(OAc)_2]$ or $[Ru(acac)_3]$) were suspended in isopropanol, and MW-irradiated. At the end of the treatment the catalysts were recovered, washed and dried. The bimetallic systems (ruthenium over magnetic carbon nanostructures) were prepared following a “one-pot” technique, where first magnetic carbon nanosupports were synthetized as described above, then the $[Ru(acac)_3]$was added inside the microwave reactor and reduced. The final product was magnetically recovered, washed and dried.

The hydrogenation reactions were carried out in an autoclave reactor equipped with

mechanical stirring. Typically, 100 mg of catalyst were dispersed in 25 ml of solvent under sonication, then pre-treated at 110°C under 30 bar of hydrogen for 1h. 0,4 g (2,54 mmol) of the nitroaromatic compound was dissolved in 25 ml of solvent and the solution was added to the autoclave. The reactor was pressurized at 30 bar of hydrogen and heated at 60°C for 2h.

3 Results and discussion

The nanocatalysts were characterized by Transmission electron microscopy (TEM) micrograph, Inductively Coupled Plasma-atomic emission spectroscopy (ICP-AES), Auger Electron Spectroscopy (AES), X-Ray diffraction (XRD) and superconducting Quantum Interference Device analysis (SQUID). The characteristics of these new systems are summarized in Table 1.

Table 1. Characteristics of the synthetized nanocatalysts

Catalysts	Ru(%)	Fe(%)	H(%)	C(%)	Dm (nm) $_{Ru}$	Dm_{Fe3O4} (nm)
Ru@CNT	1,4	---	0	91,61	1,6	---
Ru@GO	0,77	---	0	94,46	2,6	---
Fe_3O_4@CNT[a]	---	15,8	0,88	62,97	---	4,9 (6,9)
Fe_3O_4@GO[a]	---	16,36	1,32	62,26	---	3,1 (5,8)
Ru@(Fe_3O_4-CNT)	1,13	13,54	0,6	70,34	1,4	5,4
Ru@(Fe_3O_4-GO)	0,58	18,09	0,12	79,96	2,5	5

The Fe_3O_4@CNT, Fe_3O_4@GO, Ru@(Fe_3O_4-CNT) and Ru@(Fe_3O_4-GO) nanocatalysts show a remarkable magnetic behaviour able to guarantee an easy and efficient magnetic separation from the reaction medium. Their promising magnetic properties were also confirmed by SQUID analysis. Furthermore all the nanocatalysts were employed in the selective hydrogenation of 4-chloronitrobenezene (p-CNB) to 4-chloroaniline (p-CAN) under mild reaction conditions. Ru@CNT, Ru@GO, Ru@(Fe_3O_4-CNT) and Ru@(Fe_3O_4-GO) show 100% of selectivity and a remarkable conversion in the first reaction hour. In particular the Ru@(Fe_3O_4-GO) has the best Turnover frequency 328 h^{-1}, followed by the Ru@GO nanocatalyst with 286 h^{-1}.

4 Conclusions

Several magnetic nanocatalysts were prepared following a new sustainable and eco-friendly procedure and they were characterized by TEM, XRD, ICP-AES and SQUID analysis. The new catalytic systems were employed in the selective hydrogenation of pCNB to pCAN showing high selectivity. The ruthenium on magnetic graphene oxide Ru@(Fe_3O_4-GO) shows the highest catalytic activity and thanks to its magnetic properties it is easily recoverable and recyclable. This study opens the way for industrial employ of magnetic recoverable nanostructures.

Catalytic Wet Oxidation of Organic Wastewater over TiO_2 Supported Ru-Pt Bimetallic Catalysts

Gu S.Y., Wu L.H., Chen H.N.*

Sinopec Shanghai Research Institute of Petrochemical Technology, Shanghai, China

* chenhn.sshy@sinopec.com

Keywords: catalytic wet oxidation, Ru-Pt TiO_2 bimetallic catalyst, wastewater

1 Introduction

Organic wastewater from chemical industries containing hazardous pollutants can cause severe environmental problems [1]. It must be treated to satisfy the industrial process water demands or the stringent water quality regulations. Catalytic wet air oxidation (CWAO) is one of the most efficient, economical and environmental-friendly advanced oxidation process in treating wastewater. The process usually performed under high O_2 pressure (0.5–20 MPa) at elevated temperature (125–320 °C) and in the presence of catalyst [2]. In this study, bimetallic Ru-Pt/TiO_2 catalysts with total metal loading of 1wt% were prepared by impregnation method. These catalysts were characterized by XRD, N_2 physical adsorption, H_2-TPR and TEM, and applied to catalytic wet oxidation (CWO) of organic wastewater.

2 Experimental/methodology

I. Preparation and characterization of catalysts

Ru-Pt/TiO_2 catalysts with total metal loading of 1wt% were prepared by impregnation method. Briefly, 5g of TiO_2 was mixed with the appropriate amount of the $RuCl_3$ and H_2PtCl_6 precursor. After impregnation, the mixture was dried at 80 °C for 24h, and then introduced in a tubular quartz reactor and reduced under flowing hydrogen at 300°C for 2 h. The prepared catalysts were characterized by XRD, N_2 physical adsorption, H_2-TPR and TEM.

II. Catalytic oxidation reactions

Experiments were carried out in a 1 L autoclave reactor loaded with 4g catalyst and 600 mL aqueous solution (containing acrylic acid, succinic acid and PEG-1000, respectively). The reactor was then charged with N_2 twice. After heated to certain temperature, the reactor was pressurized with 5 MPa O_2, and then the stirrer was switched on. Liquid samples were periodically withdrawn from the reactor and analyzed the COD value with Hach DR2800.

3 Results and discussion

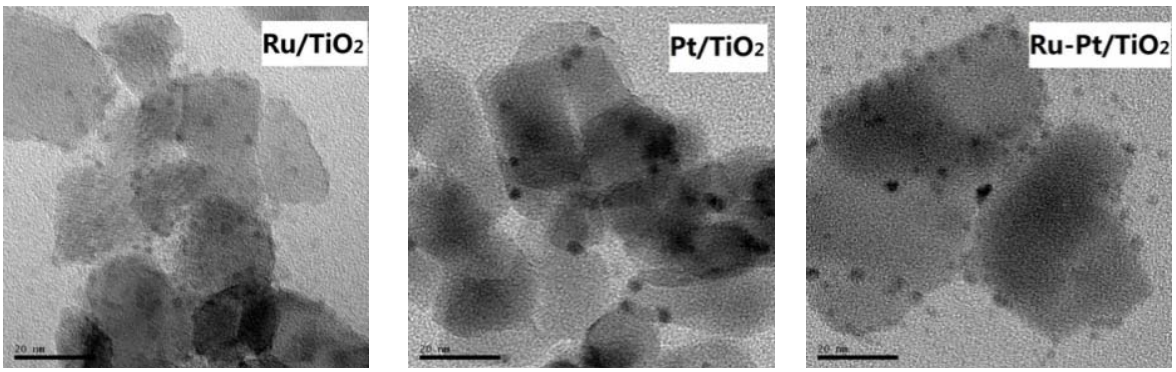

Fig. 1. TEM image of Ru/TiO_2, Pt/TiO_2 and Ru-Pt/TiO_2 catalysts

Figure 1 shows the TEM image of Ru/TiO_2, Pt/TiO_2 and $Ru\text{-}Pt/TiO_2$ catalysts. The results indicates that Ru, Pt and Ru-Pt are highly dispersed on TiO_2 support with particles less than 5 nm.

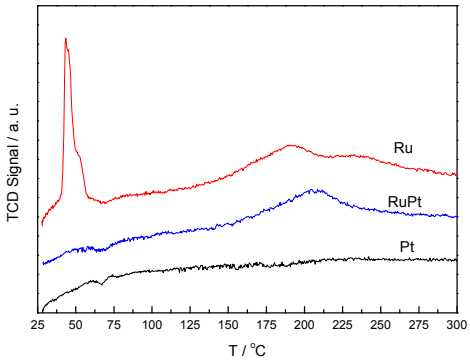

Fig. 2. H_2-TPR profiles of Ru/TiO_2, Pt/TiO_2 and $Ru\text{-}Pt/TiO_2$ catalysts

Figure 2 shows the H_2-TPR profiles of Ru/TiO_2, Pt/TiO_2 and $Ru\text{-}Pt/TiO_2$ catalysts. Different from monometallic Ru/TiO_2 or Pt/TiO_2 catalyst, bimetallic $Ru\text{-}Pt/TiO_2$ shows a wide peak at 207 °C.

Table 1. The comparison of TiO_2, $1\%Ru/TiO_2$, $1\%Pt/TiO_2$ and $0.4\%Ru\text{-}0.6\%Pt/TiO_2$ catalysts on CWO of acrylic acid, succinic acid and PEG-1000 aqueous solution

Organic substrate	Catalyst	*T* (°C)	Initial COD (mg/L)	COD removal (%)
acrylic acid	TiO_2	130	7380	18.5
	1%Pt			92.6
	1%Ru			32.1
	0.4%Ru-0.6%Pt			93.7
succinic acid	TiO_2	200	6290	8.2
	1%Pt			26.1
	1%Ru			89.7
	0.4%Ru-0.6%Pt			91.9
PEG-1000	TiO_2	170	9300	55.5
	1%Pt			95.9
	1%Ru			95.4
	0.4%Ru-0.6%Pt			96.6

Table 1 shows the reaction data of CWO of acrylic acid, succinic acid and PEG-1000. The results clearly show that bimetallic $0.4\%Ru\text{-}0.6\%Pt/TiO_2$ catalyst has higher oxidation activity than monometallic Ru/TiO_2 or Pt/TiO_2 catalyst.

4 Conclusions

The bimetallic $Ru\text{-}Pt/TiO_2$ catalyst was synthesized by impregnation method. In CWO of acrylic acid, succinic acid and PEG-1000 aqueous solution, it shows higher reaction activity than that for monometallic Ru/TiO_2 or Pt/TiO_2 catalyst. The synergic effect between Ru and Pt is the main reason that high CWO efficiency was achieved.

Decomposition of N_2O by Ruthenium Catalysts: Influence of the Support

Zheng J., Meyer S., Köhler K.*

Catalysis Research Center, Department of Chemistry, Technische Universität München, Garching, Germany

* klaus.koehler@tum.de

Keywords: nitrous oxide decomposition, support influence, ruthenium catalysts

1 Introduction

Nitrous oxide is one of the most harmful greenhouse gases, an important source of stratospheric nitrogen oxides as well as a by-product during the SCR of NO_x. Noble metal catalysts such as Ru or Rh are known to be highly active for the decomposition of N_2O, whereby ruthenium represents the better choice from an economic point of view. The properties of the catalysts can be significantly influenced by the nature of the support, leading to substantial variation of the catalytic performance [1]. Studies on the influence of the support on the properties and the activity of supported Ru catalysts for N_2O decomposition are rare and, as often found in heterogeneous catalysis, there is no conclusive picture on the role of the support up to now. The present work focuses on the impact of the support on the electronic and structural properties of Ru catalysts and their activity in N_2O decomposition.

2 Experimental/methodology

Ru particles supported on various oxides (MgO, SiO_2, CeO_2, Al_2O_3, TiO_2), activated carbon (AC) and silicon carbide (SiC) were prepared by impregnation followed by thermal treatment. Catalytic tests were performed in a fixed bed reactor using an equal catalyst volume and equal amounts of Ru for each run. The conversion of N_2O and the gaseous products formed were analyzed by FTIR and mass spectrometry. The catalysts were characterized by temperature programmed reduction (TPR), N_2 adsorption (Brunauer–Emmett–Teller, BET), transmission electron microscopy (TEM), and X-Ray diffraction analysis (XRD).

3 Results and discussion

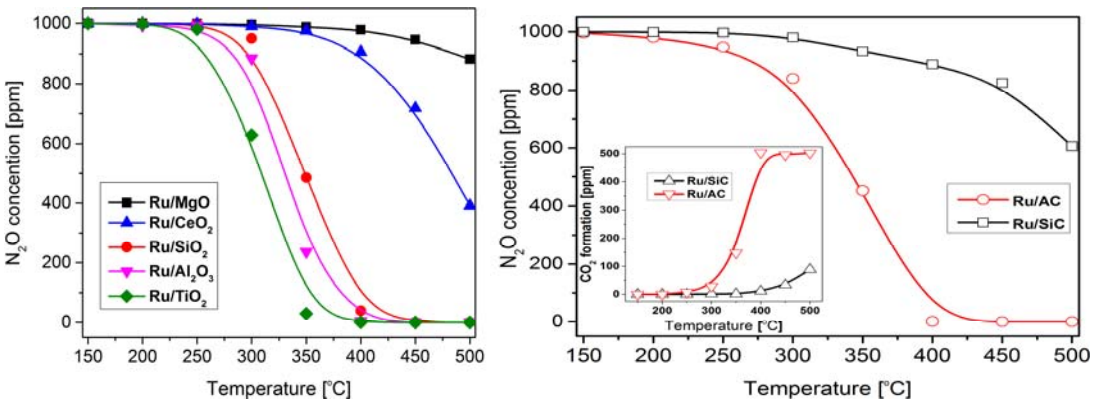

Fig. 1. Decomposition of N_2O over different Ru catalysts. The data were recorded at steady state conditions at different temperatures.

The catalytic performances are given in Figure 1. Ru/TiO_2 is found to be the most efficient catalyst and decomposes N_2O almost completely at 350 °C. The conversion of N_2O over Ru/MgO is only 10% even at temperatures up to 500 °C. For comparison, the activity of Ru catalysts supported on carbon-based materials was studied. Ru/AC possesses a high activity, which is comparable to Ru/SiO_2. Ru/SiC is less active. In both cases, CO_2 was detected in the exhaust stream during N_2O decomposition. The amount of CO_2 formation was proportional to the consumption of N_2O, indicating that AC and SiC act as stoichiometric reducing agents rather than as "inert" supports.

TEM and XRD investigations show that the particle sizes of Ru differ only slightly for the various supports. The substantial variation of the catalytic performance of the different catalysts therefore implies that the decomposition of N_2O is not preferably controlled by geometrical phenomena. H_2-TPR shows that the Ru species could be completely reduced at 250 °C for most of the catalysts except for Ru/MgO. Ru/TiO_2 possesses the lowest temperature of reduction to metallic Ru (151 °C with a shoulder at 111 °C). Based on the activity on N_2O decomposition, it can be assumed that the performance of Ru catalysts is linked to the redox properties (reducibility) of Ru.

4 Conclusions

The catalytic performance of Ru catalysts in the decomposition of N_2O is significantly affected by the support with Ru/TiO_2 exhibiting the best performance. Carbon or carbon-containing materials do not act only as support but also as stoichiometric reducing agents. The redox properties of the Ru catalyst, which are closely related to the support, must be taken into account as the key parameter for the explanation of the catalytic activity.

Catalytic Effect of Carbon Nanotubes in the Electrochemical Reduction of Nalidixic Acid

Patino Y.[1], Pilevar S.[2], De Wael K.[2], Diaz E.[1], Ordonez S.[1*]

1 - University of Oviedo, Oviedo, Spain
2 - University of Antwerpen, Antwerpen, Belgium

* sordonez@uniovi.es

Keywords: nalidixic acid, carbon nanotubes, electrocatalyst, differential pulse voltammetry

1 Introduction

In recent years pharmaceutical and personal care products (PPCPs), considered as emerging pollutants, are produced in large quantities. They enter into the environment from personal, veterinary and aquaculture uses, being able to persist in the environment and cause deleterious in organisms [1]. This kind of pollutants has been detected in surface, ground and drinking water in different countries around the world [2]. For this reason, the development of effective techniques for removing these pollutants is of key interest.

A representative antibiotic, nalidixic acid (NAL), has been selected as model compound for studying the degradation of this kind of compounds by electrochemical methods. The reduction depends on the catalytic activity of the anode which can be modified in order to increase the removal rate. In this way, carbon nanotubes (CNTs) are presented as promising catalysts since they have the ability to mediate electron transfer reactions when are used as an electrode [3].
In this study, the electrochemical reduction of NAL on bare glassy carbon electrode (GCE) and CNT-modified GCE was investigated using differential pulse voltammetry (DPV). Three different CNTs have been used -MWCNTs, MWCNT-NH_2, MWCNT-COOH- with the aim to investigate the effect of functionalization in the NAL reduction.

2 Experimental/methodology

Modified GCE were prepared by drop of MWCNTs (manufactured by DropSense) disperse into dimethylformamide (DMF) by ultrasonication until obtaining a well-dispersed suspension. The suspension was deposited on the GCE area, and then dried under room temperature before electrochemical measurements.

Differential pulse voltammetry was performed using a μ- Autolab Potentiostac/Galvanostat PGSTAT from Methrom. The used electrodes were bare GCE and MWCNTs-modified GCE as working electrode-, saturated calomel electrode (SCE) as reference electrode and platinum as auxiliary electrode. Before DPV, a constant potential was applied to enable the deposition of NAL on the working electrode surface producing an increase of nalidixic reduced.

3 Results and discussion

The effect of pH, stirring rate, scan rate (SR) and deposition time (DT) on DPV was studied obtaining the best results at the following conditions: pH=5.0, stirring rate (150 rpm), SC=50mV/s and DT=30 s.

With the optimized operation parameters, the NAL response was studied under different working electrodes (Figure 1). Modified GCE has a significant catalytic effect on NAL reduction, significantly increasing the signal intensity. The peak current follows the same order than the electrode area (determined by CV), MWCNT (0.076cm^2) > functionalized MWCNT (0.069 cm^2 –NH_2 and 0.070 cm^2 –COOH) > Bare (0.064 cm^2).

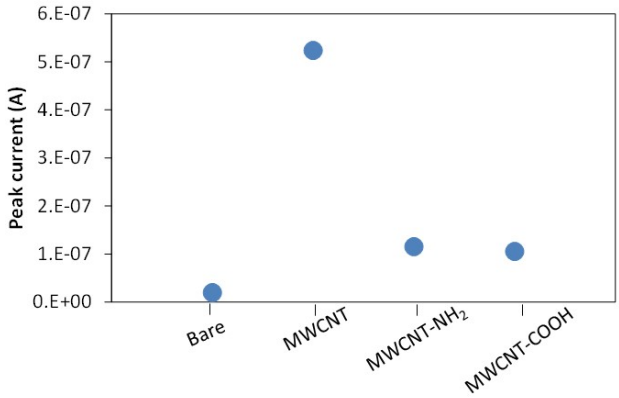

Fig.1. Electrocatalytic effect of MWCNTs for NAL degradation (1 10^{-5}M) in PBS buffer

Different cycles of DPV were carried out for NAL removal using MWCNT-modified GCE. As shows in Figure 2, NAL removal continue constant after 10 DPV cycles for a total sample volume of 5 mL. The electrode surface is blocked after several cycles such a way that the degradation cannot increase. The sample volume was reduced in order to improve the removal. A complete elimination was obtained for a total volume of 1.5 mL after 15 DPVs.

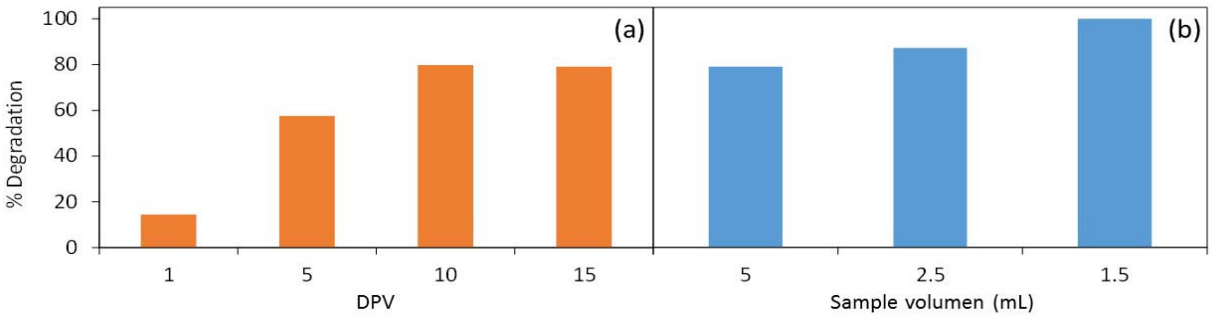

Fig. 2. Electrochemical reduction of NAL (1 10^{-5}M) by DPV using MWCNT modified GCE as working electrode in PBS buffer. (a) Different DPV at total volume of 5mL and (b) different total volume at 15 DPVs.

4 Conclusions

The MWCNT modified electrodes act as efficient catalysts for electrochemical reduction of NAL, especially the MWCNT without functional groups. The removal of NAL with MWCNT modified GCE was around 80 % after 10 DPV cycles for 5mL of total volume, increasing to 100 % when the total volume is 1.5 mL.

Perturbing the Surface Polarity of Cellulose to Improve its Catalytic Conversion to Glucose

Diaz M., Lima E.*

Instituto de Investigaciones en Materiales, UNAM, Mexico, Mexico

* lima@iim.unam.mx

Keywords: cellulose, amino, acids, catalytic conversion, glucose

1 Introduction

Cellulose (MC) conversion into useful chemicals has become a major research goal, but its highly ordered molecular structure inhibits its depolymerisation and hence reduces its reactivity.

In order to take advantage of this raw material, efforts have been made to convert cellulosic materials into valuable chemicals and renewable fuels.

Recent research showed that a small change on the surface polarity of MC significantly improves its catalytic conversion to glucose

This work intends to perturb the hydrogen bond network of MC grafting different combinations of amino acids onto its surface and then, depolymerise the material in the presence of acid catalysts. As a model of MC, cellobiose (Cb) was also perturbed and catalytically hydrolyzed.

2 Experimental/methodology

To perturb the MC and Cb surfaces and increase their reactivity, different amino acids were grafted onto the materials surface, weakening the hydrogen bond network.

Both MC and Cb were hydrothermally treated with alanina (Ala), Phe (Phe) and proline (Pro) and with three different combinations of two amino acids: Ala-Phe, Ala-Pro and Pro-Phe. This treatment leads to surface-modified materials.

The structural and textural properties of the resulting materials were analysed by XRD, SEM, and ^{13}C CP MAS NMR and IR spectroscopies

For the evaluation of the modification in the reactivity of the modified materials, an acid hydrolysis was performed. The conversion of cellulosic materials was carried out in a 50 mL stainless steel at 150 ºC under magnetic stirring, using water as solvent. Hydrolysis reactions were performed in the presence of two different acids: hydrochloric acid (HCl) or tungstophosphoric acid ($H_3PW_{12}O_{40}$). The products were anaylsed by HPLC, using water as mobile phase.

3 Results and discussion

^{13}C CP MAS NMR and SEM characterization showed remarkable differences as a consequence of treatment with amino acids for both MC and cellobiose.

When compared the grafted-celluloses ^{13}C CP MAS NMR spectra to that of MC, it can be seen some important changes in the chemical shifts on the carbonyl region (170-180 ppm), suggesting an interaction between the carbonyl group of the amino acid and the MC surface. In addition, the samples containing Phe showed peak broadening in the region of the aromatics (120-140 ppm) indicating the interaction between the planar ring and the MC chain, this interaction caused a very noticeable change in morphology, as it can be observed on Figure 1. In the samples containing Phe this is more evident, inducing the formation of porous surfaces.

In the case of modified cellobioses, from the modified samples with a single amino acid the more damaged morphologically is the one with phenylalanine, as already reported for MC [1].

Similarly, samples of modified with two amino acids, those with larger change in its

surface are those containing Phe (Cb Phe and Cb Ala-Phe, Cb Pro-Phe).

The characterization and reactivity results suggest that the surface of the MC can be modified to increase their conversion to glucose. Amino acids on the surface are likely to modify the network of hydrogen bonds, some of which can break due to the interaction between the amino acids with the MC chains, thus opening reactive sites.

The hydrolysis reaction with best results is the one conducted with $H_3PW_{12}O_{40}$ and modified materials with Ala and Phe, reaching a MC conversion of 68% and glucose selectivity of 20%.

In the case of acid hydrolysis of Cb, the amino acid modification has not a clear and significant effect on the total amount of converted Cb, the maximum difference is 12% between the hydrolysis of ungrafted Cb catalysed by HCl and the hydrolysis of modified Cb with Pro-Phe catalysed by HCl.

Moreover, where it does is clear an influence of the grafting is in the change in selectivity towards glucose: lower selectivities are obtained when Cb is not modified with amino acids. In addition, higher selectivities towards glucose are obtained with the heteropolyacid as catalyst.

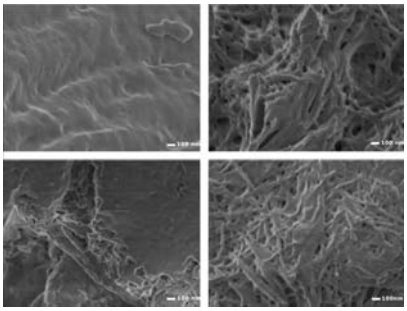

Fig. 1. Micrographs of a) MC, b) MC Ala-Phe, c) MC Ala-Pro, d) MC Pro-Phe

4 Conclusions

Amino acid grafting is insufficient to damage the primary structure of the cellulosic materials, but it does causes significant modifications at superficial level on Cb and MC.

The grafted celluloses that showed considerable textural changes were those modified with a combination of amino acids, specifically using phenylalanine. In the case of the different grafted cellobioses, their surfaces were more damaged when they were modified with Ala.

Surface modification experienced by Cb and MC, as a result of the grafting of amino acids, is sufficient to increase their reactivity. In the case of cellulose, the increase in reactivity is directly reflected in its higher conversion when hydrolyzed in the presence of HCl or $H_3PW_{12}O_{40}$. Catalytic degradation of the MC to glucose is easier and more selective when MC is simultaneously modified with Ala and Phe and the catalyst is $H_3PW_{12}O_{40}$. On the other hand, the catalytic hydrolysis of Cb is practically independent of the modification with amino acids and used catalyst. However, the change has a significant effect on glucose production. If it is desired to achieve a high conversion of Cb and high glucose production, Cb should be modified with Pro and Phe and conducting the reaction in the presence of $H_3PW_{12}O_{40}$.

Keywords: dry reforming, biogas, cobalt, alumina, spinel

1 Introduction

The dry reforming of methane (DRM) is an interesting process because it produces synthesis gas with a desirable H_2/CO ratio, contributes to the removal of two greenhouse gases and offers a solution for the valorization of biogas [1-3]. Previous results have shown that cobalt catalysts supported on $Al_2O_3$are very suitable for DRM [4], but the activity for biogas reforming was not addressed. Thus, this work is focused in the study of the catalytic behavior of Co catalysts in the DRM reaction using a oxygen containing gas mixture resembling the composition of biogas. Catalysts with a 9 wt.% nominal Co content have been prepared considering two variables: support (Al_2O_3 and $MgAl_2O_4$) and presence of K as promoter.

2 Experimental/methodology

The catalysts have been prepared by excess solution impregnation using aqueous solutions of KNO_3 and $Co(NO_3)_2.6H_2O$ (10 ml/g) of the appropriate concentration to achieve the nominal metal contents: 9 wt. % Co and 1wt.% K. The K containing catalyst was prepared by co-impregnation. The mixture was kept at 333 K until solvent evaporation. Finally the catalysts were dried in an oven at 373 K for 24 h.

Catalytic activity experiments were carried out in a fixed bed quartz reactor coupled to a gas chromatograph (HP5890 series II) with a thermal conductivity detector. The reaction conditions were: 973 K, 0.18 g of catalyst, a gas mixture $CH_4/CO_2/O_2$= 37.5/37.5/25.0, 60 ml/min, a space velocity of 22,000 h^{-1} and 6 h time on stream. Prior to the catalytic activity tests, the catalysts were reduced in situ (H_2, 40 ml/min) at 773 K for 90 min.

To determine the amount of deposited carbon, the used catalysts were submitted to Temperature Programmed Oxidation (TPO) experiments, using a thermobalance (TAInstruments SDT-2960) coupled to a mass spectrometer (BalzersThermostar), under the following conditions: 20 mg of catalyst was heated, at 20 K/min, up to 1223 K, in a gas mixture of 16 vol.% O_2 in He (100 ml/min). The amount of deposited carbon was determined from the weight loss and from the amount of evolved CO_2 (m/z = 44).

3 Results and discussion

Table 1 collects the most relevant parameters regarding the catalytic behaviour of the three catalysts studied in this work. Data corresponding to the DRM of methane with a CH_4:CO_2 = 50:50 mixture have been also included as a reference.

It can be observed that methane conversion increases and CO_2 conversion decreases when the feed contains oxygen and that these two changes show a similar magnitude. This means that CH_4 is consumed to produce CO_2, revealing that the total oxidation of methane is taking place, consuming about 10% of the fed methane.

Table 1. Catalytic activity parameters determined in the dry reforming of biogas.

Catalyst	Air (%)	Conversion CH_4(6h)	Conversion CO_2(6h)	CO (ml/min) (6h)	CO Yield [a] (6h)	Deactivation [b] (%)	Deposited carbon (6h) % molar [c]	Deposited carbon (6h) mg/g [d]
Co/Al_2O_3	0	72	83	46.4	77.3	1	0.57	290
	25	80	68	33.6	74.7	1	0.02	10
$Co/MgAl_2O_4$	0	65	74	41.7	70.0	-1	0.25	125
	25	77	65	32.1	71.3	0	0.02	10
KCo/Al_2O_3	0	58	70	38.4	64.0	2	0.08	40
	25	68	57	28.5	63.3	2	0.05	25

[a] CO yield: moles of CO produced divided by moles of CH_4 and CO_2 introduced in the feed

[b] Deactivation, calculated as the difference between conversion at 30 minutes and 6h divided by conversion at 30 minutes and multiplied by 100.

[c] (mol of deposited carbon/mol of converted carbon)*100 (at t=6h)

[d] mg of carbon deposited per gram of catalyst

Thus, it seems that three reactions occur simultaneously: CO_2 methane reforming, methane decomposition and total oxidation of methane. Note that the amount of CO produced is lower when the feed contains O_2, however the CO yield (CO moles/(CH_4+CO_2 moles)) is almost not affected. The catalysts stability is neither affected by the presence of oxygen. Regarding the carbon deposition, it is, as expected, much lower in oxygen rich conditions.

Thus, in the presence of oxygen, the Co/Al_2O_3catalyst is the most active followed by $Co/MgAl_2O_4$. For these two catalysts the carbon deposition is quite low. Finally, the KCo/Al_2O_3 catalyst is the less active and presents the largest amount of deposited carbon.

4 Conclusions

Catalysts Co/Al_2O_3 and $Co/MgAl_2O_4$ are very active for biogas reforming, with high CO yield and low carbon deposits, while the addition of K as a promoter does not bring any advantage.

Keywords: Pd nanoparticles, nitrite reduction

1 Introduction

Metal nanoparticles (NPs) research has recently become the focus of intense work due to their unusual properties compared to bulk metal. Among these metallic NPs, Pd NPs have been widely used as catalysts in hydrogenation and dehydrogenation, as well as cracking and carbon-carbon bond forming reactions such as Suzuki or Heck couplings. Some of these reactions have been often reported as structure-sensitive, being necessary the development of methods that are able to control the NPs size. The reverse microemulsion (water in oil, w/o) technique is of special interest since the NPs size can be controlled using different water-to-surfactant molar ratio (w_0) and/or different reductor-to-metal molar ratio [1]. In this work, catalytic reduction of nitrite in aqueous phase has been studied as an intermediate and critical step in the reduction of nitrate. One of the major limitations in the catalytic reduction of nitrate is the production of ammonium (*versus* N_2), being considered the nitrite hydrogenation as the key step. Therefore, the aim of this work is to study size effect in nitrite reduction in aqueous phase, using non supported Pd NPs. pH effect is also considered.

2 Experimental/methodology

The preparation of Pd NPs was carried out through the reduction of $Pd(NH_3)_4Cl_2 \cdot H_2O$ with hydrazine in AOT/isooctane reverse micellar solution. The synthesis of Pd NPs was achieved by mixing equal volumes of two reverse micellar solutions with a w_0 in a range 3-12 and AOT concentration of 0,35 M in isooctane. After a 10 min of reduction, isooctane was evapored in a rotary evaporator at 368 K and the NPs were purified from excess of surfactant by addition of methanol followed by centrifugation (this washing was carried out three times). The Pd NPs synthesized were characterized by transmission electron microscopy (TEM) at 400 kV (JEOL, mod. JEM-4000 EX).

Nitrite hydrogenation runs were carried out during 4 hours in a jacketed glass reactor where H_2 was continuously fed at 50 $N \cdot mL \cdot min^{-1}$ flow rate under vigorous stirring (500-700 rpm) in order to facilitate hydrogen distribution through the nitrite solution (150 mL and 50 mg /L). The reaction temperature, 303 K, was controlled by a thermostatic bath connected to the reactor jacket. In some experiments, CO_2 was introduced to the reaction media for buffering the solution at a pH value around 6. Nitrite and ammonium concentrations were analyzed by ion chromatography (Metrohm 790 Compact IC Plus).

3 Results and discussion

Pd NPs were prepared under different values of w0 (3, 7 and 12) in order to study the influence of Pd NPs size on the nitrite reduction. Pd NPs size increase with increasing w0, achieving values of 6.2, 7.7 and 11.6 nm. It has been reported that the role of AOT is to act as a protecting agent, allowing to control NPs growth in microemulsion. An increase of this ratio at constant concentration of surfactant will increase the average diameter of the droplets and consequently the size of the NPs [2].

Figure 1 shows the conversion results obtained with non supported Pd NPs using 2.45 mg Pd/L in all experiments. Significant differences were found in nitrite conversion depending on the Pd NPs size. Higher sizes always led to higher conversions. This behaviour contrasts with the reported in most of the works in literature, indicating the nitrite hydrogenation as a size-independent reaction [3]. The pH was found as a key parameter in nitrite reduction, since relatively higher nitrite conversion values (50–80 %) were achieved when reaction was buffered with CO_2.The reduction of nitrite led to the formation of hydroxide ion, increasing the pH of the reaction medium up to 8-9.5 and decreasing the activity.

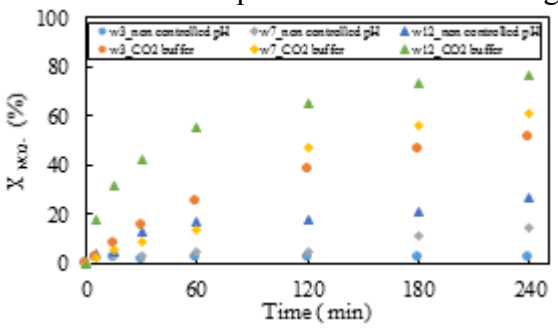

Figure 1. Influence of nitrite conversion on Pd NPs size.

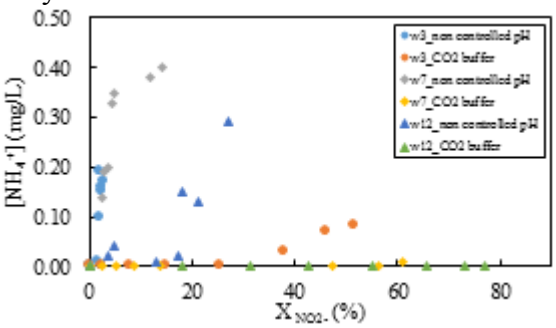

Figure 2. Influence of ammonium concentration on Pd NPs size.

Significant differences in selectivity were observed, depending on the pH (Figure 2). Ammonium selectivity increased with lower Pd NPs size in the runs developed under non-controlled pH. Moreover in the reactions with lower conversion, selectivity towards ammonium also increased with similar conversion values. Lower ammonium selectivity values were always found when the pH of the nitrite reduction was controlled, below 0,08 mg/L. It can be also seen null ammonium concentration when higher size Pd NPs were tested. Some works in literature reported that large Pd particles are favourable for selectivity to N_2 in nitrite hydrogenation, proposing that N_2 formation proceeds on terraces, whereas ammonium formation is supposed to proceed on low coordination Pd sites on edges, corners and defects.

4 Conclusions

Pd NPs with different particle sizes (6.2, 7.7 and 11.6 nm) have been prepared using water/AOT/isooctane microemulsions. Particle size has a significant role in the nitrite reduction, large particles led to a higher catalytic activity. Control of pH through CO_2 bubbling was beneficial to both nitrite conversion and N_2 selectivity.

Keywords: biodiesel, transesterification, cobalt ferrite, citrate precursor

1 Introduction

Biodiesel is one of popular alternative energy in the world due to characteristics like be biodegradable and renewable, non-toxic and low CO emission [1]. Heterogeneous catalysts had been widely investigated for offer many advantages such as simple separation in reaction medium, less consumption of energy and cost, as well as easier glycerol recovery [2]. One of the most used catalysts is CaO, due to low price, long catalyst life, high activity and requirement of moderate reaction conditions, although some disadvantages like low surface area and leaching [1]. In last years has increased the research of the use of magnetic nanoparticles as an alternative to reduce the environmental problems, due to the high surface compared to the volume of crystals, expecting that result in a excellent magnetic material [3]. Cobalt ferrite had been widely studied due to its high electromagnetic performance, excellent chemical stability, mechanical hardness, high coercivity, and moderate saturation magnetization, which makes it a good candidate for the electronic components used in computers, recording devices, and magnetic cards [4].

2 Experimental

Cobalt ferrite ($CoFe_2O_4$) was prepared by citrate precursor method. Stoichiometric quantities of $Co(NO_3)_2.6H_2O$, $Fe(NO_3)_3.9H_2O$ and $C_6H_8O_7.H_2O$ were dissolved in distilled water and this mixed (citrate-nitrate solution) was heated at 90°C with continuous stirring. After the evaporation of excess of water, first a highly viscous gel was obtained and finally a powder. It was sintered at 300°C, to acid decomposition. The ferrite synthesized was used as a support for impregnation of the calcium oxide at mass concentrations of 30, 40 and 50%. CaO supported on $CoFe_2O_4$ were obtained by calcination at 650°C for 1 hour. These materials were characterized by XRD, BET, SEM, EDS, TDP-CO_2 and SQUID.

The catalytic activity was evaluated through of transesterification between methyl acetate/ethanol and soybean oil/ethanol. The tests with methyl acetate/ethanol were performed with molar ratio = 6 /1, 4% wt/wt and temperature of 70°C. In the tests using soybean oil was varied the ratio ethanol/oil (6:1, 12:1, 24:1) at the same temperature (70°C). After the reaction, the catalyst was separated and the supernatant was recovered for composition analysis by gas chromatography (GC). The method used to evaluate the stability of the materials was the reuse of the catalysts in subsequent runs in the same reaction conditions to evaluate the catalytic activity during 1 hour for each reaction cycle.

3 Results and discussion

The hysteresis curves of the $CoFe_2O_4$ in SQUID tests showed ferromagnetic characteristic at

room temperature with a saturation magnetization of 56 emu/g. The XRD showed diffraction patterns of $CoFe_2O_4$, CaO, $Ca(OH)_2$ and $CaCO_3$, its was expected due to the rapid hydration and carbonation of CaO in presence of water vapor and atmospheric CO_2. Strong basic sites on $CaO/CoFe_2O_4$ were confirmed by TPD-CO_2, with basic sites density of 14 μmol/m^2.

The catalytic performance of the 50-$CaO/CoFe_2O_4$ catalyst in the methyl acetate transesterification showed conversion level above 85%, reaching the equilibrium after 120 minutes. The run tests of the catalysts containing 30, 40 and 50% of CaO showed that the conversion depends of the calcium content incorporated on support. The ester yield in tests with soybean oil/ethanol with the 50-$CaO/CoFe_2O_4$ catalyst represented in Figure 1 shows that varying the reaction time and the ethanol/oil ratio resulted in a gradual increase in the esters conversion. This is justified by the fact that the transesterification of vegetable oils is a kinetically favored reaction when an excess of alcohol is used relative to the triglyceride. The Figure 2 shows the recycle tests using the 50-$CaO/CoFe_2O_4$ catalyst in the methyl acetate transesterification reaction. The gradual loss of catalytic activity may be due to loss of catalyst during the reaction, which is impregnated in the wall of the reactor or had been removed of the supernatant in extraction process. To verify that the leached of the Ca^{2+} ions which were not active in the reaction, tests were made by removing the solid catalyst of reaction medium and results showed that after this removal the reaction stopped.

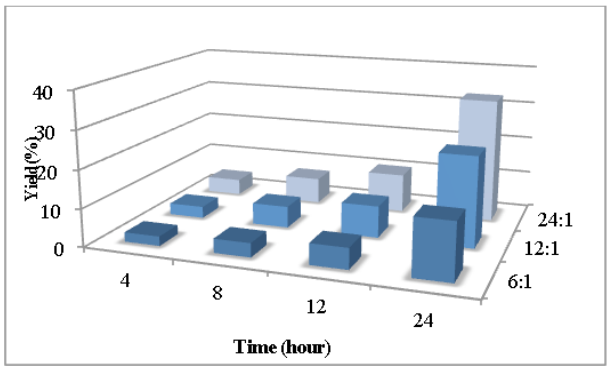

Fig. 1. Catalytic evaluation of 50-$CaO/CoFe_2O_4$ catalyst in transesterification between soybean oil and ethanol.

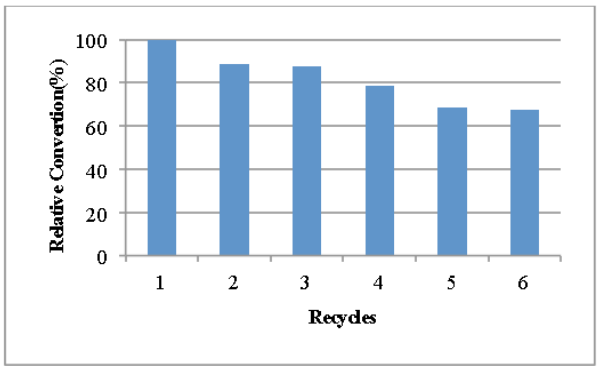

Fig. 2. Recycles of 50-$CaO/CoFe_2O_4$ catalyst.

4 Conclusions

The results confirmed that the $CaO/CoFe_2O_4$ can be considered a promising heterogeneous catalyst. It can be easily separated from reaction due to the magnetic characteristic of cobalt ferrite and be reused for successive batches, showing no contribution of homogeneous activity.

Keywords: EXAFS, gold catalysts, Co-doped ceria, CH_3OH, oxidation

1 Introduction

Supported gold nanoparticles attracted significant attention due to their high catalytic activity in various oxidation reactions at low temperatures. The catalytic oxidation of Volatile Organic Compounds (VOCs), such as methanol, is a subject of considerable interest due to their relevance in many industrial applications.

The oxidation activity of gold catalysts is closely related to the size of the Au particles and to the ability of the support to provide active oxygen species. For this reason, the selection of the proper support is a critical factor. Ceria is very attractive, due to its ability to maintain high metal dispersion and to change Ce oxidation state depending on the redox conditions, which results in rapid formation and elimination of oxygen vacancy defects. The doping of ceria can increase the concentration of oxygen vacancies. Recently, we observed a strong influence of the nature of the added oxide on the activity of ceria-based gold catalysts for catalytic abatement of VOCs and CO in waste gases [1]. Gold catalyst supported on ceria modified by Co_3O_4 exhibited the best performance. Ceria supports with different amount of Co_3O_4 were prepared in order to optimize the content of dopant.

The aim of this work was an accurate EXAFS study on the nature of the active sites exposed at the surface of highly dispersed gold catalysts supported on ceria modified by Co_3O_4. Research efforts were focused to achieve information on the local structure of the active sites in terms of position of cobalt atoms in respect to the gold metallic phase.

2 Experimental/methodology

The gold samples were prepared in two steps:
(i) mixed CeO_2–Co_3O_4 supports were prepared by a simple mechano-chemical mixing procedure: a mixture of cerium hydroxide and (5, 10, 15 wt%) Co_3O_4 was subjected to mechano-chemical milling for 30 min in a mortar and calcination at 400 °C for 2 h;
(ii) gold (3 wt.%) was introduced by the deposition–precipitation method at pH 7, temperature 60 ^oC, and full control of stirring speed, reactant feed flow rates.

After filtering and careful washing, the precursors were dried under vacuum at 80 °C and calcined in air at 400 °C for 2 h. Moreover, unmodified Au/CeO_2 and Au/Co_3O_4, used as blank samples, were also prepared.

EXAFS measurements were done in transmission mode at both Au L3 and Co K edges. All samples were measured as prepared and after an oxidation pre-treatment in O_2 at 400 °C to mimic the activation before the catalytic tests and to follow the effect of such activation on the nature of the exposed active sites. Then, a mixture of methanol vapor/O_2/He mixture (20% O_2-He) was fluxed at r.t. and the samples have been heated up to 100°C in the same mixture.

3 Results and discussion

Catalytic tests demonstrated that the addition of 5, 10 and 15 wt% Co_3O_4 significantly affected the activity of Au/CeO_2. The best performance was observed in the case of the catalyst doped by 10 wt% Co_3O_4, over which 100% CH_3OH conversion degree at 40 ^oC was obtained. The characterization data indicated that the high defectivity of ceria exposed faces, along with the presence of gold nanoparticles with the smallest size and the highest hydrogen consumption (e.g. highest oxygen mobility) were found over this gold sample.

The methanol oxidation reaction was investigated in-operando conditions. The first set of spectra was collected at room temperature. Then, starting from the catalysts previously oxidized, another set of spectra were recorded in operando conditions starting from room up to 120 °C. Au/CeO_2 as well as the bare support (ceria modified by 10 wt.% Co_3O_4) were measured as reference samples, too.

Three spectra were measured at each temperature, to evaluate the experimental uncertainty. The data analysis was performed by means of simulations and non-linear fitting procedures, paralleled by the ratio method for the first shell.

The analysis of the data at the Au L3 edge revealed that the active sites present on the most active sample (with 10 wt% Co_3O_4) are those where cationic gold sites are strongly interacting with Co.

4 Conclusions

The correlation of the catalytic activity with the findings, provided by EXAFS study about the nature and structure of the active sites allows to bridge the gap of experimental data previously obtained by HRTEM, XRD FTIR, TPR and to clarify the precise nature of the synergy between the gold phase and the Co-doped ceria support, which resulted in an excellent CH_3OH oxidation activity.

Keywords: dry reforming, HDL, cobalt, nickel, methane, synthesis, gas

1 Introduction.

The production of the synthesis gas and the hydrogen represents one stakes major in the chemical industry in the world. These two gases are obtained via the reforming of the methane by one of the three proceeded:-Dry reforming of methane: $CH_4 + CO_2$ --------- $2CO + 2H_2$

-Steam reforming of methane: $CH_4 + H_2O$ --------- $CO + 3H_2$

-Partial oxidation of methane: $CH4 + ½ O_2$ ---------- $CO + 2H_2$

The reaction of the dry reforming drew a big attention by a wide public of researchers thanks to its contribution on the decrease of the atmospheric concentration of both greenhouse gases CO_2 and CH_4.

The majority of all works had for objective to improve the yield on this reaction and to increase the life cycle of catalysts which is poisoned by the deposit of coke which is until this day the major problem of this process.

Synthetic Mg–Al layered double hydroxide materials have found many applications due to their unique physicochemical properties; Catalysis is one of these applications(5).

This work consists in the preparation of materials catalysts which can bring better performance.

2 Experimental:

Catalysts synthesis:

The Catalysts materials were synthetized by classical method of coprecipeation at basic pH (pH=11), as reported by Miyata [3]. An aqueous solution containing an appropriate amounts of nitrate salts of divalent metals and trivalent metal (Mg, Al, Ni and Co), with molar ratio of $M^{2+} / M^{3+} = 2$.

The obtained slurry was hydrothermally treated for 24 h at 60°C, centrifuged, washed several times with bidistilled water til neutral pH. The obtained solids were dried at 70°C during a night and calcined under air in 800°C during 6 hours with ramp of 4 °C / min.

Catalyst characterization:

X-ray powder diffraction patterns are recorded in a Siemens D-501 equipment, with a Bragg-Brentano configuration using Cu Kα (λ=1,5418Å) and varying of 2θ values from 5 to 80°. FTIR spectra in the region of 4000 to 400 $cm^{-1}$are obtained using Perkin Elmer spectrometer by the KBr pellet technique. The surface areas of the solids are measured by employing the BET method where a micromeritics ASAP on system 2010 apparatus is used. Elemental analyses of metals of the samples was carried out by ICP Horiba Jobin Yvon Ultima 2 type apparatus .

SEM images where obtained by Hitachi S-5200 microscopy, with a field emission filament, using accelerating voltage of 5kV.

(TPR) experiments were done according to the experimental conditions described else-where [4]. A H_2/Ar mixture (5% H_2, 50 ml/min flow) was used as the reducing atmosphere from room temperature up to 900°C, with a heating rate of 10 C°/min. A thermal conductivity detector previously calibrated using CuO and mass spectrometer in line with the TCD, calibrated with references mixtures were used to detected variations of reducing agent concentration, and possible sub-products formation.

Catalytic activity tests:

The catalytic experiments were carried out at atmospheric pressure in tubular quartz reaction. Wool is used as support for the catalytic bed. The CH_4 and CO_2 reactants were mixed at ratio of 1 diluted in He (10:10:80 in vol); The catalysts are heated from room temperature until 700°C at 1°C/min rate ; The simple stays at 700°C during 11h; Gas hourly space velocity (GHSV) :300000 L/kgh; Analysis is given by gas chromatograph (Varian CP-3800) with column Porapak Q.

Before reaction, samples were reduced under hydrogen (5%H_2/Ar) at 700°C during 1hour. (2)

3 Results and discussion:

The result of the ICP shows that the experimental composition is coherent with the nominal composition for each sample and the $M2^+/M^{3+}$ ratio is around 2.

X-ray diffraction patterns of the samples before calcination shows that training hydrotalcites structures. X-ray diffraction patterns after calcination shows oxides mixtures of NiO and MgO.

The results of BET surface areas shows that BET areas increases after calcination for all samples except in the case of Mg Al solid.

The results of H_2-TPR measurements of the calcined samples showed a single reduction peak in the case of NiMgAl at higher temperature reduction (around 800°C), indicating the existence of species of NiO with strong interaction resulting from the formation of the NiO–MgO solid solution, characterized by its high stability. The NiMgAl catalyst shows a significant CH_4 conversions such as 87,0%, 92,0 %, respectively for NiMgAl and NiMgCoAl versus 86,0% and 90,0%, for CO_2 conversions respectively.

4 Conclusions:

The present study showed that the catalysts based on nickel and which is prepared by the Local hydrotalcite way gives a good activity for CH_4 / CO_2 reaction and that the addition of cobalt also improves the activity. A good stability is also observed for the catalysts of this study.

Keywords: Ceria-praseodimia, NO oxidation, CO-PROX, redox properties

1 Introduction

Mixed oxides having a high oxygen storage capacity and reactivity of lattice oxygen are used in several applications, such as automotive catalysis, selective oxidations, oxidative dehydrogenation of organic compounds, and some other reactions [1]. Among these materials, mixed oxides containing rare earth cations with variable oxidation states deserve particular attention. Praseodymium has multiple oxidation states and it is one of the cations lastly investigated for ceria doping [2]. The corresponding mixed oxides can undergo more oxygen exchange at a lower temperature than pure ceria and it is also known that the Ce-Pr-O compositions are more promising than the trivalent rare-earth substituted ceria formulations. It could be assumed that Pr-containing mixed oxides should exhibit intermediate and close to optimal combination of capacity, stability and reactivity with respect to reversible oxygen evolution/uptake, but in catalytic oxidation reactions with practical application not all the reactive oxygen can be available and the establishment of redox-catalytic performances relationships in different environmental reactions could be of special interest [3].

The present work is devoted to prepare and characterize a series of $Ce_xPr_{1-x}O_{2-\delta}$ mixed oxides and to analyze the trends in the order of catalytic activities towards the NO oxidation to NO_2 and the preferential oxidation of CO in H_2 rich stream (CO-PROX). The correlations between catalytic performances obtained and redox properties are explored.

2 Experimental

A series of oxides with the general formula $Ce_xPr_{1-x}O_{2-\delta}$ (x=0, 0.2, 0.5, 0.8, 1.0) was prepared by a co-precipitation method in alkali media. The corresponding solids obtained after filtration were dried and calcined at 500°C for 1 hour. The catalysts were characterized by N_2 adsorption-desorption isotherms at -196°C, XRD, Raman spectroscopy, XPS, H_2-TPR and CO-TPR. They were tested for NO oxidation to NO_2 (from room temperature up to 750ºC at 10ºC/min). The gas mixture used comprised 500 ppm NOx, 5% O_2 and N_2 as balance; the gas flow was fixed at 500 ml/min (GHSV = 30,000 h^{-1}). Catalytic activity in PROX reaction was performed in the 150-500°C temperature range. The inlet total gas flow was 100 mL/min, containing 50% H_2, 1% CO, 1% O_2 and He as balance (GHSV= 12,000 h^{-1}).

3 Results and Discussion

Figure 1 shows the NO_2 production profiles for the series of catalysts investigated along

with the uncatalyzed reaction. It can be seen that a low loading of praseodymium increases significantly the activity for the NO oxidation to NO_2 with regard to pure ceria. In general terms, increasing the Pr content yields to higher activities and decreases the temperature to achieve the maximum NO_2 production. This trend is in good agreement with the redox properties of the catalysts if analyzed by H_2-TPR experiments, where the availability of oxygen under reducing atmosphere increases with the praseodymium content.

Interestingly, the trends in activity order obtained from PROX reaction are very different from those obtained in the NO oxidation reaction. Figure 2 represents the CO conversion percentages obtained on the basis of the CO_2 produced. The highest activity (86.8% of CO) is exhibited by the $Ce_{0.8}Pr_{0.2}O_{2-\delta}$ composition at 450 °C, and consequently, the order of activity cannot be correlated to the H_2-TPR results. However, CO-TPR curves, (not shown for the sake of brevity) revealed some interesting features, since the main peak of reduction is slightly and progressively moved towards higher temperatures from 330°C for $Ce_{0.8}Pr_{0.2}O_{2-\delta}$ to 423°C for $PrO_{2-\delta}$. Moreover, the samples containing Ce and Pr, show a certain relationship between the CO-TPR profiles and the catalytic behavior. Thus, at 450°C, when the reduction temperature is lower, the conversion of CO becomes higher.

Reasonable hypothesis to account for these diverse experimental trends are: the different temperature range where both catalytic reactions (NO oxidation and PROX) take place and/or the different acid character of the NO and CO molecules which interact differently with the ceria-praseodimia mixed oxides' surfaces.

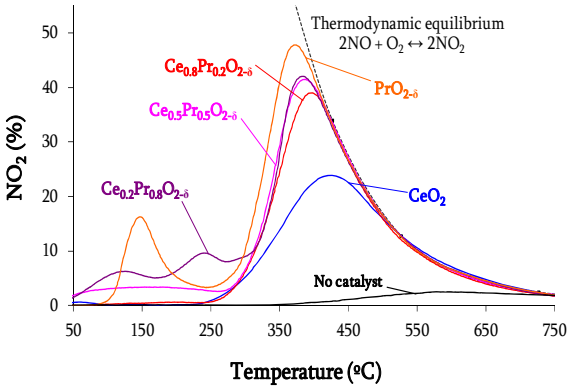

Figure 1. NO_2 production profiles versus temperature for the series of catalysts studied.

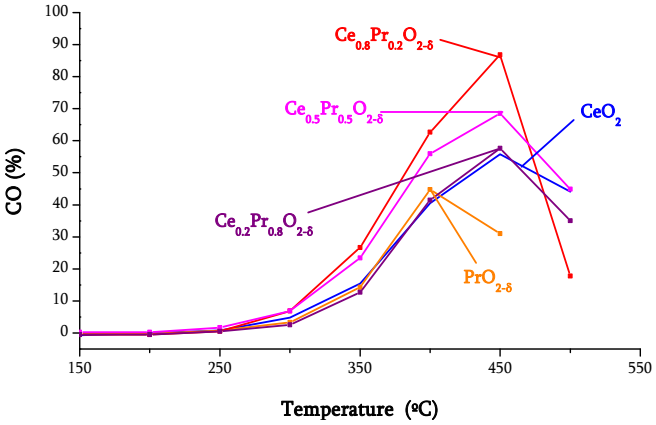

Figure 2. CO conversion in the PROX reaction for the series of catalysts studied.

4 Conclusions

The trend in activity order for a series of $Ce_xPr_{1-x}O_{2-\delta}$ mixed oxides towards the NO oxidation to NO_2 and towards CO-PROX reaction are completely different, despite both are oxidation reactions of relevant interest from an environmental viewpoint. The understanding of the features that govern the activity towards different catalytic oxidation reactions can be of key importance in the designing of effective catalysts.

Identifying the Nature of the Copper Entities over Ceria-Based Supports to Promote Diesel Soot Combustion: Synergistic Effects

Giménez-Mañogil J., García-García A.*

Keywords: copper, entities, ceria-zirconia, soot, combustion, synergy

1 Introduction

Noble metal-based catalysts have been developed to promote the oxidation of NO to NO_2 and decrease the combustion onset temperature of soot under realistic diesel conditions. However, their high cost has led to the consideration of other lower-priced materials that can be competitive in terms of catalytic activity.

Catalysts combining copper and active ceria-based materials have demonstrated promising behavior towards CO-PROX reaction [1], among others. However, these findings cannot be directly extrapolated to other oxidation reactions less studied from a fundamental point of view, such as diesel soot combustion and NO oxidation to NO_2.

Main properties of the dual system copper-ceria appear related to the synergetic interactions between the two constituents which are determined by their interfacial features [1, 2]. Therefore, by tuning the interfacial properties and generating active sites of different nature, one could explain the observed ceria promoting catalytic activity.

The aim of this research is to synthesize catalysts exhibiting a wide range of degrees of copper incorporation/distribution/contact on a ceria-zirconia mixed oxide by preparing catalysts with a high degree of copper incorporation (copper insertion), well-dispersed copper on the porosity and different degrees of physical interaction. Their catalytic activities towards diesel soot combustion and NO oxidation were studied. A different support allowing a high degree of copper dispersion (alumina) and CuO bulk were also chosen for comparative purposes.

2 Experimental

The $Ce_{0.8}Zr_{0.2}O_2$ support (CZ) was prepared by the co-precipitation method, and the solid obtained after filtration was dried and calcined at 500°C for 1 hour in air. CZ and a commercial γ-Al_2O_3 support were doped with 2 wt% of copper (Cu2/CZ and Cu2/AL, respectively) by incipient wetness impregnation (IWI). This amount of Cu was optimized in a previous study [3].

On the other hand, physically-mixed samples of CuO (obtained by calcination of $Cu(NO_3)_2 \cdot 3H_2O$ in air, at 500ºC, for 1 hour) and CZ under loose (LO) and tight (TI) contact modes, with 2 wt% of Cu, were prepared. Another catalyst was obtained by subsequent calcination of the tight contact-sample at 500ºC in air, for 1 hour (Cu2CZ-TI-500). In addition, $Ce_{0.76}Zr_{0.19}Cu_{0.05}O_2$ (CZCu-CP) was synthesized by co-precipitation, with 2 wt% of copper.

These catalysts were characterized by N_2 adsorption-desorption isotherms at -196ºC, XRD, Raman spectroscopy, XPS and H_2-TPR. They were tested for NO oxidation to NO_2 in TPR conditions (from 25ºC to 700ºC at 10ºC/min), and for soot combustion: under TPR (from 25ºC to 700ºC) and isothermal conditions (450°C). The gas mixture used comprised 500 ppm NOx, 5% O_2 and N_2 balance; the gas flow was fixed at 500 ml/min (GHSV = 30,000 h^{-1}).

3 Results and Discussion

According to XRD and Raman spectroscopy results (not shown for sake of brevity), bulk CuO entities were detected in the physically-mixed samples; but were not observed in those catalysts

prepared by IWI and co-precipitation, which means that a high copper dispersion was achieved. Regarding XPS, Cu^{2+} is mainly present in all the samples. However, Cu^{+} species were identified for CZCu-CP, allowing us to deduce that copper was inserted into the ceria lattice.

Figure 1 depicts the H_2-TPR profiles. Physically-mixed samples show two different reduction regions, the first one is invariant and corresponds to copper reduction only; the second one is related to the ceria reduction and mainly depends on the type of contact achieved. In contrast, an important decrease in the copper and cerium reduction temperatures is achieved when copper is added by IWI or co-precipitation, due to the close interfacial interactions Cu-Ce. CZCu-CP shows higher reduction temperatures than Cu2/CZ, due to the presence of Cu^{+} (as seen in XPS) and the required diffusion of H_2 into the lattice (there is no surface copper enrichment on this catalyst as detected for the IWI sample -Cu2/CZ-).

Soot combustion experiments under TPR conditions (Figure 2) reveal different trends in activity depending on the temperature range, which can be associated to interfacial interactions (as seen on Figure 1). At low temperatures, the trends in activity are similar to those observed for the NO oxidation reaction. Cu2/CZ shows the highest activity due to the synergistic effect observed between Cu-Ce and to the surface copper enrichment (as seen in XPS). However, at higher temperatures, the Cu-Ce contact in Cu2CZ-TI is enough to promote the catalytic activity, in agreement with the profile observed in the region 2 of H_2-TPR results (not achieved by LO procedure). Conversely, Cu2/AL presents a very low catalytic activity. Although copper is well dispersed onto the support, no synergistic effects between Cu and Al_2O_3 support are established.

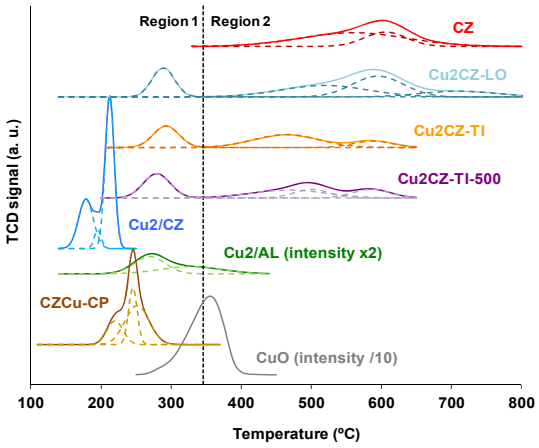

Figure 1. H_2-TPR deconvoluted profiles for the studied catalysts.

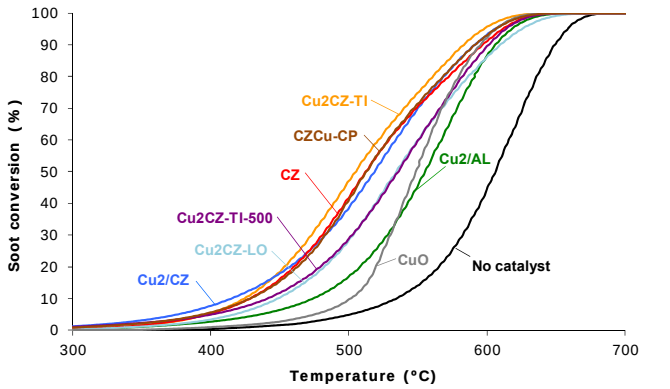

Figure 2. Soot conversion versus temperature under TPR conditions (NO_x/O_2).

4 Conclusions

The interfacial interactions between copper and ceria were found to be of key importance on the catalysts' reducibility and the catalytic activity for NO oxidation to NO_2 and diesel soot combustion reactions. These interfacial interactions can be tuned by conducting different procedures of copper incorporation onto ceria-zirconia.

Keywords: DPF, copper/ceria-zirconia, soot, combustion, NOx

1 Introduction

The CRT (Continuously Regenerating Trap) system is efficient for soot removal under determined conditions in diesel exhaust. This system is a combination of filter and an oxidation catalyst, where a DPF (Diesel Particulate Filter) is located downstream a Pt-containing DOC (Diesel Oxidation Catalyst) supported on a cordierite monolith. Both CO and unburned hydrocarbons are oxidized to CO_2 and H_2O in the DOC, where NO is also oxidized to NO_2. Particulate matter is filtered in the DPF, where the NO_2-assisted combustion takes places. Since NO_2 is more oxidant than O_2, the combustion onset temperature of soot is significantly decreased [1, 2]. During the last decade, topics of interest have been focused on: i) deposition of the catalytic coating directly onto the filter and ii) replacing Pt by cheaper active phases, being copper-doped ceria-zirconia mixed oxides one of the most promising options.

The catalytic performances of a 2%CuO/$Ce_{0.8}Zr_{0.2}O_2$ powder sample towards the soot combustion and the NO oxidation reaction have been recently reported in the literature by our group [3]. However, as far as we are concerned, the copper-doped ceria-zirconia-catalyzed regeneration of DPFs has not yet been reported, being this the main goal of the current study.

2 Experimental

The ceria-zirconia catalyst (CeZr) was prepared by the co-precipitation method and 2 wt% copper was incorporated by the incipient wetness impregnation method (2%Cu/CeZr).

A reduced scale SiC diesel particulate filter (SiC-DPF) was used as structured support, with 2.5 cm of diameter and 7.5 cm of length. The as-received DPFs were washed with water and acetone, dried at 110ºC and calcined at 700ºC for 2h. The 2%Cu/CeZr catalyst was incorporated onto the ceramic support by a single dipping of the DPFs in an aqueous solution of 2%Cu/CeZr, which were placed in an ultrasonic bath. Then, they were dried at 110ºC and calcined at 600ºC for 2h. Finally, the soot particles were loaded onto the active phase containing-DPFs by immersion into a soot/methanol suspension under vigorous stirring [1].

2%Cu/CeZr/SiC-DPF and 2%Cu/CeZr (powder) were tested for NO oxidation to NO_2 under TPR conditions and successive cycles (from room temperature up to 800ºC at 10ºC/min), and for soot combustion (TPR from room temperature up to 800ºC at 10ºC/min). The gas mixture used comprised 500 ppm NOx, 5% O_2 and N_2 balance; the gas flow was fixed at 500 ml/min. Different reactor configurations (horizontal reactor; inner diameter 3 cm and tubular reactor; inner diameter 1 cm) were needed for DPFs and powders, respectively.

3 Results and Discussion

As shown in Figure 1, a very high activity is reached by the active phase-loaded DPF towards the NO oxidation reaction, pointing out the satisfactory catalytic performance of the catalytic-coated filter. Furthermore, the catalytic profile of NO_2 production is not seen significantly modified after four successive cycles with the same DPF, allowing us to conclude that the catalytic coating

(achieved with the simple and solvent-free coating procedure consisting of immersion) is stable and the corresponding coated-DPF can be reused in several cycles without a significant decrease in its activity.

Soot combustion experiments revealed high activity shown by the loaded-filter (green line) if compared with the unloaded-DPF (blue line), as depicted in Figure 2. As can be seen the soot combustion profile obtained with the mixture of catalyst and soot under loose contact mode (very gentle mixture of soot and catalyst with a spatula) is quite similar to that obtained with the loaded-filter, verifying the good choice of conducting catalytic experiments under this procedure (loose-contact) to simulate the performance of this type of catalysts in a real filter. It should be remarked that with the purpose of conducting a proper comparison between the soot combustion profiles, an identical soot-catalyst ratio was employed in all the experiments. On the contrary, the soot conversion profile obtained under tight contact conditions (intimate mixture of soot and catalyst in an agate mortar) is very far from those mentioned above, and, consequently, does not simulate the real physical contact achieved in a diesel particulate filter.

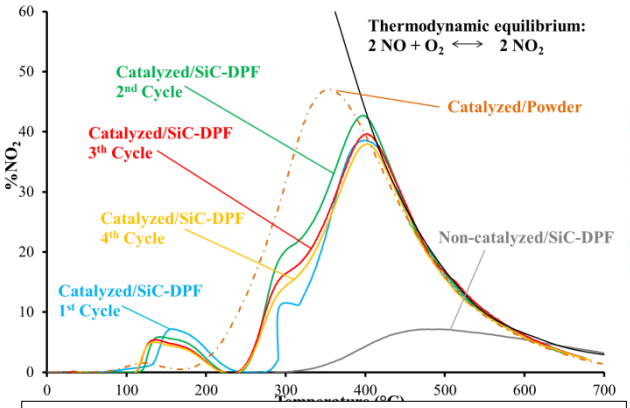

Figure 1. NO_2 production profiles under TPR conditions. Solid lines: successive cycles with the same loaded-DPF (1^{st}-4^{th}).

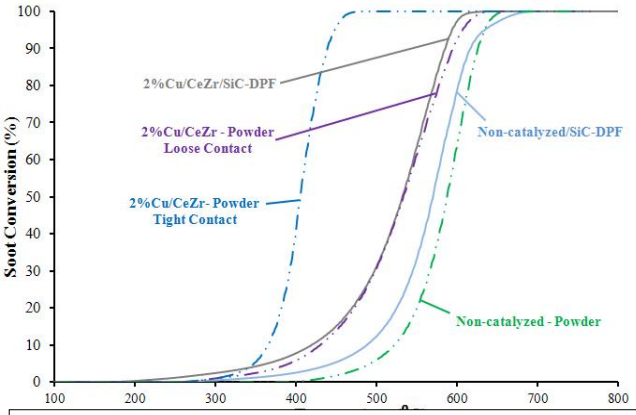

Figure 2. Soot conversion profiles under TPR conditions for different soot/catalyst configurations.

4 Conclusions

Incorporation of very active copper/ceria-zirconia active phase onto a SiC-DPF has been successfully achieved by a proper coating procedure consisting of immersion in an aqueous suspension. Very similar catalytic performances towards NO oxidation to NO_2 were obtained (when compared with the catalyst in powder form) under repeatable measurements. It was verified that the loose-contact mode is a good choice to simulate the catalytic performance of this type of active phase in a real Diesel Particulate Filter.

Keywords: Pd-Cu bimetallic catalyst, Pd-Cu nanoparticles, water-phase nitrate reduction

1 Introduction

Liquid-phase catalytic reduction of the nitrates seems to be an adequate technique for the removal of nitrate from natural water. In order to obtain greater activity and selectivity to nitrogen, different catalysts have been designed. The proposed catalysts are in majority supported bimetallic systems based on noble metals, such as Pd, Pt, Rh and Ru (1–5 weight %) promoted especially with Cu, Sn and In (0.2–1 weight %) [1].The main goal of this study was to evaluate the performance of supported bimetallic Pd-Cu nanoparticles prepared by alkaline polyol method in the selective reduction of nitrates from water to nitrogen. In this respect, the supported nanoparticles catalysts (Pd-Cu/Al_2O_3 and Pd-Cu/TiO_2) were tested in the reduction of nitrate ions in aqueous solution in comparison with bimetallic Pd-Cu catalyst obtained by impregnation method. The results were analysed in correlation with the morphological and structural characteristics of the catalytic systems obtained through X-ray diffraction (XRD), transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), atomic absorption spectrometry (AAS) and by CO chemisorption technique. Also, the influence of the pH conditions on the activity and selectivity of the NO_3^- reduction process was emphasized.

2 Experimental

In this study, a series of supported bimetallic Pd-Cu (with molar ratio Pd:Cu of 4:1 and total metal loading of 2%.) catalysts were prepared. The active components were introduced by impregnation or by deposition of nanoparticles previously synthesized (Table 1). The polyvinylpyrrolidone (PVP)-protected bimetallic nanoparticles were prepared following a modified protocol of alkaline polyol method [2]

Table 1. The prepared catalysts

Catalyst	Notation	Preparation method
Pd-Cu/Al_2O_3	PCA-np	nanoparticles by alkaline polyol method
Pd-Cu/ TiO_2	PCT-np	nanoparticles by alkaline polyol method
Pd-Cu/Al_2O_3	PCA-imp	successive impregnation
Pd-Cu/ TiO_2	PCT-imp	successive impregnation

The catalysts performance in the reduction of the nitrate ions was evaluated in a series of semi-batch experiments. The tests were carried out in a thermostated reactor (20.0 ± 0.1^{0}C) with a capacity of 250 mL, equipped with a magnetic stirrer. In a typical run, H_2 with a flowrate of 100 mL·min^{-1} at a pressure of 1 atm was bubbled in 200 mL of NO_3^- solution (100 mg.L^{-1}) in the presence of 0.10 g catalyst. Three cyclic runs were carried out for selected catalyst in order to assess his stability.

3 Results and discussion

For the nanostructured catalysts, the TEM images show good dispersion of nanoparticles on the support with a particle size in the range from 3 to 9 nm. The measured crystallographic orientation parameter of 2.25-2.27 Å, corresponds to Pd(111). Corroborating the TEM, XRD, XPS and CO chemisorption data it can be suggested that the Pd-Cu nanoparticles obtained by the modified protocol of the alkaline polyol method have a crystalline Pd core and a shell reach in amorphous cooper as metallic Cu or CuO. Compared to the catalyst obtained by successive impregnation method, the supported nanoparticles catalysts have a smaller Pd crystallite size and more important coverage of the palladium surface with copper.

The prepared catalysts were firstly tested in the reduction of nitrate anions from aqueous solutions without pH control. The Pd-Cu supported on titania show an increased activity compared to those supported on alumina. In particular, for PCT-np the conversion of nitrate overcomes 90% in the first 60 min. These differences on the catalytic activity might be explained by the type and intensity of the interactions between the active phase components and the support. The higher activity of the Pd-Cu catalysts supported on TiO_2 might be attributed to the more reduced state of the copper (due to electron transfer from the support to the metals). Also, it was observed that irrespective of the support used, higher conversions of nitrate were reached for the nanostructured catalysts.A better performance for PCT-np was obtained when the CO_2, used for the pH control, was introduced after the nearly complete removal of NO_3^-.

The stability of the PCT-np catalyst was assessed by determining the amount of Pd and Cu leached from catalyst. Furthermore, three cyclic runs were carried out for the PCT-np catalyst. As can be seen from figure 1, the catalyst performance is less affected in terms of nitrate conversion between the three cycles.

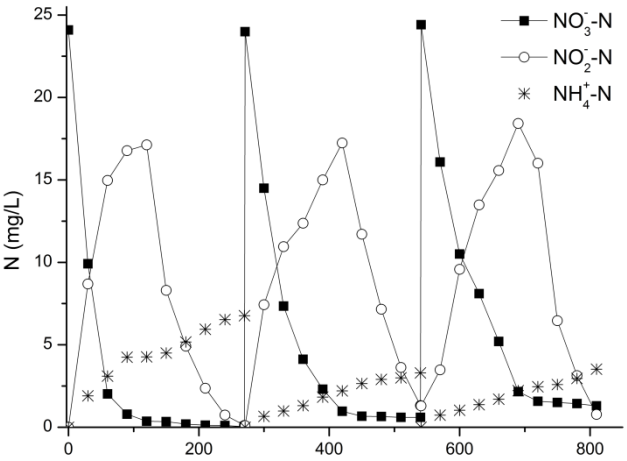

Figure 1. Nitrate reduction on PCT-np in three consecutive reaction cycles

4 Conclusions

A modified protocol of alkaline polyol method was successfully used to obtain well dispersed Pd-Cu nanoparticles for of alumina and titania supported catalysts. The supported nanoparticles catalysts have a smaller Pd crystallite size and more important coverage of the palladium surface with copper in comparison with the catalyst obtained by impregnation method. It was assumed that these specific characteristics of the nanostructured catalysts led to their superior activity in the reduction of nitrate. Nevertheless, the choice of the support appeared to be an important aspect. For the selected PCT-np catalyst, better activity and selectivity toward nitrogen were achieved within a combined uncontrolled-controlled pH process. The PCT-np catalyst was relatively stable for three consecutive cyclic runs.

Keywords: red mud, sulphide wastewater oxidation, catalysis

1 Introduction

This contribution investigates an alternative route for the valorisation of red mud (RM) industrial waste generated worldwide from the Bayer process applied in alumina refineries by utilizing it as raw material in the manufacture of oxidation catalysts. Such catalysts may be utilized for the oxidation of sulphide ions from wastewaters to elementary sulphur using air as oxidation agent. Sulphide ions often occur in industrial waste waters from oil refineries, fossil fuel gasification plants, paper and pulp mills, or after the anaerobic oxidation of sewage water. They may also be encountered in certain well waters. The sulphide ions from water have to be removed due to their toxicity and obnoxious odour [1-5]. The preparation method proposed for the obtaining of the catalysts involves the functionalization of trivalent iron sites from RM waste by treatment with polycarboxylic acids. The functionalization plays an important role in stabilizing the Fe(III) active species which otherwise could become inactive either following their conversion to Fe(II)S during the redox process or their precipitation as $Fe(OH)_3$ at high pH values reached due to the RM composition (during preparation). Two functionalization agents (e.g. disodium ethylenediamminotetraacetic acid Na_2H_2EDTA and trisodium citrate Na_3CIT) were selected bearing in mind that the coordination of Fe(III) in the ligands field should be strong enough to avoid its precipitation as sulphide or hydroxide while maintaining its ability to change the oxidation state during its involvement in the redox cycle.

2 Experimental/methodology

Red mud deposit from Tulcea alumina plant in Romania has been utilized for the obtaining of iron containing catalysts: RMN (red mud neutralized with 35% NaCl solution), RM-E and RMN-E (RM and RMN modified with Na_2H_2EDTA solution), RM-C and RMN-C (RM and RMN modified with Na_3CIT solution) and RM-E-C and RMN-E-C (RM and RMN modified with both Na_2H_2EDTA and Na_3CIT solutions). The concentration of polycarboxylic acid salt solution was calculated based on the amount of Fe in the solid undergoing treatment so that the Na_2H_2EDTA/Fe and Na_3CIT/Fe molar ratio to be 1-1,5 and respectively, 1-2. The raw red mud was submitted to contact with the corresponding sodium salts solutions (weight ratio L/S=10:1) at room temperature during 6 days with 30 min agitation (300rpm)/day. The solid was separated by filtration, washed with distilled water until the conductivity of the water decreased below 100microS/cm and dried at 60°C during 24 h.

The catalysts were characterized by DRIFT, DR-UV-Vis, XRD, surface area and porous structure determinations. The preliminary catalytic tests for the oxidation of sulphide by oxygen from air were performed using a two-necked glass flask reactor equipped with a teflon-coated stirrer bar, a gas-inlet tubing connected to a dry air supplier and a reflux condenser, at ambient temperature and pressure, under 4L/h air flow using 1 g of catalyst and 75 mL of synthetic waste water (freshly prepared by dissolving an adequate amount of Na_2Sx9H_7O in deoxygenated distilled water) containing 1 g sulphide/L, under continuous stirring (350 rpm) during 2 hours. Another set of experiments aimed to investigate their stability under operating conditions and the possibility of using it in 4 repeated reaction cycles (2 h each) has been performed. The catalyst used in one reaction cycle was separated from the reaction mixture, before being

introduced in the next cycle.

3 Results and discussion

The spectroscopic analyses of the catalysts by XRD, DRIFTS and DR-UV-Vis-NIR indicated the presence of the organic ligands in all the functionalized samples. The most significant modifications were noticed in the DRIFTS spectra. The spectra of citrate modified samples RM-C and RMN-C show a shift to lower wavenumbers of un-split bands characteristic for $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ vibrations at ~1640 cm^{-1} and 1400 cm^{-1} indicating their deprotonation following the coordination to Fe(III). A weak intensity band at ~800 cm^{-1} attributed to Fe-O-Fe vibrations may be a consequence of the citrate excess utilized in the preparation. In the spectra of Na_2H_2EDTA functionalized samples, RM-E and RMN-E, the coordination of the ligand to Fe(III) is proved by the shift to lower wavenumbers of the bands characteristic to $\nu_{as}(COO-)$ and $\nu_s(COO-)$ vibrations as well as a similar shift of the bands characteristic to C-N bonds compared to the spectrum of the free ligand. In the spectra of the samples functionalized with the mixture of ligands, RM-E-C and RMN-E-C the bands at 1626 cm^{-1}, ~1400 cm^{-1}, 1120 cm^{-1} characteristic for the coordination of EDTA and citrate anions have lower intensity and are also shifted to lower wavenumbers. Besides that, there are some spectral modifications that indicate either the perturbation of Fe(III)EDTA by the concomitant presence of the citrate anion, or the complexation of the citrate anion with Fe(III)-EDTA chelate which would mean that the iron would be coordinated by two oxygen atoms belonging to different sources. These modifications are: the shifting of the weak band around 800 cm^{-1}, related to Fe-O-Fe bonds vibrations in the iron citrate to 850 cm^{-1}, and an intense split band at 615 cm^{-1}, which is shifted compared to the band at 625 cm^{-1} characteristic to iron citrate [5-7].

The results of the catalytic tests performed with the functionalized RM and RMN samples showed an increase by 40% of the sulfide ion removal from wastewaters as well as the absence of FeS in the treated wastewaters compared to un-functionalized iron containing catalysts. The relatively low conversion values may be due both to the high concentration of sulfide ions in the synthetic wastewaters and the factors affecting the mass transfer (air flow, air dispersing system, etc). Another advantage of the functionalization is the enhanced stability of the solids towards deactivation. The most stable are RM-E-C and RMN-E-C for which the decrease of activity after 4 reaction cycles is only about 15%.

4 Conclusions

The preparation method for iron containing solids prepared using RM is simple and does not need expensive apparatus and technology. Besides the formation of Fe(III) complexes on the surface of the RM and RMN solids, this method allows also the re-adsorption of the complexes formed in the solution following the dissolution of iron by the complexation agents. The catalysts obtained by functionalization present catalytic activity for sulfide oxidation under mild reaction conditions even at room temperature and avoid the formation of Fe(II)S in treated wastewater. Even if the activity of these solids is lower, taking into account the low price of the RM the subject deserves further investigation.

Keywords: ZnAlW, LDH, photocatalyst, phenol, degradation, structure

1 Introduction

Contaminant organic compounds in aqueous effluents have exceeded permitted levels, causing pollution of rivers, lakes and drinking fountains [1]. The main problem deals with the discharges from industries: pesticides, fertilizers, drugs and other recalcitrant chemicals [2]. One of these pollutants is phenol and its derivatives, whose use is quite extensive and present high toxicity [2]. To destroy these chemicals, it has been proposed several approaches, being catalytic photoconversion one of the most promissory methods. Among others, TiO_2, Fe_2O_3 and ZnO, have been used to degrade persistent organic pollutants [3]. However, it is necessary to explore the development of new materials that have new and improved adsorption and photocatalytic properties in order to obtain higher degradation efficiency. On this regard, in the present work is reported the synthesis of layered double hydroxides (LDHs) of Zn^{2+}:Al^{3+} and Zn^{2+}:Al^{3+}:W^{6+}, their structure properties as well as their photocatalytic activities in the degradation of phenol in aqueous medium.

2 Experimental/methodology

LDHs were prepared by the co-precipitation method, using $Zn(NO_3)_2.6H_2O$ and $Al(NO_3)_3.9H_2O$ with a molar ratio Zn/Al = 3/1 as precursors; H_2O_4W was added to the mixture to obtain a concentration of 5wt% of W^{6+}. Urea was added (molar ratio H_2O/urea 2/1) as precipitating. The resulting solution was heated at 363 K with vigorous stirring for 48 h. The obtained solids were washed with distilled water at 363 K, followed by drying at 373 K for 12 h and calcination at 573 K for 12 h. The samples were denominated ZnAlW-X where X indicates de treatment temperature. The solids were characterized by N_2 physisorption, XRD and UV-Vis spectroscopy. Photocatalytic activity of the materials was carried out in a batch-type photo-reactor under UV radiation (λ= 254 nm) containing an aqueous solution of 80 ppm of phenol.

3 Results and discussion

Table 1 shows the textural properties of ZnAl and ZnAlW LDH treated at 373 and 573 K. It can be seen that the S_{BET} and VP_T of ZnAl-373 were low (13.0 m^2g^{-1} and 0.1 cm^3g^{-1}), but when it was calcined at 573 K, its S_{BET} and VP_T increased to 62.0 m^2g^{-1} and 0.17 cm^3g^{-1} respectively. The presence of W^{6+} produced a significant increment of S_{BET} and VP_T even at 373 K, i.e., 85.0 m^2g^{-1} and 0.42 cm^3 for ZnAlW-373. The N_2 adsorption isotherms of ZnAl and ZnAlW are of type IV and their hysteresis loop is of the H3-type indicating the presence of aggregates of plate-like particles or slit-shape pores (Fig.1). XDR patterns showed loss of crystallinity and structural changes in both, the ZnAl-573 and ZnAlW-573 (Fig.2). Fig.3 shows the photocatalytic activity

for the ZnAl and ZnAlW LDH. The photoconversion of phenol over ZnAl-373 was rather low (~10%). In contrast, ZnAl-573 reached 66%. Whereas, improved phenol photoconversion was obtained in ZnAlW-373 (~75%) and ZnAlW-573 (~92%).

Table 1. Textural properties of ZnAl and ZnAlW LDH.

Material	S_{BET} ($m^2.g^{-1}$)	APS (nm)	VP_T ($cm^3.g^{-1}$)
ZnAl-373	13.0	3.0	0.1
ZnAl-573	62.0	1.1	0.17
ZnAlW-373	85.0	2.0	0.42
ZnAlW-573	84.0	2.7	0.57

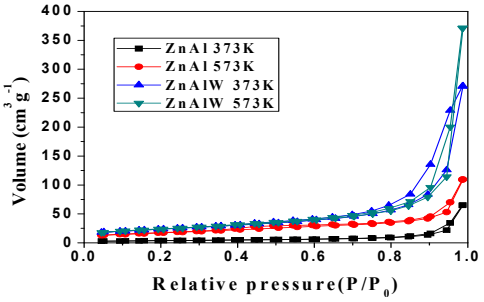

Figure 1. N_2 adsorcion - desorption isotherms

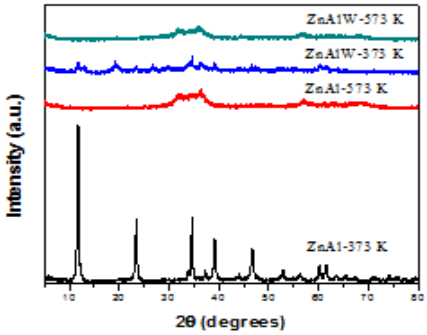

Figure 2. XRD patterns of ZnAl and ZnAlW

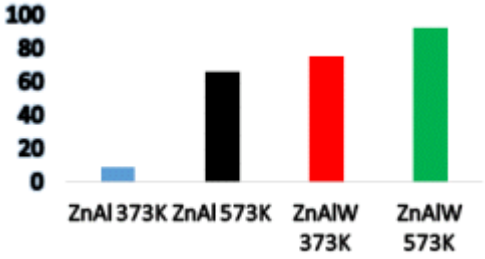

Figure 3. Photocatalytic degradation of phenol on ZnAl and ZnAlW after 4 h of UV irradiation

4 Conclusions

ZnAl and ZnAlW LDH were prepared by the co-precipitation method. ZnAl contain slit-shape pores which are enlarged with doping with W^{6+}.The photocatalytic activity of ZnAl is improved both with treatment temperature and doping with W^{6+}. In the last case the photoconversion is significantly increased obtaining 75% for ZnAlW-373 and 92% for ZnAlW-573 at 4h of UV irradiation.

Keywords: phenol photodegradation, Al_2O_3-Nd_2O_3 nanomaterials, structure

1 Introduction

In recent years, great efforts have been devoted to the development of alumina nano-structured materials due to their interesting scientific and technological applications [1]. A special case deals with alumina nanomaterials containing rare earths oxides because they can be used in several catalytic applications. The use of the alumina-lanthanide oxide nanomaterials is attractive especially in the photodegradation of contaminant organic compounds in aqueous medium since rare earths oxides modify the characteristics of alumina. Previously, it has been reported that Al_2O_3-Nd_2O_3 binary oxides show a high capability to photodegrade phenol in aqueous medium [2]. However, it is necessary to improve the photocatalytic performance of Al_2O_3-Nd_2O_3 nanomaterials. For this purpose, the photodegradation of phenol over Al_2O_3-Nd_2O_3 nanomaterials doped with 1.0 wt% of Fe, Mg or Zn oxide is reported in the present work. These nanomaterials were characterized N_2 physisorption, X-ray diffraction, UV-Vis and Raman spectrocopy.

2 Experimental/methodology

The nanomaterials were synthesized by a combined method of dissolution of organic precursors at high temperature [3] and the conventional sol-gel route. Al_2O_3-Nd_2O_3-M_xO_y (M = Fe, Mg, Zn) nanomaterials (Al-Nd-M) with 5 wt% of Nd_2O_3 and 1 wt% of metal oxide were prepared by dissolving 0.011 moles of hexadecyltrimethyl-ammonium bromide (CTAB) and 0.18 mol of aluminium tri-sec-butoxide in 0.22 mol of butanol and 0.078 mol of 2-methyl-2,4-pentanedione at 70°C for 1h with continuous stirring. Separately required amounts of Nd acetylacetonate and Fe, Mg, or Zn acetylacetonate were dissolved in a solution containing 0.009 mol of oleic acid, 0.012 mol of oleylamine and 0.004 mol of octadecene at 330ºC for 1h with continuous stirring. After that, the acetylacetonate dissolution was cooling down to 70ºC. Afterwards, both dissolutions were mixed at 70°C for 1h with continuous stirring. Then, a required volume of deionized H_2O was added. The obtained gels were aged at 70ºC for 12h and washed with ethanol for several times. The gels were dried at 100ºC for 12h and calcined at 500ºC for 2h. Then nanomaterials were characterized by N_2 physisorption, X-ray diffraction, UV-Vis and Raman spectroscopy. The photocatalytic activity experiments in the degradation of phenol were carried out by using a Pen-Ray UV lamp (λ=254 nm), 200 mL of aqueous phenol dissolution and 200 mg of Al-Nd-M photocatalyst. Aliquots of the irradiated phenol dissolution were collected each hour for a period of 6h.

3 Results and discussion

Textural properties of the Al-Nd-M nanomaterials are shown in Table 1. The S_{BET} of Al_2O_3

(306.0 m^2g^{-1}) was improved by addition of 5 wt% of Nd_2O_3 (322.0 m^2g^{-1}), however the S_{BET} of Al-Nd-M decrease to a values close to 300 m^2g^{-1} being the nanomaterial with 1 wt% of MgO that with the highest S_{BET} (312 m^2g^{-1}). The specific pore volume is constant for all the nanomaterials (~1.1 cm^3g^{-1}). Conventional XRD patterns (Fig. not shown) of Al-Nd-M nanomaterials show crystalline planes corresponding to the γ-Al_2O_3 phase and the appearance of a small diffraction feature at about 2θ = 32º is attributed to the (110) plane of Nd_2O_3. Small angle XRD patterns of Al-Nd-M show a small diffraction peak at about 1° indicating the presence of metal oxide nanoparticles.

Table 1. Textural properties of Al_2O_3-Nd_2O_3-MO (M: Fe,Mg and Zn).

Sample	S_{BET} (m^2g^{-1})	VP_T (cm^3g^{-1})	Degradation % after 5h of UV irradiation
Al_2O_3	306.0	1.0	69
Al-Nd	322.0	1.2	79
Al-Nd-Fe	294.0	1.2	55
Al-Nd-Mg	312.0	1.1	91
Al-Nd-Zn	307.0	1.1	84

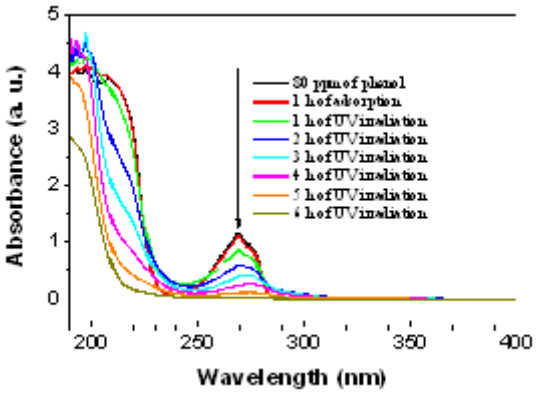

Fig. 1. UV photodegradation of phenol over Al-Nd-Mg nanomaterial.

The presence of metal oxide nanoparticles is corroborated by the appearance of a small absorption band at 205 nm in their UV-Vis spectra. Photocatalytic activity data (Table 1), shows that pure γ-Al_2O_3 exhibit high photoconversion of phenol (~ 60%) at 5h of UV irradiation. However, addition of 5wt% of Nd_2O_3 improved the phenol photoconversion for about 14%. With exception of Al-Nd doped with 1 wt% of Fe oxide showing a lower phenol photoconversion (~ 55%), Al-Nd doped with 1 wt% of Zn or Mg oxide (Fig. 1) enhanced their phenol photoconversion to 84 and 91% respectively after 5h of UV irradiation.

4 Conclusions

Al_2O_3-Nd_2O_3 nanomaterials doped with 1.0 wt% of Mg or Zn oxide exhibited high specific surface area (> 300.0 m^2g^{-1}) and high specific pore volume (□1.1 cm^3g^{-1}). The photodegradation of phenol over Al-Nd was improved by doping with 1 wt% of Zn or Mg oxide obtaining phenol photoconversions near to 90% after 5h of UV irradiation. In contrast, doping with 1 wt% of Fe oxide was in detriment of the specific surface area and phenol photoconversion.

Keywords: desulfurization, epoxidation, polyoxometalates, hydrogen, peroxide, functional, polymers

1 Introduction

Polyoxometalates (POMs) have found applications in various disciplines, of which catalysis is by far the most important [1]. POMs, especially those comprising Keggin polyanions, serve as precursors of efficient catalysts for environmentally benign biphasic oxidations with hydrogen peroxide. These reactions typically involve phase-transfer catalysis with peroxo polyanion transport through the water-organic interface and require an efficient agent to move the peroxo polyanions from the aqueous phase into the organic phase. Commonly, quaternary ammonium cations with C_8–C_{18} alkyl groups are used as phase-transfer agents to facilitate organic phase solubility of the POM. However, more efficient biphasic oxidation processes using the POM/H_2O_2 system could address specific challenges which include improving catalyst activity and recyclability in alkane-water two-phase systems. This is particularly important for reactions such as the POM-catalyzed oxidative desulfurization with aqueous H_2O_2 as the "green" oxidant. Here we report on the use of amine terminated polyisobutylene (PIB) oligomer as a highly efficient phase-transfer agent for Keggin POM catalysts in oxidative desulfurization and alkene epoxidation with H_2O_2 in a heptane-water two-phase system [2]. Both reactions are the subject of much current interest.

2 Experimental

The oxidation of dibenzothiophene (DBT) and epoxidation of cyclooctene were carried out in a two-phase system containing heptane as an organic solvent and aqueous H_2O_2 at 25-60 ^oC in a 50-mL glass reactor equipped with a magnetic stirrer, a reflux condenser and a heat circulator. The reactions were monitored by GC. The amount of unreacted H_2O_2 was determined by titration with $KMnO_4$ for the efficiency of hydrogen peroxide use to be estimated [2].

3 Results and discussion

We found that PIB oligomer-bound Keggin POMs are highly active and easily recyclable catalysts for DBT oxidation with H_2O_2 in a heptane-water biphasic system, yielding DBT sulfone as the sole product (Table 1). The two catalyst components can simply be added separately to the reaction mixture to form the active catalyst *in situ*. The PIB amine was introduced as a 0.5 M heptane solution of diethylamine terminated PIB (PIB_{1000}-$CH_2N(CH_2CH_3)_2$) synthesized from commercially available PIB oligomer with a molecular mass of 1000 Da [2]. The POM was a heteropoly acid hydrate $H_3PW_{12}O_{40}$, $H_3PMo_{12}O_{40}$ or $H_4SiW_{12}O_{40}$, hereafter abbreviated as PW, PMo and SiW. The catalyst activity increased with the PIB/POM molar ratio, levelling off at a ratio of 4:1 – 6:1. PW exhibited the highest activity followed by PMo. With PW, the conversion of DBT reached 100% in 0.5 h at 60 ^oC and a

PIB/PW molar ratio of 6:1. In contrast, SiW predictably showed no activity in agreement with its well-known resistance to form peroxo species. Importantly, practically no decomposition of H_2O_2 took place in the PIB-POM reaction system, giving >99% efficiency of H_2O_2 utilization. Excellent recyclability of the PIB-PW catalyst was observed – 5 times without loss of activity.

Table 1. Oxidation of DBT by H_2O_2 catalyzed by PIB-POM in heptane-H_2O two-phase system.[a]

POM	PIB/POM (mol/mol)	Temp. (°C)	Conv. (%)	H_2O_2 efficiency (%)
PW	1:1	60	70	> 99
PW	4:1	60	97	>99
PW	6:1	60	100	>99
PW	4:1	40	49	>99
PW	4:1	25	30	>99
PMo	4:1	60	73	>99
SiW	4:1	60	0	>99

[a] Heptane (10 mL), DBT (0.50 mmol, 1 wt%), aqueous 30% H_2O_2 (0.15 mL); molar ratios: DBT/POM = 90:1, DBT/H_2O_2 = 1:3; 0.5 h reaction time. DBT sulfone was the only reaction product observed.

The PIB-POM catalyst was also found efficient for cyclooctene epoxidation (Table 2). This reaction is the standard test for epoxidation catalysts and was used here for proof of concept. The PW catalyst was more active than PMo, as in the case of DBT oxidation, yielding 100% at 60 °C in 0.5 h reaction time. Again, the decomposition of H_2O_2 was negligible (>99% efficiency of H_2O_2 utilization), and the catalyst could be reused.

Table 2. Epoxidation of cyclooctene by H_2O_2 catalyzed by PIB–POM in heptane-H_2O two-phase system.[a]

POM	Temp. (°C)	PIB/POM (mol/mol)	Time (h)	Yield[b] (%)	Initial rate[c] (mmol/min)
PMo	60	6:1	0.5	99	0.059
PW	60	6:1	0.5	100	0.083
PW	60	4:1	0.5	92	0.075
PW	60	3:1	0.5	96	0.080
PW	30	3:1	2.5	94	0.031
PW	60	1:1	0.5	88	0.056

[a]Heptane (10 mL), cyclooctene (9.71 mmol, 1.0 mL), aqueous 10% H_2O_2 (1 mmol, 0.3 mL), $H_3PW_{12}O_{40}\cdot 20H_2O$ or $H_3PMo_{12}O_{40}\cdot 28H_2O$ (6.48 μmol). [b]Yield based on the initial amount of H_2O_2. [c]Initial rate calculated over the first 10 min of the reaction.

4 Conclusions

We have demonstrated that the PIB oligomer-bound Keggin POMs are efficient and recyclable catalysts for environmentally benign biphasic oxidations with H_2O_2, including the oxidation of DBT to DBT sulfone and cyclooctene epoxidation, in a heptane-water system. These catalysts self-assemble in situ by mixing commercial Keggin POMs and amine terminated PIB oligomer. The activity of PIB-POM compares well with the results reported so far.

Keywords: MnOx-CeO_2 mixed oxides, solid solution, catalytic combustion, toluene

1 Introduction

Volatile organic compounds (VOCs), are a major class of atmospheric pollutants, that are released in the atmosphere by different manufacturing processes, motor vehicles and domestic activities [1,2]. The VOC's generated by industrial processes are generally eliminated by thermal combustion, however, the catalytic combustion is more advantageous as it enables to operate at lower temperatures which leads to the limitation of the formation of by-products, such as dioxins and nitrogen oxides and carbon monoxide [2]. In the present work, two MnO_x-CeO_2 solids were prepared using co-precipitation and redox methods and then the catalytic performance of these systems was probed in the toluene combustion reaction.

2 Experimental

2.1. Catalysts Preparation

The solids, MnO_x-CeO_2 with a molar ratio Mn/Ce=1, were prepared by two methods, carbonate route (MnCe-CPC) and redox route (MnCe-RED), the solids were dried at 100°C and calcined at 500°C for 5 hours (heating rate 5°C/min). The Pure oxides were also prepared using the carbonate route and were labeled MnO_x and CeO_2.

2.2. Catalysts characterization

The prepared solids were calcined at 500°C, and characterized by XRD, H_2 temperature-programmed reduction (H_2-TPR) , nitrogen adsorption-desorption technique and SEM.

3 Results

The XRD analysis of the solids showed that the only crystalline phase detected is cerium oxide.

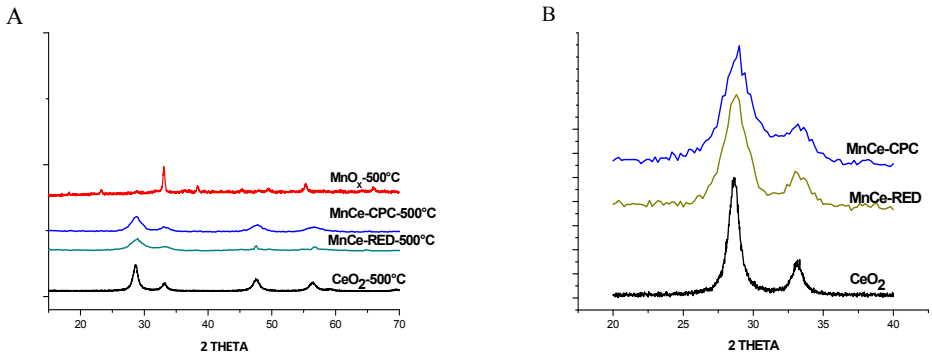

Fig 1. XRD patterns of solids : the vertical lines correspond to the position of diffraction lines of CeO_2 JCPDF#34-0394 B :shift XRD lines.

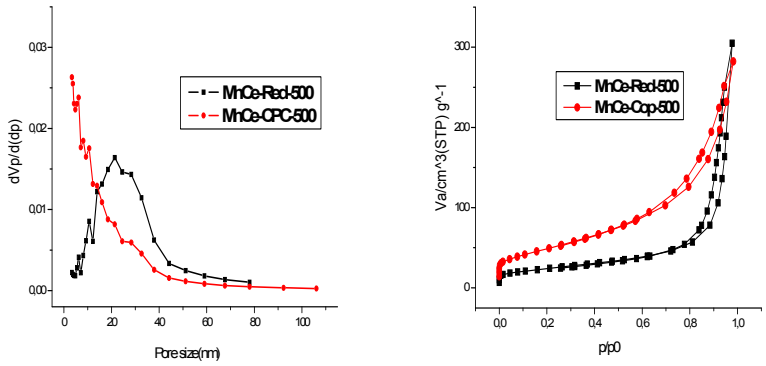

Fig 2: The nitrogen adsorption/desorption isotherms and pore distribution.

The N_2 adsorption/desorption isotherms of all catalysts belong to type II according to the IUPAC classification and have a pore distribution in the mesopores region.

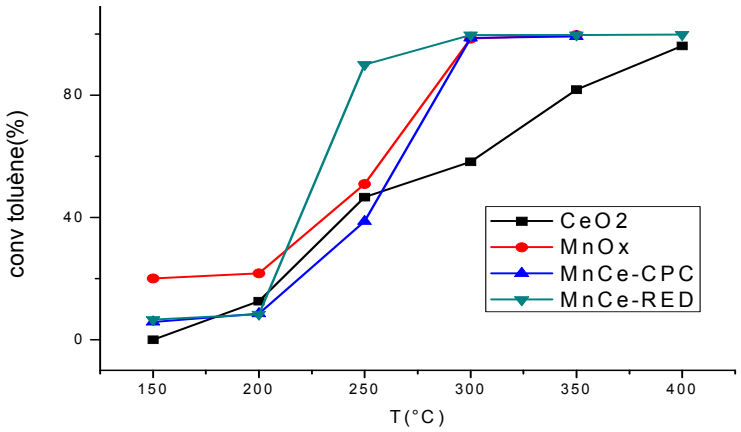

Fig 3: Toluene conversion on pure and mixed oxides.

The solids showed good performances in the toluene combustion reaction which seemed to depend strongly on the preparation method. The catalyst prepared by the redox method exhibited the best catalytic activity, over which the conversion of toluene could achieve 90% at 250°C and 100% at 300°C.

4 Conclusion

MnO_x-CeO_2 mixed oxides prepared by the co-precipitation and redox methods lead to a good catalytic activity in the total oxidation of toluene. The textural properties and catalytic behavior depend on the preparation method. The XRD analysis suggested the formation of a solid solution between manganese and cerium oxide.

Keywords: nitrous oxide, catalytic decomposition, cobalt oxides, IR spectroscopy, XRD, Raman

1 Introduction

Nitrous oxide (N_2O) has a high global warming potential (310 times higher than CO_2) and contributes to the destruction of stratospheric ozone. The low-temperature catalytic decomposition of N_2O (up to 450°C) to nitrogen and oxygen offers attractive solution for decreasing N_2O emissions in tail gas from nitric acid production plants.

Cobalt spinel catalysts are supposed as ones of the most active catalysts for N_2O decomposition [1-6]. The catalytic activity of spinels depends essentially on the degree of substitution and the occupation of the tetrahedral and octahedral sites. The preparation method of the spinel precursors determines final oxide texture, surface composition and plays a crucial role in ultimate performance of these materials [4].

The present article is dealing with comprehensive analysis of the effect of preparation method on the N_2O decomposition performance of Co-Mn-Al mixed oxide catalyst prepared by three different methods to obtain new information about key parameters influencing catalytic activity for N_2O decomposition.

2 Experimental

Co-Mn-Al mixed oxides were prepared by three different methods while the Co:Mn:Al molar ratio of 4:1:1 was kept constant in all catalysts. At first, Co-Mn-Al layered double hydroxide with the Co:Mn:Al molar ratio of 4:1:1 was prepared by co-precipitation of the corresponding nitrate solution in an alkaline Na_2CO_3/NaOH solution at 25 °C and pH 10 (Co-Mn-Al-ht-ex). The washed and dried product was calcinated for four hours at 500 °C in air. The second method of catalyst preparation was the mechanochemical reaction of Co, Mn, Al nitrates with NH_4HCO_3 (Co-Mn-Al-carb). The third method of catalyst synthesis was calcination of corresponding nitrates for four hours at 500 °C in air (Co-Mn-Al-nitr).

The catalysts were characterized by AAS, XRD, Raman, FTIR, H_2-TPR, TPD-CO_2 and NH_3 and tested for N_2O decomposition in inert gas and simulated waste gas from HNO_3 production.

3 Results and discussion

The chemical analysis data, textural data and redox properties of calcined samples are listed in the Table 1. The highest specific surface area was observed for Co-Mn-Al mixed oxide prepared for carbonate precursor. From XRD patterns (not show) one can see that the diffraction lines are attributed to the Co-Mn-Al spinel-like phase for all samples. FTIR and Raman spectra of measured samples (not shown) showed characteristic bands of Co-, Mn- and Al-O vibrations but they are not identical for all samples. Differences were observed also in reducibility of samples. Results of N_2O catalytic decomposition in inert and simulated industrial conditions are

presented in Fig. 1. The highest catalytic activity was achieved on the calcined precursors having carbonates in their molecules, Co–Mn–Al-carb and Co–Mn–Al-HT-ex, the lowest one on the calcined Co–Mn–Al nitrates, probably due to the lowest surface area, less advantageous porous structure and worse reducibility. Simulating industrial conditions by adding oxygen, water and NO to the inert, the N_2O conversions decreased for all samples, the least affected conversion being that for the Co-MnAl-carb.

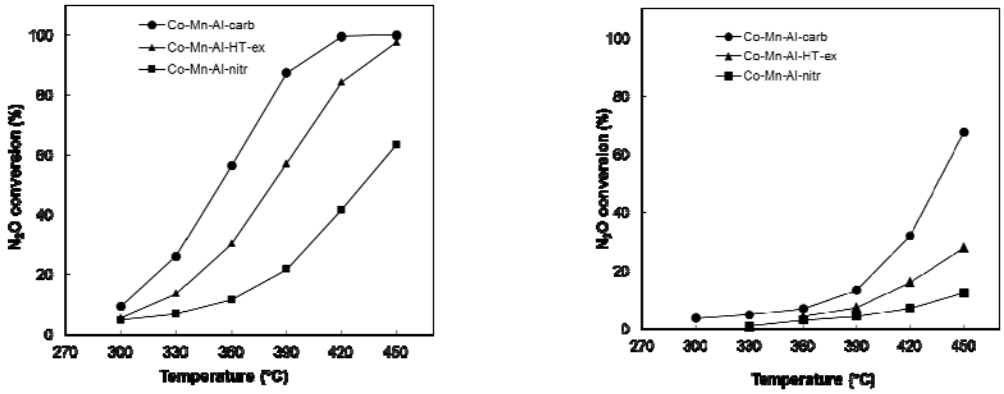

Fig. 1. Temperature dependence of N_2O conversions over Co-Mn-Al mixed oxide. Conditions: 1000 ppm N_2O in He (a) and 1000 ppm N_2O + 5%O_2 + 3%H_2O + 200ppm NO/He (b) atmospheric pressure, GHSV=20 l $g^{-1}h^{-1}$

Table 1. Chemical composition, textural data and redox properties of Co-Mn-Al mixed oxide

Sample	Co	Mn	S_{BET}	V_{meso}	V_{micro}	r_{meso} [a]	TPR-H_2	T_{max} °C
	wt %	wt %	$m^2.g^{-1}$	$cm^3\ g^{-1}$	$cm^3\ g^{-1}$	nm	25-1000 °C	
Co-Mn-Al-carb	45.7	11.7	134	0.78	0.058	12.4	13.12	352, 731
Co-Mn-Al-HT-ex	49.6	13.3	93	0.48	0.046	10.8	12.50	337, 637, 789
Co-Mn-Al-nitr	48.4	12.9	35	0.15	0.015	21.7	13.48	418, 595, 697

4 Conclusions

Co-Mn-Al mixed oxides with the molar ratio of Co:Mn:Al = 4:1:1 were prepared by three different methods, characterized and tested in N_2O catalytic decomposition. The preparation method influenced the physical-chemical properties of the catalysts and their catalytic activities. The highest activity showed Co-Mn-Al-carb prepared mechanochemically due to the highest surface area and pore volume.

1 Introduction

Catalytic decomposition of N_2O, strong greenhouse gas, which is typically present in the tail gases from nitric acid plant, is well known from the scientific literature. However, only small number of catalysts has been commercialized and only few studies devoted to the catalysts tested in pilot plants were reported [1-4]. Depending on the location in the process, the approaches of lowering of N_2O from nitric acid plants can be classified into three groups: (i) preventing of N_2O formation in the ammonia burner, (ii) N_2O removal from NO_x gases between the ammonia burner and the absorption column, and (iii) N_2O removal from the tail gas downstream (low temperature deN_2O). The choice of suitable deN_2O technology depends on the current arrangement of the nitric acid plant, which can be radically different, which means that each approach is necessary to be developed. The offer of commercial catalysts suitable for low temperature N_2O decomposition available nowadays at the market is very limited [4].

Our recent research activities have been focused on development of a catalyst for the low temperature N_2O decomposition, covering the catalysts development and preparation, their laboratory and pilot plant-scale testing in N_2O decomposition including the long term activity and stability tests and assessment of usage of such a catalyst in the full scale plant based on the mathematical model of pilot plant reactor.

2 Experimental/methodology

The K-doped Co-Mn-Al mixed oxide deN_2O catalyst was prepared by heating the coprecipitated Co-Mn-Al layered double hydroxide with Co:Mn:Al molar ratio of 4:1:1, subsequent impregnation with KNO_3, pelletizing into 5x5 mm tablets and heating at 500 °C. Testing of catalytic N_2O decomposition was performed in a pilot-plant fixed bed stainless steel reactor (310 mm i.d, temperature range from 300 to 450 °C, inlet pressure 0.6 MPa); reactor inlet was connected to the bypassed tail gas from the nitric acid production plant downstream the SCR NO_x/NH_3 catalyst. Feed to the reactor varied between 300 and 600 kg h^{-1} and contained typically 400-700 ppm N_2O together with oxygen, water vapor and low concentration of NO, NO_2 and NH_3. The infrared (N_2O, NO, NH_3) and chemiluminescence (NO, NO_2) on-line analyzers were used for analysis of the gas at the catalyst bed inlet and outlet. Reactor was equipped with on-line monitoring concentrations of all measured gas components, temperature in catalyst bed and pressure drop. Fresh and used catalysts were characterized by AAS, XRD, XPS, N_2 physisorption, He pycnometry, Hg porosimetry, thermal alkali desorption and H_2-TPR.

3 Results and discussion

The catalyst prepared in the pilot plant-scale contained slightly lower amount of Mn and Al than intended (Table 1); however, its activity in N_2O decomposition was comparable with that of samples prepared in laboratory. Performance of the catalyst tested in the pilot plant-scale conditions was very good and stable (Fig. 1).

Table 1 Physicochemical characterization of the fresh and used K/Co_4MnAlO_x catalyst

Catalyst	Co:Mn:Al:K[1)]		S_{BET}	V_{meso}	TPR[3)]
	AAS	XPS	($m^2\ g^{-1}$)	($cm^3\ g^{-1}$)	(mmol H_2/g)
Fresh	4:0.66:0.74:0.17	4:0.7:1.9:0.38	93.0	0.213	5.61
Used [2)]	4:0.73:0.91:0.15	4:1.1:2.5:0.52	86.8	0.205	5.73

[1)] Molar ratio [2)] For 112 days [3)] (25-500°C)

The long term testing showed slight increase in N_2O conversion; average N_2O conversion of 90 % at 450 °C, GHSV=8 620 $m^3\ m_{bed}^{-3}\ h^{-1}$ and p=0.6 MPa was determined. This increase could be connected with changes of surface composition observed by XPS, which confirmed slight reduction of Co^{3+} to Co^{2+} and enrichment of the surface with K; observed changes in pore structure could also contribute to this finding.

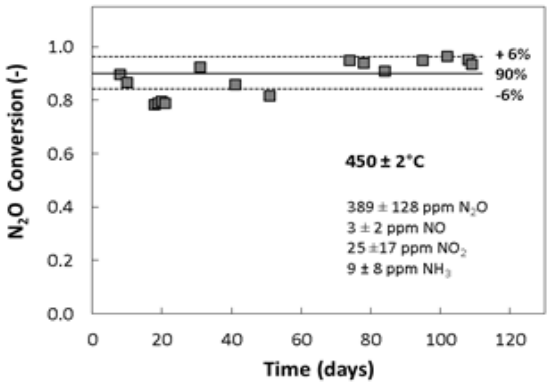

Fig. 1. Stability over K/Co_4MnAlO_x in the pilot plant test (GHSV=8 620 $m^3\ m_{bed}^{-3}\ h^{-1}$, p=0.6 MPa)

The kinetic parameters of N_2O decomposition evaluated from experiments performed over the catalyst tablets in the pilot plant reactor describe the reaction rate including internal diffusion hindering effect and can be fitted by the 1st order rate law. At the assumption that these data are not influenced by macrokinetic phenomena of the pilot plant reactor, they were directly used for the reactor scale-up calculations.

4 Conclusions

The K/Co_4MnAlO_x catalyst designed on the basis of laboratory tests was successfully prepared in the pilot plant-scale. The catalysts showed the same catalytic activity in laboratory and pilot plant-scale testing of N_2O decomposition, when high and stable output in N_2O removal was reached. The slight changes in surface composition observed after 112 days catalyst testing in the pilot plant reactor did not negatively affect the catalytic performance. The developed deN_2O K/Co_4MnAlO_x catalyst can be considered as very promising for commercial application.

DFT Studies on the Mechanisms of Nickel-Catalyzed Reductive Carboxylation of Styrenes Using CO_2 as the Building Block

Yuan R.M.[1*], Lin Z.[2]

Keywords: carbon, dioxide, reductive carboxylation, DFT studies, nickel catalyst

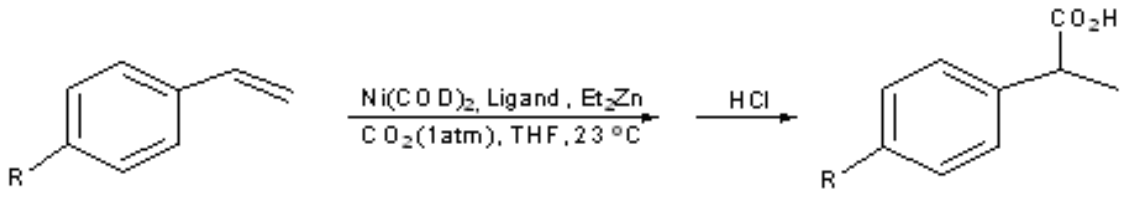
1 Introduction

Greenhouse effect has been recognized as one of the important environmental issues, and CO_2 makes up a significant percent of total greenhouse gas (GHG) emissions.[1] On the other hand, CO_2 is an attractive C1 building block for organic synthesis because of its low cost and abundance. However, its high stability and low reactivity are the biggest challenge to development of useful chemical reactions involving carbon dioxide. Recently, significant efforts have been devoted to convert CO_2 into carboxylic acids and derivatives.[2] Among those reported reactions, carboxylation of unsaturated organic compounds catalyzed by low-valent nickel complexes is well investigated. Here, we studied the detailed mechanisms of the nickel-catalyzed reductive carboxylation of ester-substituted styrenes H_2C=CHAr using CO_2 as the building block to form α-carboxylated products (eq 1) by DFT calculations. [3] With the aid of the DFT calculations, we obtained important insights regarding the substrate scope, ligands and reaction conditions used.

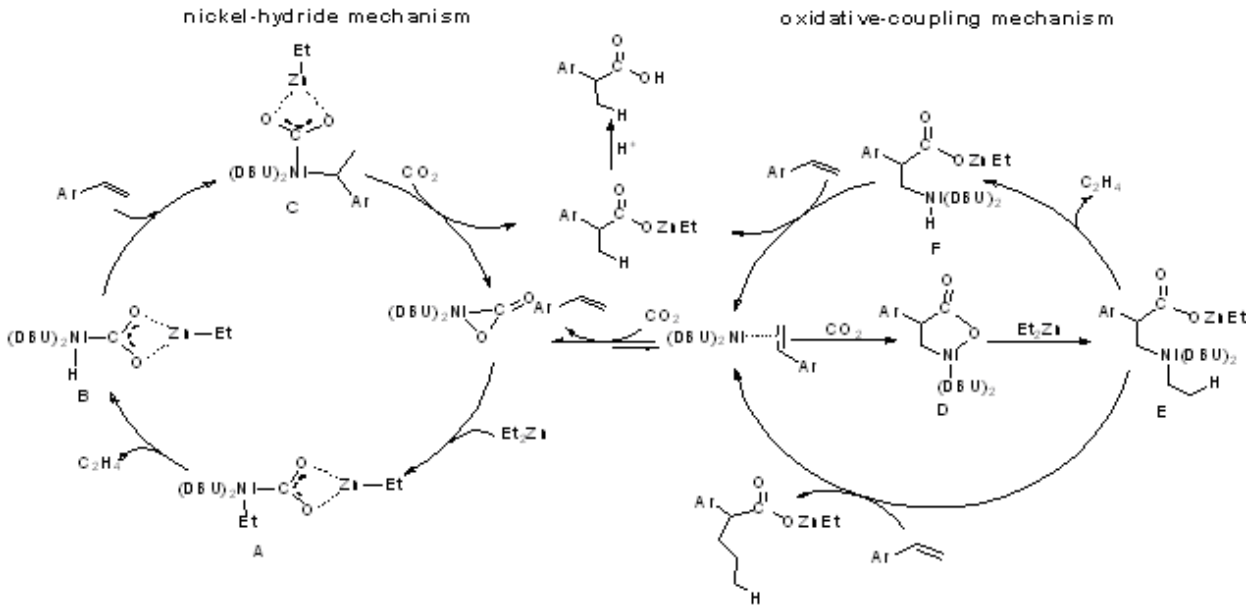
2 Experimental/methodology

Two possible mechanisms, the oxidative-coupling mechanism and the nickel-hydride mechanism, were calculated and compared.

Scheme 1 gives the detailed aspects of the oxidative-coupling and the nickel-hydride mechanisms calculated.



(1)



3 Results and discussion

Our calculation results show that in the oxidative-coupling mechanism, the metallacycle intermediates (**D**) (Scheme 1) generated from oxidative coupling between CO_2 and a styrene substrate molecule on the nickel(0) metal center corresponds to a thermodynamic sink. i.e., both the barriers for the reverse and forward steps from the intermediates are particularly high (30.3 and 33.4 kcal/mol). In other words, CO_2-styrene oxidative coupling should be avoided in order for smooth reductive carboxylation of styrenes.

In the nickel-hydride mechanism, the nickel-hydride species **B** (Scheme 1) is the active species, from which styrene insertion into the Ni-H bond followed by reductive elimination to produce α-carboxylated product. Calculations show that when the ester-substituted styrene H_2C=CHAr (Ar = C_6H_4-*p*-COOMe) is used as the substrate either of these two steps (insertion and reductive elimination) can be the rate-determining step, and both the transition states $\mathbf{TS_{6\text{-}8}}$ and $\mathbf{TS_{8\text{-}1}}$ (Figure 1) are only slightly more stable than the oxidative coupling transition state (19.8 vs 21.0 kcal/mol) leading to the thermodynamic sink. The very limited preference for the nickel hydride pathway over the oxidative coupling pathway suggests that the reaction outcome can be easily manipulated/affected by substituents on the aryl ring of a styrene substrate as well as other factor such as the pressure used in the reactions.

Consistent with the experimental observation, the calculation results show that electron-withdrawing substituents such as NO_2, CN and COOMe, promote the nickel hydride mechanism and facilitate the reductive carboxylation reactions. It was also found that high CO_2 pressure promotes the formation of the thermodynamic sink, explaining why 1 atm of CO_2 was used in the experimentally reported reactions.

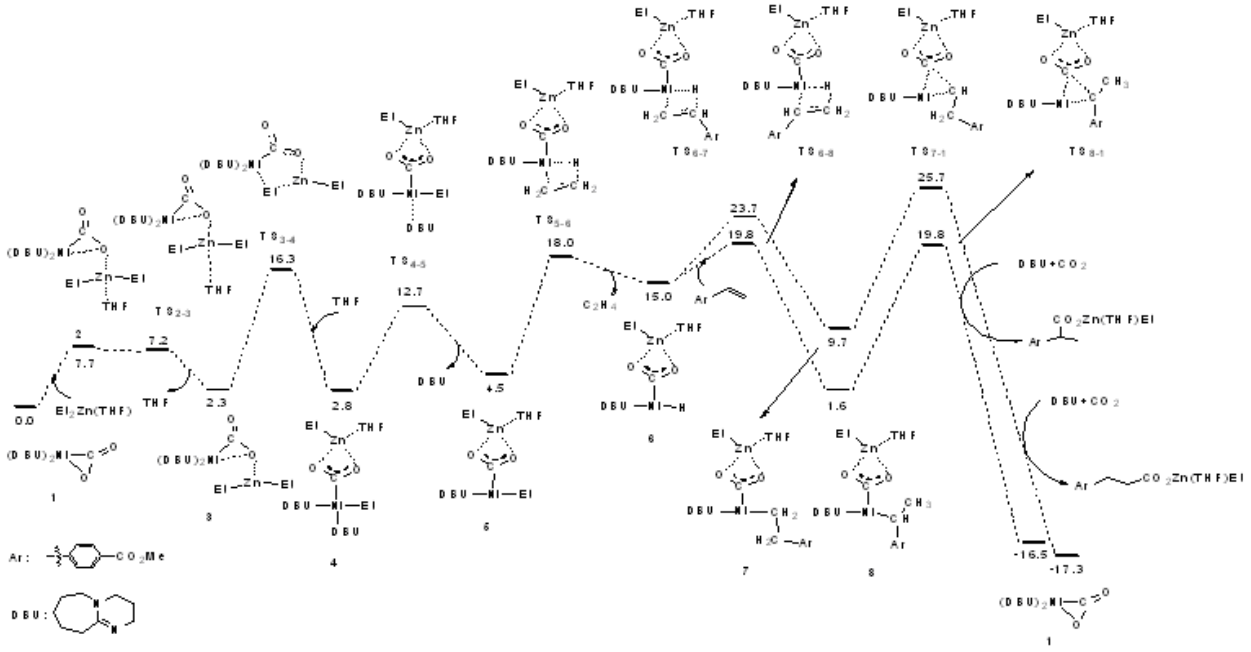


Figure 1. Free energy profiles calculated for the nickel-hydride mechanism based on the catalytic cycle shown on the left-hand side of Scheme 1. The free energies are given in kcal/mol.

4 Conclusions

In the most favorable pathway of the nickel hydride mechanism, it was also found that ligand (here DBU) dissociation and association are often involved, explaining why bidentate ligands such as COD and bipyridine are ineffective for the catalytic reactions. When Cs_2CO_3 and KHMDS were used as ligands, it was found that the oxidative coupling between alkyne and CO_2 can be effectively suppressed. However, both the Cs_2CO_3 and KHMDS ligands are not very effective ligands to promote the reductive carboxylation. All these results are consistent to the experimental observations.

Catalytic Decomposition of NF_3 Exhausted in Semiconductor Manufacturing Process over γ-Al_2O_3 Catalyst with H_2O or without H_2O

Lee J.W.[1], Lee T.H.[1], Seong Y.B.[1], Kim M.J.[1], Park C.J.[1], Choi W.Y.[1], Park N.-K.[2], Lee T.J.[1*], Chang W.C.[3], Choi H.-Y.[4]

Keywords: NF3, γ-Al2O3, hydrolysis

1 Introduction

Nitrogen fluoride (NF_3) has been widely used as plasma etching and cleaning gas in semiconductor production. NF_3 has an enormously large global warming potential of 17,000 times than that of CO_2 and long lifetime for the decomposition in atmospheric condition. Therefore, it is required to remove the wasted NF_3 by safe and low cost method. The energy consumption required for the decomposition of NF_3 by the hydrolysis or oxidation reactions with the catalytic process is relatively lower than that of the direct decomposition. Therefore, the catalytic reaction of NF_3 decomposition can be very useful for commercialization of NF_3 decomposition process.

Table 1. Experimental/methodology

It is known that solid acid catalysts have been mostly used for NF_3 decomposition. In this study, γ-Al_2O_3 catalyst was prepared in order to decompose NF_3. NF_3 and H_2O were used for reactant. This study was progressed two ways. One way is hydrolysis and other is reaction without H_2O. These catalytic activity tests were carried out at 400℃, space velocity of 15000ml/g cat·h for 35 h, respectively.

In hydrolysis of NF_3, hydrogen fluoride (HF) is produced as presented in reaction (1). HF produced by hydrolysis of PFCs over Pt/Al_2O_3[1] leads a rapid deactivation of the catalyst due to the formation of AlF_3 by interaction of Al_2O_3 with HF as presented in reaction (2). Γ-Al_2O_3 is also conversed into AlF_3 by the gas-solid reaction of NF_3 and Al_2O_3 in the absence of water according to reported paper[2].

(1) $2NF_3 + 3H_2O \rightarrow 6HF + NO + NO_2$
(2) $Al_2O_3 + 6HF \rightarrow 3H_2O + 2AlF_3$
(3) $2NF_3 + Al_2O_3 \rightarrow 2AlF_3 + NO + NO_2$

Table 1. Results and discussion

Fig. 1 shows NF_3 conversion by the catalytic hydrolysis and gas-solid reaction without H_2O. In case of reaction without H_2O, reactivity was highly maintained for 1 h of initial time, but the conversion of NF_3 gradually decreased during reaction of decomposition. After the activity test of 15 h, the conversion of NF_3 was indicated less than 20%. On the other hand, in case of hydrolysis, catalytic activity was rapidly reduced in initial time. After that the conversion of NF_3 was maintained at about 40% for 35 hours.

Fig. 2 shows XRD patterns of fresh and reacted catalysts. AlF_3 was observed in XRD pattern of reacted catalysts and the different crystal structures, which is hexagonal and orthorhombic AlF_3 structures, were confirmed by hydrolysis and gas-solid reaction.

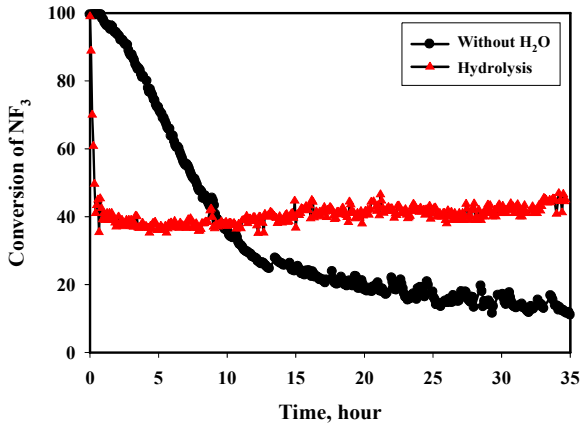

Fig. 1. Conversion of NF_3 by hydrolysis and without H_2O.

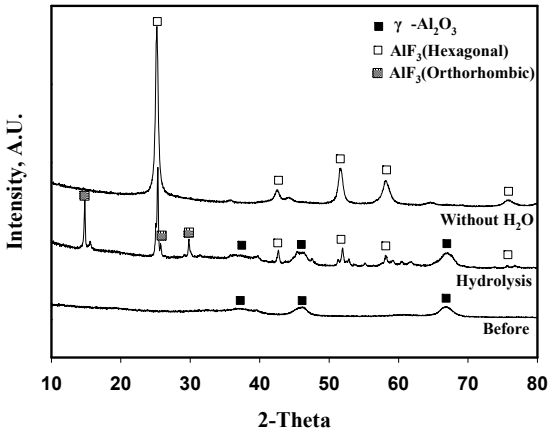

Fig. 2. XRD patterns of fresh and reacted γ-Al_2O_3 catalysts.

Catalyst	Fresh	Reacted	
		Hydrolysis	Without H_2O
Surface area(m^2/g)	205	139	21

Table 1. BET surface area of fresh and reacted catalysts

Meanwhile, the surface area of γ-Al_2O_3 catalysts decreased after hydrolysis and reaction without H_2O. The different surface area of catalyst was exhibited with hydrolysis and gas-solid reaction, as shown in Table 1.

4 Conclusions

In hydrolysis, the conversion of NF_3 rapidly decreased from 100% to 40% in 30 min after reaction start due to formation of AlF_3. The conversion of NF_3 was also kept at about 40% for 35 h after 30 min. In case of reaction without H_2O, the conversion of NF_3 was significantly reduced for 35 hours without H_2O condition because of the gas-solid reaction of NF_3 and Al_2O_3. It was confirmed by XRD analysis of fresh and reacted catalyst that Al_2O_3 was conversed into AlF_3. However, the catalytic decomposition was occurred by hydrolysis over γ-Al_2O_3. Therefore, it was concluded that catalytic hydrolysis was more effective NF_3 decomposition process than gas-solid (NF_3-Al_2O_3) reaction without H_2O in long term test.

Keywords: zeolite, fast-SCR, beta, manganese, iron, cerium

1 Introduction

Iron-containing zeolites (mostly FeZSM-5 and FeBeta) are widely used as the catalysts for selective catalytic reduction of NO_x by ammonia. Our preliminary results indicated that a favorable low-temperature performance in NH_3-SCR can be attained by additional impregnation of Fe-Beta with 8-16% Mn [1]. In this study we focused on two issues: 1) to improve additionally the performance of Mn/Fe-Beta by modification with Ce; 2) to discriminate a contribution of the zeolite component (FeBeta) to the SCR activity of Mn-Ce/zeolite catalyst.

2 Experimental/methodology

The catalytic systems based on FeBeta and HBeta zeolites were prepared by co-impregnation with $Mn(NO_3)_3$ and $Ce(NO_3)_3$ followed by drying and calcination. Catalytic activities of Mn-Ce-Fe/Beta were evaluated using gas mixture composed of 550 ppm NH_3, 520 ppm NO, 10% O_2, 6% H_2O balanced by N_2 at GHSW = 270 000 h^{-1}. Mn-Ce-Fe/Beta catalyst was characterized by H_2-TPR and XRD.

3 Results and discussion

1) Improvement of low-temperature performance by the modification with Ce

SCR activities of Mn-Ce-Fe/Beta are compared in Fig. 1(A). One can clearly see that the introduction of Ce improves low-temperature activity at 150-250°C. Introduction Ce also

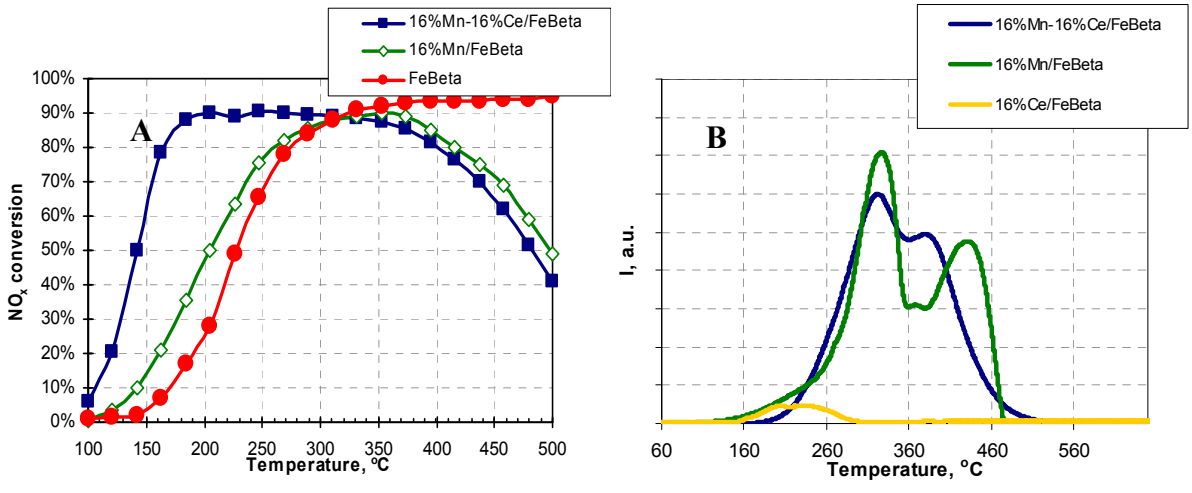

Fig 1. A) SCR activities of Mn-Ce-Fe/Beta; **B)** H_2-TPR profiles

increases oxidative activity at temperatures above 400°C, which leads to NH_3 depletion and

formation of additional NO_x.

Figure 1(B) shows Ce effect on H_2-TPR profiles of Mn-Ce-Fe/Beta catalysts. Introduction of Ce evidently decreases of the temperature of $Mn_3O_4 \rightarrow MnO$ transition. The decrease of the reduction temperature indicates that the reducibility of manganese oxides and ceria were enhanced, possibly due to the formation of solid solution, in which the mobility of the oxygen species was increased significantly. In turn, this results in the increased activity of Mn-Ce-Fe/Beta in NO oxidation (not shown).

2) Discrimination of the zeolite component contribution to the SCR activity of Mn-Ce/zeolite

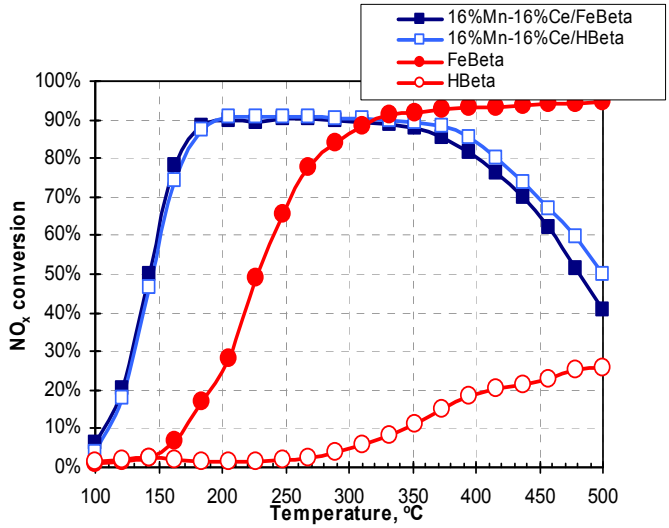

Fig.2. NO_x conversions over MnO_x-CeO_2/FeBeta and MnO_x/FeBeta

It is important to discriminate a contribution of the Standard SCR activity of FeBeta "carrier" to the overall activity of MnO_x-CeO_2/FeBeta. In order to minimize this contribution, MnO_x-CeO_2/HBeta and MnO_x/HBeta were prepared by loading Mn-Ce and Mn species over HBeta, which is essentially inactive in Standard SCR.

NO_x conversions over MnO_x-CeO_2/FeBeta and MnO_x-CeO_2/HBeta are compared in Fig. 2. It is clear, that the contribution of the Standard SCR activity of FeBeta to the overall activity of MnO_x-CeO_2/Beta catalyst is marginal. The data indicate that the bifunctional pathway evidently predominates.

All these results suggest that the observed improvement of low-temperature $DeNO_x$ over Mn-Ce-Fe/Beta stems from the SCR "bi-functional" pathway comprising two steps: (1) oxidation of NO to NO_2 over Mn-Ce oxide species followed by (**2**) fast-SCR over zeolite component [2]

$$\mathbf{2NO + O_2 \rightarrow 2NO_2} \qquad \mathbf{(1)}$$

$$\mathbf{4NH_3 + 2NO + 2NO_2 \rightarrow 4N_2 + 6H_2O} \qquad \mathbf{(2)}$$

4 Conclusions

NH_3-$DeNO_x$ activity of the Mn/Beta at 150-300°C can be significantly enhanced by additional modification with and Ce. Modification with Ce leads to enhanced oxidation activity of Mn-Ce species thus promoting "bi-functional" SCR mechanism.

Our data indicated that the "bi-functional" pathway predominates over MnO_x-CeO_2/Beta, and a contribution of the standard-SCR activity of zeolite component is negligible.

V-PP82

Increase of CO Photocatalytic Oxidation Rate on Titania under Moderate H_2O Coverages

Barsukov D.V.*, Subbotina I.R.

Zelinsky Institute of Organic Chemistry RAS, Moscow, Russia

* barsukovdenis@mail.ru

Keywords: photocatalysis, adsorbed water, TiO_2, carbon, monoxide, oxidation, oxygen, species

1 Introduction

Photocatalytic oxidation method is commonly used for removing volatile organic compounds from air, but for CO this method is usually considered as ineffective mainly due to competition for adsorption sites between H_2O and CO. This work demonstrates that the role of water is more complex than just a competitive adsorbent, and the positive influence of adsorbed water on CO oxidation rate occurs at moderate H_2O coverages.

2 Experimental/methodology

Catalytic measurements were carried out in closed glass reactor (V = 91.7 cm^3) with quartz (S_{ill} = 4.2 cm^2) and CaF_2 windows for UV-illumination and DRIFT measurements, respectively. Gas mixture of CO and O_2 (1:1, 10 torr total pressure, typically) was used for photocatalytic oxidation reactions. DRL-400 lamp was utilized as UV-light source, with 5-cm length water filter to prevent overheating. Electron impact ionization mass-spectrometer was used for gas phase measurements. TiO_2 undoped samples: Hombifine N (~300 m^2/g) and Degussa P25 (~50 m^2/g), 0.2% wt Pt-doped TiO_2 – Hombifine N and 2.5% Mo^{6+}/SiO_2 single site photocatalyst were inspected in activity tests under varied water coverages. The latter were determined by integration of broad IR band (4710-5400 cm^{-1}) with calibration by thermogravimetry.

3 Results and discussion

Conducted experiments revealed the dependence "CO photocatalytic oxidation rate — water coverage" is not monotonous for titania. Figure 1 demonstrates the effect of adsorbed water coverages on CO photocatalytic oxidation (**PCO**) rate over TiO_2. This result is in opposition of anticipations.

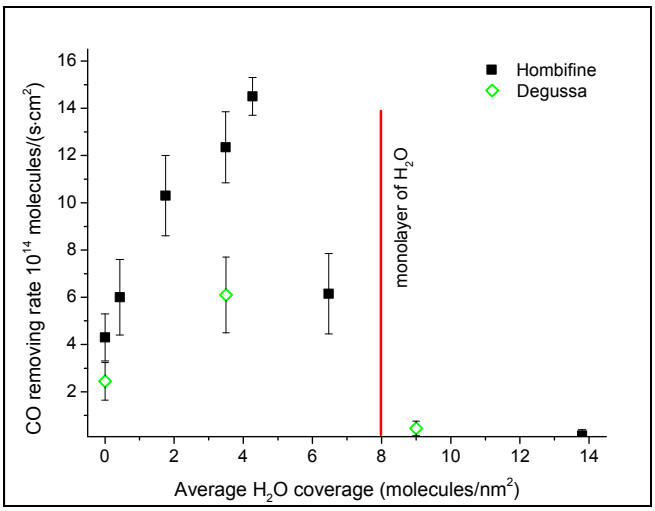

Fig. 1. Influence of water coverage on CO photocatalytic oxidation rate over TiO_2.

Vacuum treatment with strong heating (>150°C) doesn't increase oxidation activity of TiO_2, but only decreases, so the maximal activity of TiO_2 is about moderate water coverages (~4 molecule/nm^2) for both examined undoped TiO_2 samples.

It is well known that high temperature pretreatment greatly improve TiO_2 photocatalytic oxidation activity with regard to CO by generation of oxygen vacancy sites [1]. On the other hand, carbon monoxide PCO rate just decreasing in a wide range of water concentration from 0% RH at ambient temperature [2]. Thus, if H_2O acted as just competitive adsorbent then TiO_2 activity would reduce in Mo^{6+}/SiO_2 activity manner (see Table 1). The table indicates that even at relatively low surface concentration water poisons the active $2.5Mo^{6+}/SiO_2$, while TiO_2 oxidation activity significantly rises and even exceeds 0.2% Pt/TiO_2 activity.

Table 1. Catalyst activities of photocatalytic CO oxidation under degassed and partially H_2O covered surfaces.

Sample	CO removing rate, 10^{14} molecules/(s·cm^2)	
	Degassed surface	**0,5 monolayer of H_2O**
TiO_2 Hombifine N	4.3	14.5
TiO_2 Degussa P25	2.4	6.1
2.5% Mo^{6+}/SiO_2	25.4	1.4
0.2% Pt/TiO_2	6.2	6.8

In contrast of CO, many organic substances have an extremal dependence of their PCO rates on water pressure with optimal H_2O concentration at ambient temperature usually lying in 5-50% room humidity, according to a substance [3] with corresponding water coverages from 1 to 3 monolayers and more. For organic substances the positive role of water is usually assigned to preventing deactivation of active sites by generated organic intermediates. This explanation seems to be less suitable for CO because it is hardly to propose generation of stable intermediates in CO oxidation process. The more likely cause is that adsorbed water contribute to formation of active oxygen forms (O_2^{2-}, $O_2^{-}\cdot$, $HO_2\cdot$, H_2O_2 and other) from gaseous oxygen since that amount of photosorbed oxygen is enhanced in presence of adsorbed water [4].

From these materials it is easy to suggest that on TiO_2 the process of carbon monoxide photocatalytic oxidation is greatly influenced by adsorbed water and active oxygen species generated from gaseous oxygen play key role in the increase of CO photocatalytic oxidation rate.

4 Conclusions

It was found that under moderate coverages adsorbed water unexpectedly increase the rate of photocatalytic CO oxidation on TiO_2.

These results allow to suggest that for TiO_2 in presence of adsorbed water, CO oxidation mechanism is distinct from that one for fully degassed TiO_2 surface and forms of photosorbed oxygen play key role in oxidation rate enhancement.

Keywords: bimetallic catalysts, polymer-modifier catalysts, n-octane, hydrogen peroxide oxidation

1 Introduction

Recently the development of new highly efficient and selective catalysts for hydrocarbon oxidation under mild conditions is of theoretical and practical interest. Biomimetic approach to the preparation of catalysts for the above mentioned process is one of the promising directions of research [1-3]. Organic compounds, surfactants and polymers can be used as ligands in the design of metal complex catalysts.

In this paper we present the results of the development of bimetallic nickel-iron polymer-containing catalysts supported on sorbents and their use as catalysts for oxidation of n-octane by hydrogen peroxide under mild conditions.

2 Experimental/methodology

The catalysts were prepared by adsorption of $NiCl_2$ and $K_4[Fe(CN)_6]$ from water solution on inorganic sorbents such as alumina, silica-alumina, silica, zinc oxide modified with the polymer. The total percentage content of the active phase was 1% at a ratio of Ni:Fe = 1:3. Water-soluble polyhexamethylene guanidine (PHMG) was used as polymer modifier.

Oxidation of n-octane was carried out in a thermostated glass reactor in acetonitrile at 40ºC and atmospheric pressure [4]. The duration of the process was 240 minutes. The oxidant was 30% aqueous solution of hydrogen peroxide. Analysis of the reaction products was carried out by chromatography ("Crystal-2000", Russia).

The catalysts were studied by electron microscopy.

3 Results and discussion

In the beginning the developed catalysts were tested in the process of hydrogen peroxide decomposition. The maximum rate of the reaction ($6.5 \cdot 10^{-4}$ mol/s) was achieved on the 1% Co-Ni-PHMG/Al_2O_3 catalyst. Low reaction rate was observed on the catalyst supported on zinc oxide.

Chromatographic analysis of the reaction products indicates the formation of alcohols and ketones. The highest degree of conversion of the substrate is observed in the presence of 1% Co-Fe (1:3)-PHMG/Al_2O_3 catalyst. The lowest activity showed 1%Co-Fe(1:3)-PHMG /ZnO (Table 1).

Table 1. Oxidation of n-octane on 1% Co-Fe(1:3)-PHMG/support catalysts.
Reaction conditions: $[H_2O_2] = 0.31 \cdot 10^2$ mole/l, CH_3CN - 5 ml, T = 40ºC, P = 1 atm, duration - 360 min.

Catalyst	Products of reaction		Conversion, %	Selectivity,%
	ol %	one %		
1% Co-Fe(1:3)-PHMG/Al_2O_3	10.0	2.2	12.2	$S_{\Sigma ol}$ – 82.0
1% Co-Fe(1:3)-PHMG/AlSi	6.1	3.2	9.3	$S_{\Sigma ol}$ – 65.6
1% Co-Fe(1:3)-PHMG/SiO_2	4.0	2.4	6.4	$S_{\Sigma ol}$ – 62.5
1% Co-Fe(1:3)-PHMG/Al_2O_3	1.3	0.5	1.8	$S_{\Sigma ol}$ – 72.2

The developed cobalt-iron catalyst was studied by TEM. According to TEM images, the metal particles of 10 nm are evenly spread in the polymers which are fixed on the surface of Al_2O_3 (Figure 1).

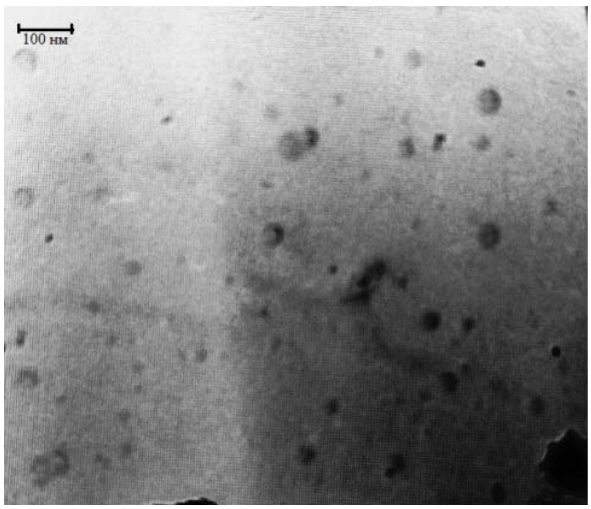

Fig. 1. TEM images of 1% Co-Fe(1:3)-PHMG/Al_2O_3

4 Conclusions

Thus, the developed heterogenized catalysts based on polymer-metal complexes fixed on inorganic sorbents are active in both decomposition of H_2O_2, and the reaction of n-octane oxidation under mild conditions. The optimum catalyst for n-octane oxidation is PHMG-containing cobalt-iron complexes supported on alumina. n-Octane conversion was 12.2%.

Keywords: oxidative desulfurization, diesel fuel, CuZnAl-O catalyst, dibenzothiophene, adsorption

1 Introduction

During the last decade the requirements to the limits of sulfur content in motor fuels have been constantly toughened. In accordance with the current emission standard EURO-V, the content of sulfur in diesel fuel should not exceed 10 ppmw [1]. The sulfur compounds become more resistant to hydrodesulfurization with increasing boiling point, as the dominant compound class changes from thiols, sulfides and thiophene in the naphtha to substituted benzothiophenic derivatives in the distillate [2]. In the vacuum gas oil and vacuum residue, the sulfur is contained mainly in compounds of the dibenzothiophene family. One of perspective methods for diesel fuels desulfurization is selective oxidation of their sulfur-containing compounds over catalysts with oxygen (ODS). During this process sulfide and heterocyclic sulfur-compound transform to sulfur dioxide, and hydrocarbon fragments are oxidized to carbon dioxide and water [1]. According to [3] CuZnAl-O catalysts can be promising for ODS. Their catalytic properties in oxidation of sulfur-containing compounds may be connected also with high affinity of some of their components – namely Cu and Zn to sulfur. The goal of this work is to study sulfur adsorption capacity of CuZnAl-O in a model (DBT-Toluene) and a straight-run diesel fuel. Catalyst textural properties, XRD and chemical composition as well as conditions of sulfur removal from spent catalyst have been studied with the aim to elucidate main correlations between stages of adsorption and oxidation of sulfur compounds of diesel fuel.

2 Experimental

CuZnAl-O catalysts were prepared by the precipitation [5]. The chemical composition of the catalysts was studied by AAS-ICP. Cu content was 45 wt.%, Zn 25 wt.%. Textural properties of the spent catalysts were studied by N_2 adsorption at 77 K, using an adsorption unit ASAP-2400. The XRD composition of catalysts was studied in HZG-4C diffractometer. Temperature-programmed reduction with hydrogen (TPR-H_2) was carried out in a flow reactor equipped with a thermal conductivity detector at 25-800^{o}C, with heating rate 10^o/min. DTA-TG-MS was studied using PG NETZSCH STA 409. Analysis of gas products was carried out in a mass spectrometer NETZSCH QMS 403C. CHNS analysis was performed by Vario MicroCube.

The catalysts were tested in the sorption process in model hydrocarbon fuel containing 0.1wt.% S as dibenzothiophene (DBT) in toluene and 1.0 wt.% S in straight-run diesel fuel. Samples were studied in a flow reactor placed in a furnace with a fluidized bed of quartz sand. A loading of the catalyst granules (0.5-1.0 mm) was 2 g. Adsorption was studied at GHSW = 3000 h^{-1}, WHSV = 6 h^{-1}, temperature was 380oC for model fuel and 470^{o}C for diesel fuel. These conditions were found optimal for ODS [6]. Liquid product was collected in the reflux condenser cooled to 5°C. Analysis of total sulfur was performed using a sulfur analyzer ASE-2. GC analysis was performed in a GC Crystal-2000M equipped with TCD and flame photometric detector.

3 Results and discussion

XRD study has shown that the fresh CuZnAl-O catalyst contains CuO and ZnO phases as well as highly dispersed spinel phase. According to TPR-H_2 results the catalyst is reduced by hydrogen in a single step at a temperature of 200-300°C, and are characterized by the fact that the H_2 uptake is slightly less than that of stoichiometric reduction of Cu(II) of the catalyst composition. Comparison with [4] allows us to conclude that Cu is in the Cu(II) state and likely located in CuO and $CuAl_2O_4$. The sorption time of sulfur compounds was about 1 and 3 hours for the model fuel and the diesel fuel, respectively. The total amount of sulfur adsorbed during this time is presented in Table (M_s^{sum}, g/g). At identical experimental conditions, the sorption capacity of the catalyst with respect to sulfur depended on the nature of sulfur compound. Taking into consideration the composition of sulfur compounds of diesel fuel, we concluded that the sorption capacity decreased with the change of sulfur-compound family from thiophene to DBT.

XRD composition of CuZnAl-O catalyst changes during experiments on sulfur sorption, the only changes observed in XRD are reduction of Cu (II) to Cu_2O and CuO. The CHNS analysis showed that the spent catalysts have sulfur and carbon accumulated on the catalyst surface (Table). According to DTA-TG-MS analysis, thiophene and its derivatives (prevailing in straight-run diesel fuel) adsorb on the catalyst surface via the mechanism of the chemical adsorption. Hence, the sulfur in spent catalysts is represented mainly by metal sulfates, which are decomposed at 700-850°C with the evolution of SO_2. At the same time, DBT and its derivatives are adsorbed via the physical adsorption mechanism. In this case, sulfur and carbon are removed from the surface simultaneously at temperature ca. 200°C as a mixture of CO_2, SO_3 and H_2O. Carbon deposits are products of the hydrocarbon condensation, they are oxidized into CO_2 and H_2O at 200-500°C.

Table. Physico-chemical properties of spent catalysts.

#	Fuel	M_s^{sum}, g/g	CHNS data, wt.%			Textural properties		
			C	H	S	S_{BET}, m^2/g	$V_\Sigma(N_2)$, cm^3/g	D_{BJH}, nm
1	DBT(0.1wt.% S)-Toluene	$0.35 \cdot 10^{-2}$	1.75	0.49	0.45	79.5	0.20	10.3
2	Diesel Fuel (1.0 wt.% S)	$1.6 \cdot 10^{-2}$	8.39	0.47	2.71	57	0.20	14.2

4 Conclusions

It has been shown that CuZnAl-O catalysts actually possess sorption capacity. The trend of an increase of the sorption capacity of sulfur at the transition from DBT derivatives to simpler sulfur containing molecules has been observed. DTA-TG-MS analysis has shown that sulfur on the catalyst surface is represented by adsorbed sulfur compounds or sulfides/polysulfides and sulfates of metals. Carbon deposits on the surface are products of the hydrocarbon condensation

Role of Electron-Acceptor Sites during Destructive Sorption of CF_2Cl_2 over MgO and VO_x/MgO Aerogels

Keywords: destructive sorption, EPR, MgO, aerogels, halocarbons

1 Introduction

Halocarbons, especially the ones containing no hydrogen atoms, are extremely stable and are believed to destroy the Earth ozone layer. Therefore, development of active destructive sorbents capable of their decomposition without harming the environment is of substantial practical interest. Particular interesting nanocrystalline mesoporous materials with high reactivity are aerogel-prepared alkaline-earth metal oxides prepared by sol–gel method followed by drying in an autoclave. This method yields samples with high specific surface areas and developed mesoporous structure due to the release of organic solvents under supercritical conditions avoiding the detrimental effect of the surface tension on the texture of the materials [1].

Small amounts of vanadium added to nanocrystalline MgO aerogels were shown to promote their activity in destructive sorption of halocarbons. This reaction is characterized by a prolonged induction period, which is considerably shortened after the vanadium addition [1, 2]. However, the origin of this induction period remained mysterious. In this study we characterized electron-donor and electron-acceptor sites [3] during the destructive sorption reaction of dichlorodifluoromethane on the surface of MgO and VO_x/MgO aerogels.

2 Experimental/methodology

VOx·MgO aerogels were prepared using an earlier reported method [1]. Mg ribbon was dissolved in methanol, diluted with toluene and slowly hydrolyzed with added dropwise distilled water. When a clear gel was prepared, vanadium (V) triisopropoxide oxide was added to the gel and mixed. The obtained mixed gel was dried in an autoclave to remove the solvents under supercritical conditions followed by calcination in air at 500°C.

In the reaction with CF_2Cl_2, the samples of nanocrystalline MgO aerogels with vanadium concentrations 0, 1, 5, 10 and 26 wt. % were studied. The sample was loaded into an ampoule used for EPR measurements and activated in 30 ml/min nitrogen flow for 1 hour. Then the reaction with CF_2Cl_2 was carried out with the following spin probe adsorption. Perylene and anthracene dissolved in toluene ($2*10^{-2}$ M) were used as spin probes for characterization of weak electron-acceptor sites. 1,3,5-Trinitrobenzene was used as the spin probe for characterization of electron-donor sites. The concentration of active sites was measured by EPR immediately after adsorption and after heating for 18 hours at 80°C.

3 Results and discussion

It was found that addition of vanadium had a catalytic effect on the interaction of nanocrystalline MgO aerogels with halocarbons, accelerating the formation of the active sites on the surface of the nanoparticles. The electron-acceptor sites on the surface of initial samples of MgO and VOx/MgO were not observed. Their concentration gradually increased during the

induction period, reaching a clearly defined maximum in the active state when the rapid topochemical destructive sorption reaction occurred. As the vanadium concentration was increased, the time for reaching the active state decreased. It was shown that even small amounts of vanadia added homogeneously as a mixed aerogel or as a separate phase had a catalytic effect on the MgO reaction with CF_2Cl_2.

A good correlation was observed between the rate of the halocarbon destructive sorption and the concentration of weak electron-acceptor sites characterized using anthracene or perylene as spin probes (Fig. 1). The concentration of electron-donor sites decreased during reaction with CF_2Cl_2 and did not correlate with reactivity. These results clearly demonstrate that weak electron-acceptor sites are accumulated on the MgO surface during the induction period of its reaction with CF_2Cl_2. Apparently such sites are somehow related to fluorine and/or chlorine atoms accumulated on the MgO surface during the induction period.

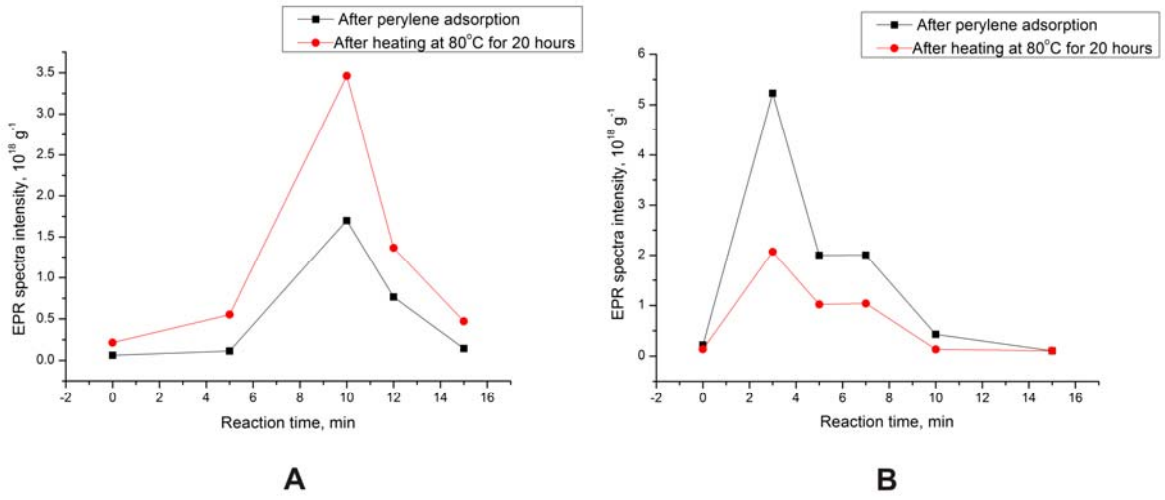

Fig. 1. Dependence of the intensities of EPR spectra observed after perylene adsorption from toluene solution on AP-MgO (A) and AP-MgO modified with 5% of vanadium (B) on time on their reaction with CF_2Cl_2.

4 Conclusions

The obtained results clearly demonstrate that surface electron-acceptor sites are formed during the induction period of reaction between nanocrystalline pure or modified MgO samples and halocarbons and account for the beginning of the fast bulk reaction. This process seems to be one of rare examples when surface active sites are shown to be responsible for a bulk solid-state reaction.

The Synergistic Effect for [RedOx + Zeolite] CombiCat in NH_3-SCR: Contributions of Different Pathways to the Overall Mechanism

Keywords: synergistic effect, Fast SCR, Standard SCR, ceria–zirconia, zeolite

1 Introduction

Recently we have shown that combined catalysts (CombiCats) with high performance in selective catalytic reduction of NO_x (SCR NO_x) can be obtained by mixing RedOx component and zeolite [1]. For [CeO_2-ZrO_2 + FeBeta] and [Mn/CeO_2-ZrO_2 + FeBeta] compositions a pronounced synergistic effect was observed and the catalytic activity of the CombiCats significantly exceeds activity of the individual components. It was suggested that the synergistic effect over CombiCats stems from the "bifunctional pathway" comprising NO oxidation over RedOx component followed by Fast SCR on FeBeta.

$$2\ NO + O_2 \leftrightarrow 2\ NO_2$$

$$NO + NO_2 + 2\ NH_3 \rightarrow 2\ N_2 + 3\ H_2O$$

The "bifunctional pathway" operates in parallel with the Standard SCR pathways over Mn/CeO_2-ZrO_2 and FeBeta.

$$2\ NO + 2\ NH_3 + ½\ O_2 \rightarrow 2\ N_2 + 3\ H_2O$$

Thus, the SCR activity of the [Mn/CeO_2-ZrO_2 + FeBeta] CombiCat is the summation of three pathways. In this study we attempted to discriminate semi-quantitatively their contributions. For this purpose NH_3-SCR activities of individual components and CombiCats were measured. CombiCats were prepared by mixing Mn-Ce/CeO_2-ZrO_2 with FeBeta (high Standard and Fast SCR activity), H-Beta (only Fast SCR activity), USY and SiO_2-Al_2O_3 (no activity in Standard and Fast SCR) in order to easily distinguish Standard SCR and "bifunctional pathway" contributions.

2 Experimental/methodology

SCR activities of composite catalysts prepared by mixing zeolites (H-Beta, FeBeta, USY, SiO_2-Al_2O_3) with Mn-Ce/$Ce_{0.75}Zr_{0.25}O_2$ (loaded with 8 wt% Mn and 8 wt% Ce by incipient wetness co-impregnation) at 1/3 volumetric ratio were measured. Feed gas composition: 500 ppm NO, 600 ppm NH_3, 10 vol% O_2 and 6 vol% H_2O balanced with N_2.

3 Results and discussion

NH_3-SCR performances of the individual components and CombiCats based on Mn-Ce/$Ce_{0.75}Zr_{0.25}O_2$ are compared in Fig. 1. Individual Mn-Ce/$Ce_{0.75}Zr_{0.25}O_2$ demonstrates a reasonable NH_3-SCR activity at 100–180°C, however at T_{react}>180°C NO_x conversion passes through a maximum and rapidly decreases. Standard SCR activities of H-Beta, USY and SiO_2-Al_2O_3 are negligible in whole temperature region, while NO_x conversion over FeBeta exceeds 60% at 500°C.

Mixing Mn-Ce/$Ce_{0.75}Zr_{0.25}O_2$ with FeBeta results in a significant change of the overall reaction pattern. Firstly, NO_x conversion is improved within 100–200°C, though at T_{react}>250°C

steep decrease in NO_x conversion is observed. Presumably, this is the result of competitive NH_3 oxidation over Mn-Ce/Ce-Zr component.

Remarkably, [Mn-Ce/Ce-Zr + FeBeta] and [Mn-Ce/Ce-Zr + H-Beta] demonstrate essentially identical performance despite very different Standard SCR activities of FeBeta and H-Beta. This observation suggests primary importance of Fast SCR activities of zeolite components which are similar [2].

When we used components inactive in Fast SCR (USY and SiO_2-Al_2O_3) performance of CombiCat is essentially identical to that of individual Mn-Ce/CeO_2-ZrO_2 and no synergistic effect is observed. A minor improvement of NO_x conversion can be attributed to marginal Fast SCR activity of USY and SiO_2-Al_2O_3, however the overall effect is incomparable with that observed for [Mn-Ce/Ce-Zr + H-Beta] composition.

Quantitative analysis of NO_x conversion data allowed us to distinguish contributions of three main pathways. At 100 – 180ºC SCR proceeds through Standard SCR on Mn-Ce/Ce-Zr and "bifunctional pathway" on [Mn-Ce/Ce-Zr + zeolite]. In the temperature range of 210 – 410ºC "bifunctional pathway" predominates. Contribution of Standard SCR activity of FeBeta is minor and becomes apparent at T_{react}>250ºC as indicated by somewhat better NO_x conversion over [Mn-Ce/Ce-Zr + FeBeta] as compared to [Mn-Ce/Ce-Zr + H-Beta].

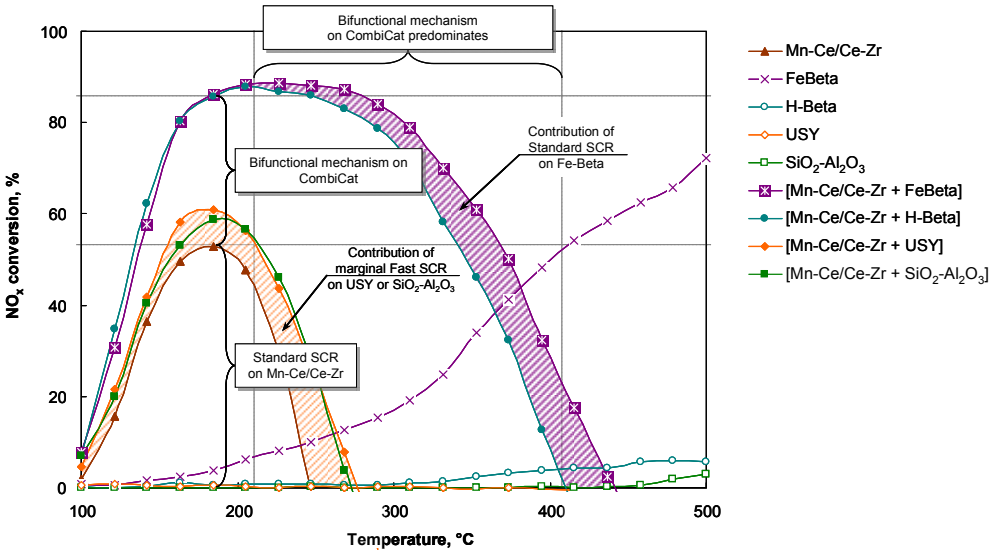

Fig. 1. NH_3-SCR activities of individual components and CombiCats.

4 Conclusions

Three different pathways in NH_3-SCR on CombiCats were discriminated. It was shown, that Fast SCR activity of zeolite component is a prerequisite of synergistic effect, while Standard SCR activity plays a minor role in the overall performance of CombiCats.

Keywords: lignin, lignosulphonate, depolymerisation, sub- and supercritical water

1 Introduction

Research in the field of processing of plant biomass is of considerable interest for developing technologies based on renewable raw materials. The main components of biomass are polysaccharides, such as cellulose, hemicellulose, and lignin. Lignin is a framework biopolymer consisting of guaiacylpropane, syringylpropane, and p-hydroxyphenylpropane structural units linked by C–O and C–C bonds. Lignocellulose materials are wastes of industry, agriculture, forestry, and household. Currently there are no technologies of complete processing of lignin-containing waste to produce useful products; instead, in some cases, extremely environmentally unfriendly processes, involving mineral acids and alkalis, are used. From this point of view, studies of the conversion of lignin in sub- and supercritical water, which could form the basis for developing energy effective and environmentally friendly processes of recycling of anthropogenic waste, in particular from the pulp and paper and hydrolysis industries, is of paramount importance.

2 Experimental

Conversion of sodium lignosulphonate (LS) is studied in sub- and supercritical water (SCW) in the temperature range 200-430°C at 220 atm and the residence times 2.5-10 min. Soluble products of the LS depolymerization are analyzed using HPLC and GC-MS. Thermogravimetric, elemental, IR and NMR spectral analyses of insoluble products of LS conversion are carried out [1] .

3 Results and discussions

The interaction of SLS with sub- and supercritical water produced a dark brown precipitate and water soluble phenolic compounds. It is shown that methoxyaril ether bonds and aromatic structures do not undergo any destruction in SCW. The formation of insoluble precipitate is related to decarboxylation and desulfonation of lignin polymeric fragments. The soluble part the conversion products of LS in SCW consists of the unreacted fragments of the LS macromolecule that retained hydrophilic S- and O-containing groups. It also includes soluble products of the depolymerization of lignin having phenylpropane fragments in their structure, such as vanillin, guaiacol, etc., and the products of secondary transformations: low molecular weight acids and aldehydes. The products of the depolymerization of LS predominantly consist of compounds containing guaiacyl aromatic structure. The chemical diversity of the products is due to transformations of only the propyl fragment of the structural unit of lignin under hydrothermal conditions.

Hydrogenolysis of C–C bonds, dehydrogenation, and oxidation provide the formation of alkyl, olefin, alcohol, aldehyde, and ketone substituents of the guaiacyl structure in the products of conversion of lignin in SCW. In addition, the depolymerization products contain phenol and 4-(propene-3)phenol. As shown above, the hydrolysis of aryl–alkyl ether bonds in the lignin

model compounds under the influence of supercritical water takes a long time (5 min). This suggests that, during treatment of LS with SCW, phenol is formed from p-hydroxyphenylpropane structural fragments. The absence of branched alkyl substituents at the aromatic nucleus in the conversion products of LS indicates that the process of depolymerization is associated with the rupture of ether bonds between structural fragments of lignosulfonate. In [2, 3], the conversion of lignin from cedar and beech wood in SCW is discussed. The authors believe that the β-O-4 (alkyl–aryl) ether bond is easily cleaved in supercritical water.

To establish how the parameters of the process (temperature, reaction time) influence the yield of monomeric products, we determined the content of vanillin, guaiacol, and phenol in the products of the conversion of LS by HPLC. During treatment of SLS in subcritical water (200–373°C), guaiacol and phenol are virtually not formed. The yield of vanillin decreases as the temperature increases from 200 to 320°C. It is known that ether bonds are hydrolyzed when catalyzed with acids. However, despite the low value of pKw, 11.0–11.5, no depolymerization of LS is observed. This is because the hydrolysis of ether bonds of lignin competes with condensation reactions. With increasing temperature and acidity of the medium, the hydrolysis speeds up, as does the condensation reactions, with the latter becoming predominant under certain conditions. Therefore, when wood is treated with concentrated mineral acids, only polysaccharides pass into a soluble state, whereas lignin is produced in the form of an insoluble residue, because the condensation reaction dominate the hydrolytic cleavage [4]. With a further increase in temperature above the critical point of water, the yield of conversion products increases by an order of magnitude. The increase in the depolymerization rate may be associated with a change in the depolymerization mechanism. In supercritical water, free radical reactions dominate over ionic reactions [5]. Another factor affecting the product yield is the reaction time. It increases from 2.5 to 10 min (410°C, 220 atm), the concentration of vanillin and guaiacol increase from 4.5 · 10–4 to 7.6 · 10–4 mol/l and from 7.4 · 10–4 to 1.8 · 10–3 mol/l, respectively. However, the yield of phenol decreases from 9.5 · 10–4 mol/l to 0, which can be attributed to the participation of phenol in the formation of new bonds between the aromatic structures.

Thus, varying the temperature and reaction time makes it possible to adjust the rate and extent of LS depolymerization. In the subcritical region, the conversion proceeds through hydrolysis. In the supercritical region, it is dominated by free radical processes.

Keywords: hydrodeoxygenation, hydrogenation, phenol, aqueous phase, catalysis, ruthenium, nafion

1 Introduction

Biomass is considered as a perspective feedstock for production of fuels and chemicals through the depletion of fossil fuels and the increasing concern over environmental protection. Biomass is exposed to pyrolysis and liquefaction with formation of bio-oil. It contains a lot of phenolic compounds together with high water concentration. Bio-oil hydrodeoxygenation is one of available process for removal of oxygenates and increasing of its value. Highly selective hydrodeoxygenation of phenolic compounds to cycloalkanes in aqueous phase has been reported using bifunctional catalysts in batch reactor [1]. For enhancing efficiency and for more convenient operation of process, it is reasonable to use flow reactors.

2 Experimental

The hydrodeoxygenation of phenol was carried out in a fixed-bed vertical flow high-pressure reactor (an inner diameter of 0.4 cm and a length of 25 cm). Phenol conversion was performed at 150–250°C and 7.5 MPa. A ruthenium catalyst supported on active carbon (Ru/C, 5 wt % Ru) was prepared by the wetness impregnation method. The catalyst volume was 0.5 cm^3 (0.21 g), and the remaining volume of the reactor was filled with quartz particles. As the acid function phosphoric acid (0.5 wt %) in an initial solution of phenol or DuPont Nafion SAC-13 (0.5 $см^3$) in the form of a mechanical mixture with Ru/C were used. Phenol conversion was studied in aqueous solution with a concentration of 1 wt % (0.106 M). A scheme of the laboratory setup and experimental details were presented in [2]. The phenol solution was supplied at a rate of 0.2 or 1.0 ml/min, keeping the ratio of phenol-to-hydrogen at 1:15 or 1:30 respectively. Liquid and gaseous products were analyzed by gas chromatography (using capillary column Thermo TR-5MS 30 m × 0.25 mm) and were identified with chromatograph–mass spectrometer system (Focus GC/DSQII, Thermo Fisher Scientific, the same column). Internal standard butanol-1 was used to determine the product concentration in aqueous phase. C_2-C_6 hydrocarbons including cyclohexane were detected only in gas phase.

3 Results and discussions

Phenol was selected as the model compound of bio-oil to investigate the hydrodeoxygenation process in aqueous solutions. The major products obtained when the aqueous phenol solution and hydrogen were passed over supported ruthenium catalyst were cyclohexanol and cyclohexane. C_2-C_6 hydrocarbons were also formed in small amount as a result of hydrocracking of cyclohexane. The formation of benzene was not detected under studied conditions. Some results of the phenol transformation on catalysts Ru/C + acid are presented in Table 1. After shift of solution acidity from neutral to acidic using H_3PO_4 (pH 2.5) the complete conversion of phenol was obtained. This was accompanied by changing in the composition of products: cyclohexanone disappeared and a yield of cyclohexane increased. The same trend was observed using a solid acid as Nafion. The reaction pathway for conversion of phenol to hydrocarbons in aqueous phase is shown in Fig. 1. The following sequence of

reactions takes place. Initially hydrogenation of phenol leads to cyclohexanone and cyclohexanol. Further the alcohol undergoes dehydration to form cyclohexene which quickly hydrogenates to cyclohexane. Also ring opening was observed with the formation of light hydrocarbons C_2-C_6.

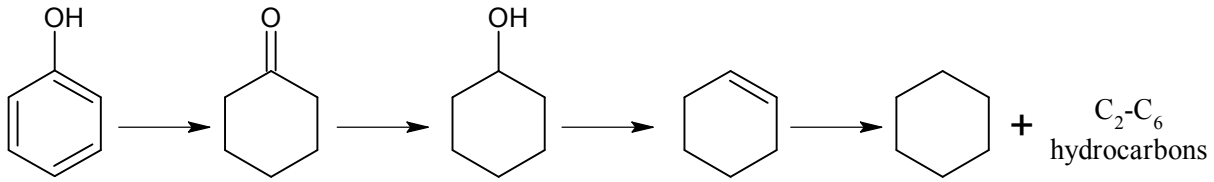

Fig. 1. Schema of aqueous phase hydrodeoxygenation of phenol on Ru/C + acid

Table 1. Aqueous phase hydrodeoxygenation of phenol

Catalyst	Feed flow-rate, g $g_{Ru/C}^{-1}$ h^{-1}	*T*, °C	Conv., %	Selectivity, %			
				Cyclo-hexanol	Cyclo-hexanone	Cyclo-hexane	C_2-C_6
Ru/C	2.9	200	93	83	5	9	3
Ru/C - H_3PO_4	2.9	200	100	76	0	19	5
Ru/C - H_3PO_4	0.6	150	100	51	0	46	3
Ru/C - H_3PO_4	0.6	250	100	0	0	34	66
Ru/C - Nafion	0.6	150	100	81	0	16	3

4 Conclusions

Phenol, a lignin monomer model compound, was converted to cyclohexane and fully hydrogenated hydrocarbons using bifunctional catalyst systems (Ru/C and acid) in a fixed-bed flow reactor. Addition acid function as mineral acid (H_3PO_4) or solid acid (Nafion) to the ruthenium catalyst leads to increasing of cyclohexane selectivity at a complete conversion of phenol. It indicates the acidity of the catalyst system is the determinative factor for cyclohexane formation from phenol in an aqueous medium.

Keywords: carbon, monoxide, xylene, spported, copper, catalysts, platinum, total, oxidation

1 Introduction

One of effective and economic ways for the removal of toxic impurities of chemical plants is their total catalytic oxidation. Supported copper catalysts are active ones in total oxidation of CO and aromatic hydrocarbons. Their activity can be increased at addition of small amounts of noble metals. Such catalysts can be more active than ones containing only noble metal [1, 2]. Kinetics of CO oxidation over Cu-catalysts can be corresponded to Langmuir-Hinshelwood [3] (when adsorbed CO and O_2 (in molecular or atom forms) interact on the surface in the slow step), or Eley-Rideal [4] (the interaction proceeds between an adsorbed molecule/particle and a molecule from gas), or Mars-van Krevelen [5, 6] (adsorbed on copper CO interacts with lattice oxygen) mechanisms. It was proposed an adsorption [7] or Mars-van Krevelen [8] mechanisms for total oxidation of xylene on oxide catalysts. This work is devoted to the study of kinetics and mechanism of separate and mutual CO and p-xylene oxidation on Cu/CeO_2 catalysts without and with Pt.

2 Experimental

Catalysts were prepared by the urea nitrates combustion method. $Ce(NO_3)_3.6H_2O$, $Cu(NO_3)_2.3H_2O$, (H_2PtCl_6 complex for Pt-catalysts) and urea $CO(NH_2)_2$ were mixed in a minimum volume of distilled water in order to obtain a transparent solution. The catalysts were investigated by TPR, XRD, TEM, BET, EDS-methods. The kinetic experiments were carried out in a gradientless flow circulating system at atmospheric pressure, the temperature range was 125-250°C. The values of initial partial pressure of carbon monoxide (P^o_{CO}), p-xylene (P^o_{xyl}), oxygen ($P^o_{O_2}$), and specially added carbon dioxide ($P^o_{CO_2}$) and vapor water ($P^o_{H_2O}$) were varied in the range: 2.5÷20; 2.1÷11.3, 35÷210, 0-25 and 0÷ 32 hPa, respectively. Transient response method was applied to study the process mechanism. Relaxation curves, describing a transition of the system to a new steady state, were obtained by a jump change of the corresponding concentrations. The installation contained 3 independent lines and was connected with mass-spectrometer. The residence time was 5 s. For all the experiments the relaxation time was lower than the turnover time. This allowed characterizing the observed relaxations as own ones.

3 Results and Discussion

A change of Cu and Pt concentrations in the limit of 5.0-10.0 and 0.05-0.3 % (wt.), respectively, showed that the optimal contents of Cu and Pt were 7.5 and 0.1%, respectively, for

CO and xylene oxidation. These catalysts are denoted as Cu/Ce and PtCu/Ce. The data of TPR showed that the presence of Pt resulted in the increase of the dispersity of Cu and its reduction degree. The rate of CO oxidation (r_{CO}) was considerably more than the rate of xylene oxidation ($r_{xyl.}$) on both catalysts. The form of kinetic equation for CO oxidation was equal on Cu/Ce and PtCu/Ce, but the values of the constants were different. Too most can tell about xylene oxidation. The following equations were obtained for separate oxidation of CO and p-xylene:

$$r_{CO} = \frac{k_{CO} P_{CO} P_{O_2}^{0.5}}{P_{O_2}^{0,5} + k_1 P_{CO_2}}, \qquad r_{xyl.} = \frac{k_{xyl.} P_{xyl.} P_{O_2}^{0.5}}{P_{O_2}^{0.5} + k_2 P_{xyl.} + k_3 P_{H_2O} + k_4 P_{CO_2}}.$$

These equations are corresponded to the proceeding the reactions in the middle surface coverage. The presence of Pt increased the values of all constants but the constants in the numerators were increased in more extent than in denominators, that's why the rates of CO and xylene oxidation were higher on PtCu/Ce. Xylene had a big influence on CO oxidation at mutual oxidation but CO little affected on xylene oxidation. The presence of small amounts of xylene (2.1 hPa) considerably decreased the rate of CO oxidation, the further increase of xylene (till 11.3 hPa) had a little influence on CO oxidation. Complex mutual influence exerted at oxidation of such different in nature substances. New intermediate compounds, which are oxidized with low rate in comparison with separate oxidation, are formed at mutual oxidation of CO and xylene. This resulted in a change of process kinetics.

Data of unstationary investigations showed that the introduction of Pt resulted in the increase of bond strength of all reaction components. Data showed that carbon monoxide and xylene as well as oxygen participated in the reaction as adsorbed species and the steps of their adsorption were quick. It was shown that at CO oxidation the amount of adsorbed O_2 was more than CO and at xylene oxidation the amount of adsorbed xylene exceeded adsorbed O_2, what agreed with stationary kinetic data. The lattice oxygen made a little contribution in the reactions. The step-schemes of CO and xylene oxidation were proposed.

Thus, obtained data showed that oxidation of CO and xylene and their mixtures proceeded on adsorption mechanism.

4 Conclusions

Active supported copper catalysts were proposed for CO and xylene oxidation, their properties, kinetics and mechanism of total oxidation of CO and xylene were studied.

Catalytic Flow Syntheses of Oligopeptides in the Glycine – Trimetaphosphate – Imidazole System

Serov N.Yu.*, Shtyrlin V.G.

Kazan Federal University, A.M. Butlerov Chemistry Institute, Kazan, Russia

* Serov.Nikita@gmail.com

Keywords: flow, chemistry, glycine, trimetaphosphate, imidazole, oligopeptides, kinetics

1 Introduction

One of the most important and unsolved problems of modern science is prebiotic peptide synthesis. Despite of numerous research efforts, the optimal conditions, kinetic parameters and mechanisms of peptide synthesis in early stages of biochemical evolution are still not established. To develop the prebiotic peptide synthesis problem the oligopeptides formation kinetics in the glycine – sodium trimetaphosphate – imidazole system in water has been investigated in flow conditions at different temperatures and pH values. It should be mentioned that trimetaphosphate has been firstly used for the peptide synthesis by Rabinowitz et al. [1] and imidazole was introduced only for the solid state oligoglycines production [2].

2 Experimental

The syntheses have been performed using Syrris ASIA-330 flow chemistry system in the following cyclic regime: after passing through the heated tube reactor reaction mixture returned to the stirred vessel where the desired pH value has been maintained with automatic titrator Metrohm Basic Titrino 794 by adding sodium hydroxide solution. Then the reaction mixture was pumped to the tube reactor again. The flow rate and temperature of the tube reactor have been strictly controlled. The kinetics of the processes has been monitored by the HPLC and NMR methods. Probes from the flow system have been automatically taken, diluted with eluent, injected into the Knauer Smartline HPLC system, and analyzed by the ion-pairing reversed-phase chromatography. For several experimental runs probes have been manually taken and diluted with D_2O. The ^{1}H and ^{31}P NMR spectra of these probes have been recorded on a Bruker Avance III 400 NMR spectrometer.

3 Results and discussion

The formation of significant amounts of glycylglycine and diglycylglycine has been established. Kinetic dependences for the oligopeptides concentrations approach plateau through 10-30 hours. Glycylglycine yields after 20 hours are 10-50 % (depends on conditions), diglycylglycine yields reach 2 %. Oligopeptides yields increase with temperature increasing from 45 to 75 °C. Final dipeptide yields at pH 9.5 and 10.5 are the same and at pH 11.5 nearly two times smaller. At the same time tripeptide yields at pH 9.5 are more than two times higher than that at pH 10.5 and at pH 11.5 only minor amounts of the tripeptide are observed. Figure 1 shows the examples of kinetic dependences for the glycylglycine and diglycylglycine concentrations at different pH values. Some dependency of the oligopeptides yields from the tube reactor residence time has been established.

The formation of the glycine N-triphosphate, cyclic glycylphosphate, and imidazole N-phosphates as intermediates in the oligopepides synthesis has been observed by the ^{1}H and ^{31}P NMR method.

Several experimental runs have been performed without imidazole for comparison. The small catalytic effect of imidazole on the dipeptide formation has been revealed. At the same

time imidazole addition has great influence on the diglycylglycine yield.

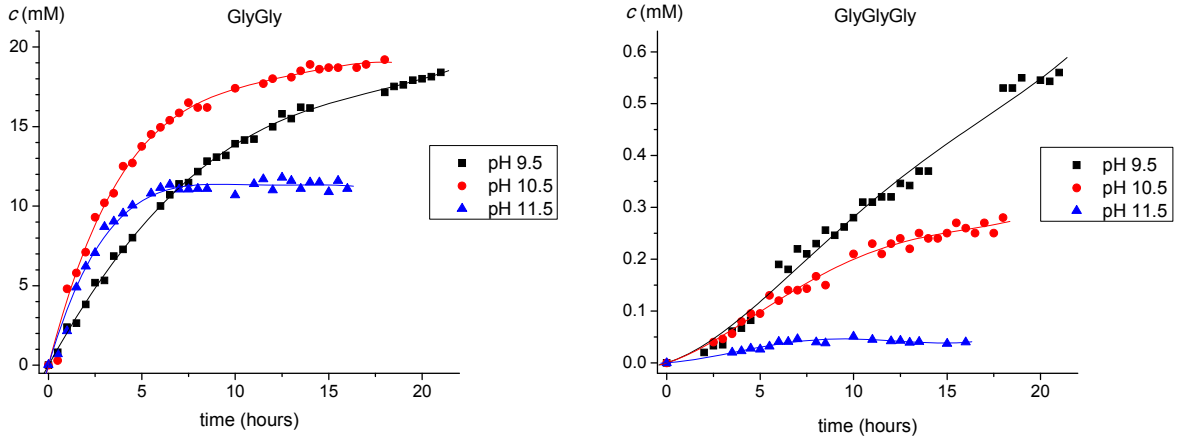

Fig. 1. Time dependences of glycylglycine and diglycylglycine concentrations for the glycine – trimetaphosphate – imidazole (1:1:1) system; all initial concentrations are equal 0.1 M; the tube reactor residence time is 1 hour; $T = 60$ °C.

Kinetic dependences obtained have been modelled with the MAT DS computer program from V.N. Govorukhin [3]. The kinetic parameters of oligopeptides formation reactions have been calculated. On the basis of the literature, experimental data, and mathematical modelling the oligoglycines formation mechanism has been proposed. For validation of this mechanism the structures of reagents, products, intermediates, and some transition states have been optimized by the GAMESS program [4] on different computation levels. The polarisable continuum model (C-PCM) [5] was used to account for solvent effects.

4 Conclusions

The oligopeptides synthesis kinetics in the glycine – sodium trimethaphosphate – imidazole system has been investigated in flow regime at different temperatures and pH values. The synthesis conditions were optimized. The reaction mechanism was proposed and grounded on the basis of quantum-chemical computation results. The system investigated may be used as a good model for peptide synthesis in prebiotic conditions.

Keywords: waste polyethylene terephthalate, glycolysis, ethylene, glycol, zinc, acetate

1 Introduction

Chemical recycling of plastic waste is mainly focused on the use of polyethylene terephthalate (PET) waste. This type of recycling is economical and environmentally safe way – depolimerization (glycolysis) of PET bis(2-hydroxyethyl)terephthalate, which can be used in resynthesis of PET. Another common method of chemical recycling of PET is directed on producing an inexpensive unsaturated polyester resin used in other areas of the chemical industry.

2 The experimental

The investigation of recycling of PET wastes by glycolysis in the presence of a catalyst - zinc acetate was carried out. Glycolysis of PET was conducted in two ways: in the temperature range of 140-180°C and with using microwave irradiation (MW). Catalyst concentration ranged from 0.125 to 1.0 wt%. The reaction was carried out until the complete decomposition of polymer. The resulting product was identified by IR spectroscopy and titrimetric by determination of hydroxyl number.

3 Results and discussion

Investigating the degradation of PET in the presence of zinc acetate (1 wt%) in the temperature range of 140-180°C showed that the increased temperature results in an increase in the conversion of PET (fig. 1).

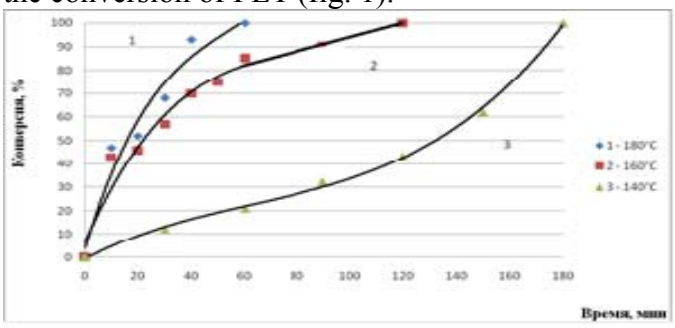

Figure 1. Conversion of PET in the presence of zinc acetate (1 wt%) in function of time for different temperatures, °C: 1 - 180; 2 - 160; 3 - 140

Investigation of dosage of catalyst (fig. 2) showed that increasing the concentration of the catalyst leads to decrease in time of destruction of polymer.

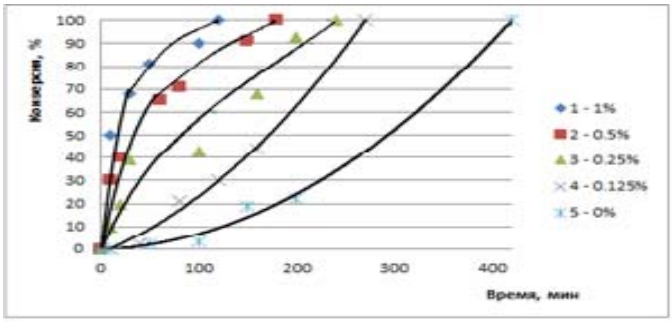

Figure 2. Conversion of PET in function of time for different catalyst concentration (at 160°C), %: 1 - 1; 2 -0.5; 3 - 0.25; 4 - 0.125; 5 - 0

A significant improvement in the quality of occurring chemical recycling of PET and the shortening of the required thermal effects can be achieved by using the energy of the electromagnetic field of MW range.

According to our results the same time of reaction (60 min.) leads to the same yield of the monomer at a different concentration of catalyst - 1.0; 0.5 and 0.25 wt% (power of MW - 450W). Therefore, an optimal concentration of catalyst is 0.25 wt%.

The resulting product was studied by IR spectroscopy (fig. 3); key functional groups are identified. The infrared spectrum of product was compared with the spectrum of bis-2-hydroxyethyl terephthalate: they are almost identical.

Figure 3. IR spectrum of product of PET degradation – bis-2-hydroxyethyl terephthalate

4 Conclusion

1. The optimum conditions of degradation of PET: temperature degradation, concentration of catalyst, the ratio of initial components were estimated.

2. It was identified by IR spectroscopy that the resulting product is a bis-2-hydroxyethyl terephthalate and it can be used as a valuable raw material for synthesis of biodegradable polymers for medical purposes.

Keywords: catalyst regeneration, supercritical, fluid extraction, cosolvent

1 Introduction

Activated aluminum oxide is used as a catalyst for the dehydration of methyl phenyl carbinol. During the dehydration reaction of methyl phenyl carbinol the carbon deposition occurs on the catalyst surface which reduces the catalyst activity [1].

2 Results and discussion

Activated aluminum oxide catalyst was regenerated at temperature of 423 K and within the pressure range 10÷30 MPa [2].

As it was mentioned above if modifiers 0.1 - 20 wt % such as methanol, ethanol etc. are added the dissolution ability of SC CO_2 is increased On this basis the impact of various co-solvents on the catalyst mass during the regeneration was studied. Chloroform, methanol, acetone and dimethylsulfoxide (DMSO) were chosen as co-solvents. Co-solvents concentration varied from 1 to 9 wt. %. The optimum value of co-solvent concentration falls within the range of 1.5–2.5%.

The analysis of catalyst mass change in the course of its regeneration using the modified SC carbon dioxide with the optimum co-solvent concentration was made at the temperature of T= 423 K and pressure P = 20 MPa (Fig. 1). . It is seen from the diagram that the regeneration efficiency with the DMSO adding has increased by 140% due to polar compounds removal.

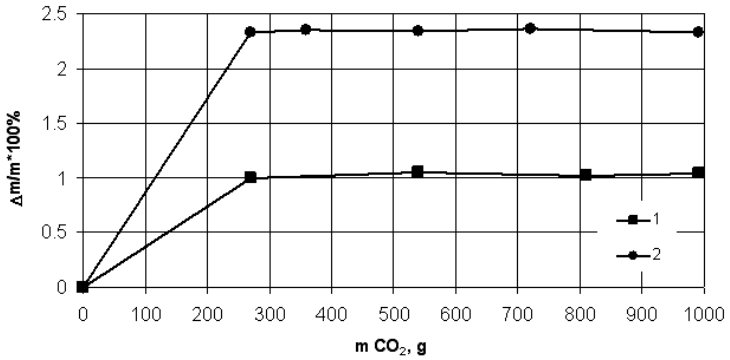

Fig. 1. Change in the mass of the catalyst in the course of its regeneration versus the mass of extractant used (modified CO_2) : 1 – SC CO_2; 2 – SC CO_2 + 2% DMSO

This data is supported by the IR spectra of the deactivating compounds for catalysts samples regenerated with pure and modified SC CO_2 (Fig. 2).

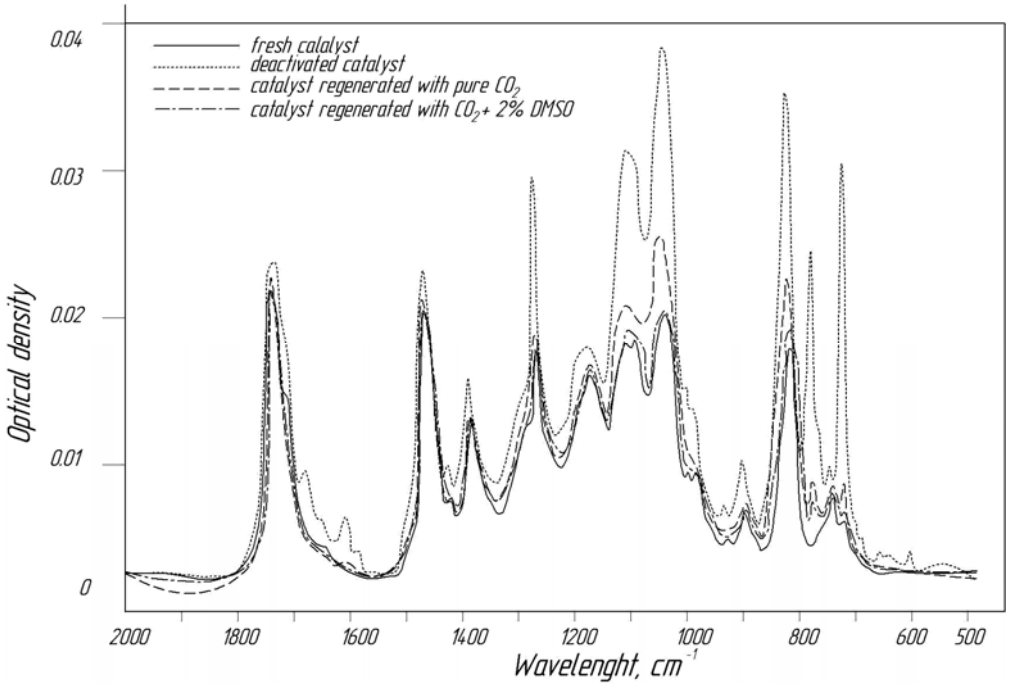

Fig. 2. The IR spectra of the deactivating compounds for catalysts samples regenerated with pure and modified SC CO_2

In this case the conversion rate of methyl phenyl carbinol (methyl phenyl carbinol conversion) and selectivity to styrene were the criteria for activated aluminum oxide catalyst activity evaluation. The results of methyl phenyl carbinol conversion and activated aluminum oxide catalyst selectivity analysis are in the Table

	Fresh catalyst	**Catalyst regenerated by air-steam mixture**	**Catalyst regenerated by pure supercritical CO_2**
MPC Conversion, %	99.80	99.69	99.77
Styrene Formation Selectivity (towards decomposed MPC), % mol.	100	86.99	93.97

4 Conclusions

Regenerated catalyst MPC conversion value, i.e. the catalyst regenerated activity, proves the SCFE method efficiency for removal of contaminants from the surface of activated alumina.

The Composite Rubberized Material with Coated Photocatalytic Layer

Salyakhova M.A.*, Pukhacheva E.N., Zaripova V.M., Uvaev V.V.

Open Joint Stock Company "Kazan Chemical Research Institute", Kazan, Russia

* milya_salyah@mail.ru

Keywords: titanium, dioxide, self-decontamination, photocatalytically, active antibacterial properties, the composite rubberized material

1 Introduction

Protective clothing made from rubberized material provides protection from toxic, corrosive chemicals and flame. Materials are used for the manufacture of protective clothing for workers in the chemical, oil and gas, metallurgical industry, working in conditions of flame action and carrying out various rescue operations. After infection by toxic chemicals protective clothing requires decontamination by special solutions, which makes certain load on the environment - pollution from wastewater.

A photocatalytic decomposition of these substances adsorbed on the surface of rubberized material is an alternative to this method of decontamination of chemical clothing.

2 Experimental

The composite rubberized protective material is developed. It comprises a fabric basis, a polymeric rubber coating and a thin film layer which contains the photocatalytically active titanium dioxide with a particle size of 10-15 nm. The photocatalytically active titanium dioxide obtained at the laboratory of the Boreskov Institute of Catalysis was used for produce the rubberized composite material. The coating of photocatalytic layer does not reduce protective properties of the rubberized material.

Figure 1 shows the micrograph of the composite rubberized material obtained by the universal digital high definition video microscope HIROX KN-7700, Japan (an increase of 140 times).

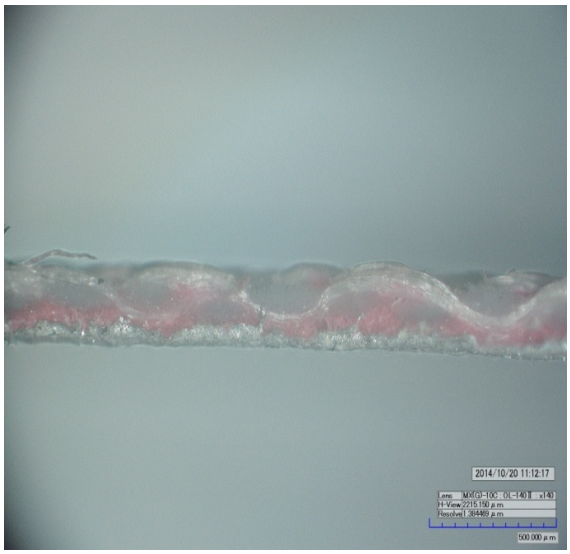

Fig. 1 The micrograph of the composite rubberized material

We have determined the photocatalytic activity of the composite rubberized material by

the oxidation reaction of methyl orange indicator at UV irradiation with falling radiation power of 10 mW/cm^2. The results of determining the degree of methyl orange indicator decomposition at UV irradiation are shown in Table 1.

Table 1 - The degree of methyl orange indicator decomposition at UV irradiation of the composite rubberized material

Specimen	Ratio Rubber: TiO2	The degree of methyl orange indicator decomposition,%
TiO_2	------	45
Material 1	1:1	27
Material 2	1:2	40
Material 3	1:3	53

3 Results and discussion

We have evaluated antibacterial properties of the material coated with titanium dioxide by the standard method, which has concluded at the study of the sensitivity of microorganisms, placed on a solid nutrient medium - agar, to the action of the photocatalyst at UV irradiation. Test culture: gram of positive spore forming bacterium Bacillus subtilis and gram of negative non spore forming bacterium Escherichia coli. The method is based on the formation of so-called zones of inhibition around the test specimen material. Tests have shown that the bacteria do not grow at UV irradiation for 3-4 hours, the growth delay zone of Bacillus subtilis culture is 3.5 cm and the growth delay zone of Escherichia coli culture is 3,5 cm (Figure 2).

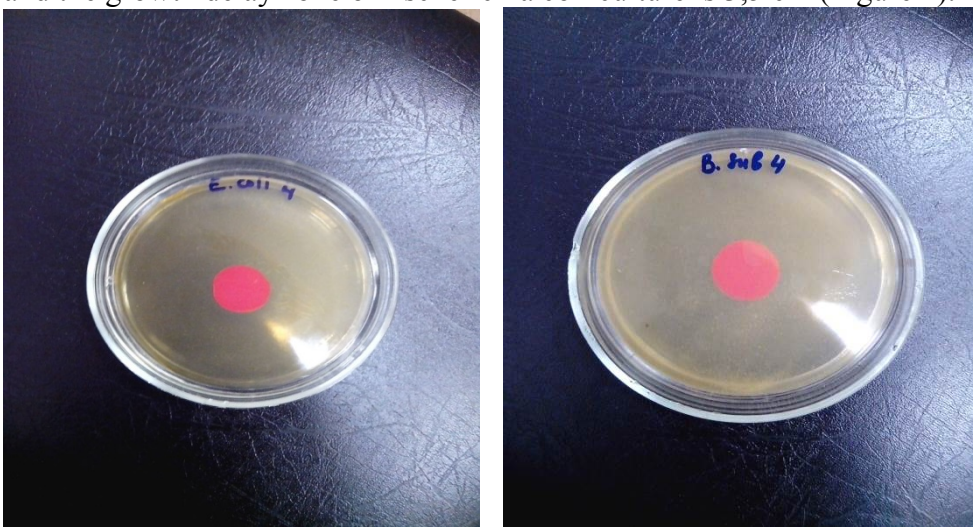

Fig. 2 - The growth delay zone of Escherichia coli culture and the growth delay zone of Bacillus subtilis culture

3 Conclusions

Using of materials with photocatalyst will allow to decontaminate the outer surface of clothing after exposure to toxic chemicals and bacteria without special decontaminating solutions by UV or sunlight irradiation, i.e. as a result of self-decontamination.

Electromagnetic Catalytic Reactor of Water Treating from Oils and Hydrocarbons

Bachurikhin A.L.[1,2*], Efendiev M.S.[1,2]

1 - Zelinsky N.D. Institute of Organic Chemistry of the Russian Academy of Science, Moscow, Russia

2 - OJSC DagNefteProduct, Makhachkala, Russia

* mesckalin@yandex.ru

Keywords: clearing of water from oil pollution, hydrocarbons, electromagnetic processing

1 Introduction

The problem of clearing of water resources from oil pollution is rather actual now. Annual total emission of mineral oil in the seas and oceans as a result of consequences of extraction and emergencies is estimated on different sources, including the National academy of sciences the USA on the average from 6 up to 8 million tons. Nevertheless, the problem of operative and effective liquidation of consequences of similar emissions is far from the decision in view of low efficiency of existing technological decisions, and including, absence high-efficiency the reactor equipment. The majority of known processes of clearing of water environments from oil pollution is based on use the methods of oxidation **[1]**, flotation **[2]**, absorbtion **[3]**, and also methods of biological clearing **[4]**. Under the total characteristics, including productivity, a degree of clearing, simplicity of technological decisions, the economic and power efficiency, the mentioned ways are conditionally suitable for the decision of similar problems.

3 Experimental

The clearing process of water environments from oil pollution and dangerous hydrocarbons aromatic and olefinic the lines, based on use is developed and tested in industrial scale as basic reactionary unit of the device of electromagnetic processing water environments. The principle of work is based on the phenomenon of acceleration microparticles association of mineral oil in conditions of interaction of an external variable magnetic field with ferromagnetic sorbent which particles have own constant magnetic field. As a result of such interaction there are intensive association processes the hydrocarbonic components being consequence of concentration in places of impacts of ferromagnetic particles of electromagnetic, thermal and mechanical energies. Further, passing through the polysorbtional layers, the integrated particles of hydrocarbons are absorbed much faster, than similar particles of smaller diameter.

Working parameters of a reactor electromagnetic association:

Initial concentration of mineral oil	—	100 ÷ 1 mg/L
Final concentration of mineral oil	—	0,5 ÷ 0,05 mg/L
Working volume of a reactor	—	30 L
Productivity on initial water	—	Up to 100 m3/h
Operating mode	—	Continuous
Working temperature	—	0 ÷ 50ºC
Working pressure	—	0 ÷ 1,0 MPa

Besides direct use of the specified installation during water treating, there are variants of her modification, allowing her use in a number of adjacent tasks of oil extracting and processing. In particular, her use is planned during preliminary processing, tars, bitumen sand, in manufacture of dyes, etc. spheres.

3 Conclusions

The general distinctive characteristics of installation:

1) High efficiency
2) Stability to a high level of pollution of communications (a rust, sand, fine stones)
3) Standardization of a design with an opportunity of fast replacement of elements (a grid, a pipe, nozzles and so forth)
4) Absence of a problem of deterioration in case of use the plastic case of a reactor

Installation has passed industrial tests in a zone of the Caspian pool: Russia, Republic Dagestan.

Optimization of Catalytic Gas-To-Liquid Technology for Better Carbon Efficiency

Ermolaev I.S.[1,2*], Ermolaev V.S.[1,2], Mordkovich V.Z.[1,2]

1 - Technological Institute for Superhard and Novel Carbon Materials, Moscow, Russia
2 - INFRA Technology, Moscow, Russia

* ermolaevis@tisnum.ru

Keywords: GTL, Fischer–Tropsch synthesis, synthesis gas, reformer, carbon efficiency

1 Introduction

The prospects of industrial application of Gas-to-Liquid technologies (GTL) depend strongly on the overall carbon efficiency of this complex combination of catalytic processes.

The gas-to-liquids (GTL) technology for liquid hydrocarbons (LHs) production on the basis of Fischer-Tropsch (FT) process includes two main catalytic stages[1]: 1. Conversion of methane into syngas (mixture of CO and H_2); and 2. Fischer-Tropsch synthesis to produce liquid hydrocarbons from the syngas.

The syngas production technology is the most capital-intensive stage, the cost of which is up to 60% of the construction costs of a GTL plant. Selection of technological solutions for the production of syngas is usually determined by the required H_2/CO molar ratio. For FT synthesis, the optimum molar ratio of H_2/CO is 2.0–2.2[2]. This ratio can be obtained using various methods of conversion of hydrocarbon gases.

A combined steam and dry reforming (SDR) as a version of steam reforming is the most common method for syngas production. The injection of carbon dioxide into the steam reformer allows controlling the H_2/CO ratio. It was shown elsewhere[3,4,5] that the efficiency of SDR-including GTL can be controlled by re-circulation technique of FT tail gases, which allows to reach high energy efficiency of GTL process. The alternative methods are represented by more recently developed autothermal reforming (ATR)[2,6,7] and partial oxidation (POX)[2,8], which are used by the most recent industrial GTL plants ORYX GTL by Sasol-Chevron and Pearl GTL by Shell, respectively.

2 Experimental

The purpose of this work is to study the effect of different methods of natural gas-to-syngas conversion with different circulation loops of FT tail gas on the GTL efficiency.

Overall process flow diagram for the GTL process is shown in figure 1, where SC – small circulation loop of tail gas; BC – big circulation loop of tail gas; SBC – stabilized blowdown circulation loop. Simulation of this flow diagram was done by using mathematical models, which allow considering all main steps of this technology.

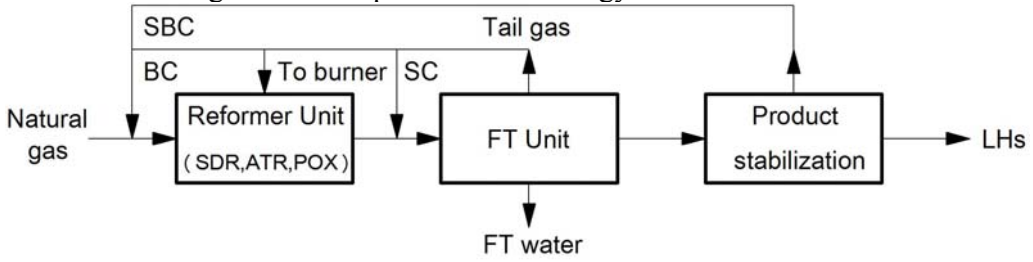

Fig. 1. Overall GTL process flow diagram for the GTL process.

3 Results and discussion

The results of simulation (Fig.2a) show that the best carbon efficiency for no-recirculation flowsheets is achieved in the case of SDR and reaches 52.15%, which is 5.25% higher than the

efficiency of ATR-based flowsheet and 6.05% higher than that of the POX-based flowsheet. However, the carbon efficiency of these processes can be significantly increased by introduction of circulation loops. As a result, the highest carbon efficiency of appr. 63% was demonstrated by the ATR-based flowsheet with combined SBC-SC loop.

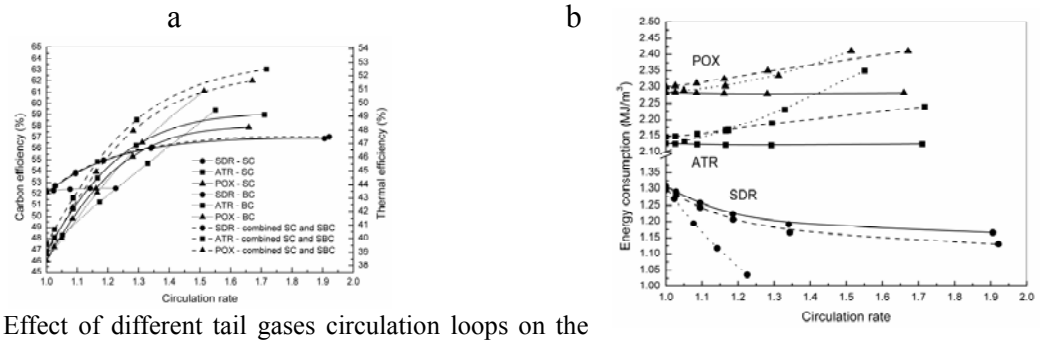

Figure 2. Effect of different tail gases circulation loops on the efficiency (a) and on the energy consumption of GTL process (b) using SDR, ATR and POX.

Application of the most obvious SC loop allows increasing efficiency of technology for all methods of syngas production. The optimum value of the SC re-circulation rate is around 1.3 for all three methods of syngas production and provides the flowsheet carbon efficiency of appr. 56 %. A further increase of the re-circulation rates beyond the optimum value does not lead to significant increase in process efficiency. The efficiency jump provided by the introduction of SC loop is more significant for ATR and POX cases. The reason is related with the main effect of the SC loop, i.e. with the decrease of circulation purge directed to burners. In the case of SDR-based flowsheet it means that the tubular furnace requires more fresh natural gas, which leads to suppression of efficiency growth.

Although the best carbon efficiency is achieved in the case of the ATR with combined SC-SBC loops, the technology choice is burdened by much higher energy expense of ATR- and POX-based processes in comparison with the SDR-based process, which consumes almost two times less energy (Fig.2b). Moreover, the introduction of circulation loops leads to even lower energy consumption values for SDR case. The ATR- and POX-based processes, in contrast, increase their energy consumption with introduction of circulation loops. So high energy consumption is determined by the use of ASU, which consumes almost half of necessary power. The POX-including GTL requires more energy than the ATR-including one just because of higher oxygen consumption and hence more powerful ASU.

4 Conclusions

The results of simulation suggest that the highest carbon efficiency can be reached with ATR- or POX-based GTL. However, it is reasonable to suggest that a better way of producing syngas in GTL technology is combined steam and dry reforming (SDR) due to much lower power consumption. The practical choice of syngas production method can be different due to factors, which lie outside the process energy efficiency, such as cost of reformers, or operating costs, or access to electricity and water, etc.

Keywords: CO_2 methanation, Ni-based catalysts, composite oxides support, metal-support, interaction

1 Introduction

Increasing emissions of carbon dioxide arising from the widespread production of energy from fossil fuels is a critical matter regarding the global warming. The hydrogenation of CO_2 into oxygenates and/or hydrocarbons have been the most investigated reactions to obtain fuels [1]. Among several hydrogenation reactions, methanation of carbon dioxide following the Sabatier reaction is the most advantageous one regarding thermodynamics. Nickel based catalysts are the most studied materials for the latter reaction, because of their high activity and low price, but metal sintering at reaction conditions diminishes their industrial viability [2]. The type of support used for heterogeneous catalysts is an important factor to consider on solving such problems. Metal-support interactions play a role on catalyst performance in terms of the active site dispersion, activity and stability of the catalysts [3]. In this work, we focused our attention on the selection of different supports for Ni-based catalysts with constant Ni content. A series of composite oxide supported Ni-based catalysts were prepared using an impregnation-precipitation method for synthesis of the composite supports and wet impregnation technique to load Ni metal. The as-synthesized catalysts were characterized using X-ray diffraction (XRD), transmission electron microscopy (TEM), N_2-adsorption-desorption isotherms, temperature programmed reduction by H_2 (H_2-TPR) and CO chemisorption.

2 Experimental

I.Commercial γ-Al_2O_3 (Sasol-Puralox SCCa-20/200) was impregnated with aqueous solutions of Zirconyl nitrate, Titanium (IV) isopropoxide and Cerium (III) nitrate hexahydrate salts in different ratios to get the desired percentages. 3 g of each composite support were taken and impregnated with an aqueous solution of Ni $(NO_3)_2.6H_2O$ with a predetermined amount of nickel to obtain a final loading of 20%Ni on the composite supports. The impregnated samples were dried in an oven at 120°C for 16 hrs and calcined at 450°C for 5 hrs. For comparison 3 g of commercial γ-Al_2O_3 was taken and impregnated with 20%Ni and treated equally with the newly synthesized supports.

II.Methanation reaction was performed at atmospheric pressure on pre-reduced catalysts in a pilot reactor with a fixed catalytic bed , 1 cm length and at space velocity of 25000 h^{-1}. 10 mg (i.e. pre mixed with an inert) of catalyst were exposed to a CO_2/H_2 (1:4 ratio) mixture in a temperature range of 300-400°C. Products were analyzed by on-line GC equipped with a TCD detector.

Catalysts were designed as 20%Ni/100% γ-Al_2O_3 = Ni/A; 20%Ni/85% γ-Al_2O_3-5% ZrO_2-5%TiO_2-5%CeO_2 = Ni/C11; 20%Ni/70% γ-Al_2O_3-10% ZrO_2-10%TiO_2-10%CeO_2 = Ni/C12 and

20%Ni/55% γ-Al_2O_3-15% ZrO_2-15%TiO_2-15%CeO_2= Ni/C13.

3 Results and discussion

The significant difference in XRD patterns (fig 1a) of the γ-Al_2O_3 support and the composite oxides confirm the successful loading of the mixed oxides (ZrO_2-TiO_2-CeO_2) in the different percentage range 5-15% for each one. It is also found that the average crystallite size of NiO, calculated from measured values using the Scherrer formula (d= kλ/Bcosθ), is increasing as the percentage of the loaded oxides increased (12 nm-16 nm).

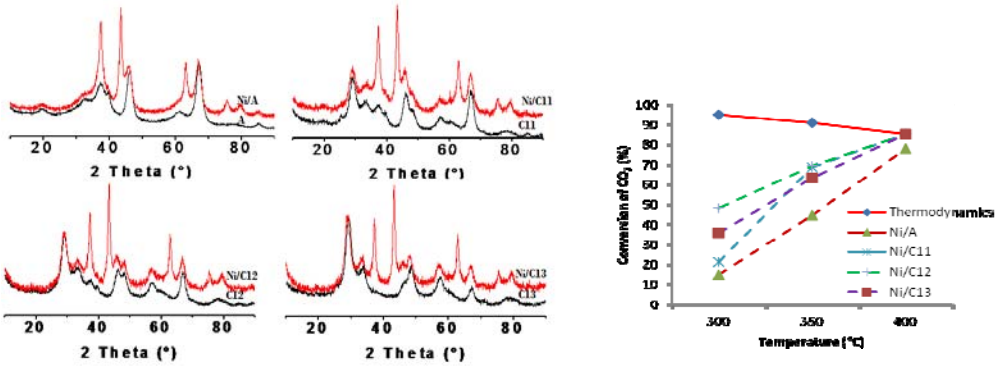

Fig. 1 (a) XRD Pattern of supports compared with the Ni/composite supported catalysts

(b) Effect of composition of the different supports on CO_2 conversion

Fig. 1b shows CO_2 conversion over supported Ni catalysts as a function of reaction temperature. CO_2 conversions gradually increased as the temperature was raised, and at 400°C reached the equilibrium represented by the continuous line in Fig. 1b calculated by taking CO_2 methanation and RWGS reactions into account. Apparently among the catalysts investigated the Ni/C12 catalyst which has 10% of each loading oxide shows better activity (69.36% conversion of CO_2 to CH_4 at 350°C). This might be mainly attributed to the fact that it is the optimum loading of the composite oxides to the conventional support (γ-Al_2O_3) which influence the metal-support interaction inhibiting the incorporation of nickel species into the lattice of γ-Al_2O_3, as confirmed by TPR profile. Furthermore, except for Ni/A and Ni/C13 catalysts no CO was detected at the reactor outlet in all temperature ranges.

4 Conclusions

Methanation of CO_2 has been studied over Ni-based quaternary system composite supported catalysts. Loading of composite oxides to γ-Al_2O_3 was found to be beneficial for the high conversion and stability of the catalysts at relatively low temperatures.

Keywords: cobalt, titanate, coprecipitation, spinel type structure, water treatement, photocatalysis

1 Introduction

Cobalt titanates are known as useful materials because of the possibility of their technical application as green pigments, catalysts or in electric devices. Three cobalt titanates are known. They are the following: cobalt methatitanate, $CoTiO_3$, having the ilmenite structure, cobalt orthotitanate, Co_2TiO_4, with inverse spinel structure, and pseudobrookite-type cobalt dititanate, $CoTi_2O_5$ [1]. Several methods were used for the preparation of cobalt titanates. The most popular is a solid-state reaction between titanium dioxide and cobalt oxide [2]. Although, this method needs high temperature, long time and small amounts of unreacted initial compounds can be expected. Therefore, the methods based on the synthesis in the solution phase, like precipitation [3], sol-gel [4], or Pechini process [5], providing suitable mixing of the reagents, have recently been studied intensively. Photocatalytic degradation processes have been widely applied as techniques of destruction of organic pollutants in waste water [6]. With an appropriate light irradiation, the photocatalyst generates electron/hole pairs with free electrons produced in the empty conduction band and leaving positive holes in the valence band. These electron/hole pairs are capable of initiating a series of chemical reactions that eventually mineralize the pollutants [7].

2 Experimental/methodology

5 ml of titanium chloride was transferred a beaker, mixed with 100 ml of distilled water (DW). 2.2 g of Cobalt chloride was transferred into a 100 ml beaker and 20 ml of DW was added to it and the contents were stirred for 5 minutes till the solution was clear. These as prepared solutions were stirred together for 30 minutes at 40°C. Then, required quantity of KOH was transferred dropwise by means of burette into the beaker containing the mixed solutions. The contents were continuously stirred after addition of KOH. After 2 hours, the content was filtered, washed with hot DW for 10 to 15 times in order to eliminate chloride ion. After sufficient washing, the precipitate was dried in air oven for 8 hours at 90°C. The dried powder was annealed at 600°C and 900°C for 2 hours in a furnace. Nitrogen adsorption isotherms allow determining the specific surface area by means of the BET method, was recorded on a Quantachrome Novawin 2. XRD patterns of the powders were recorded on Xpert-pro diffractometer, with Cu K_α radiation in the 2θ range from 5 to 90° at 3° min^{-1}. Raman spectroscopy was performed on Horiba Labram HR Evolution. Microstructural characterization was performed by scanning electron microscopy (SEM) in a Zeiss Supra mke apparatus. XPS spectra were recorded with a Thermo VG Scientific ESCALAB 250 spectrometer equipped with a monochromatic Al Kα X-ray source (1486.6 eV and 500 µm spot size). The photocatalytic activity of as prepared catalysts was evaluated by degradation of aqueous solution of methylene blue (MB) under UV light irradiation. 50 mg of catalyst was added to 50 ml of 10 mg/L aqueous

solution of MB. Before illumination, the mixture was stirred in dark for 30 min to achieve adsorption desorption equilibrium between catalyst and dye solution. The solution was exposed to UV light under stirring. At given time intervals, 5 ml of aliquots was withdrawn and centrifuged to remove catalyst. The concentration of methylene blue in aqueous solution was determined with the help of UV-Vis spectrophotometer.

3 Results and discussion

The XRD patterns of the powders calcined at different temperatures (Fig.1 (a)); showed a clear difference in the peak position between the XRD patterns of powders calcined at 600 °C and 900 °C. Pure cobalt titanate phase (Co_2TiO_4) with inverse spinel structure was obtained at 900 °C. The main lines of Co_2TiO_4 (JCPDS PDF 39-1410) were clearly identified. The patterns also indicate that higher calcinations temperatures promote an increase in crystallite size. The values of crystallite size are listed in table 1. The XPS samples surveys (Fig.1 (b)) indicate that cobalt, titanium and oxygen are the major components on the surface of theses powders.

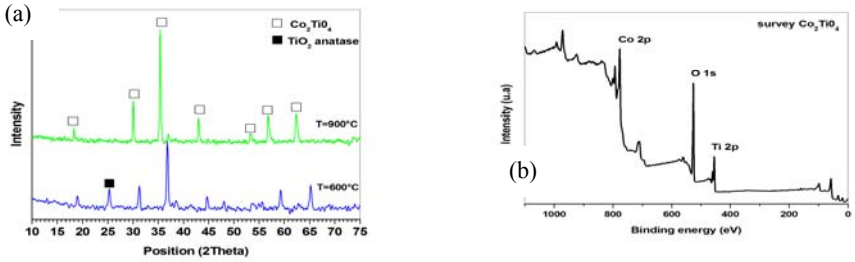

Fig.1. (a) XRD patterns of powder obtained at 600 °C and 900 °C. (b) XPS survey of powder calcined at 900°C.

Table 1. The phase, crystallites grain sizes and surface BET of coprecipited samples.

Catalysts	Phase	Phase (%)	Cs (nm) XRD	S_{BET} (m^2/g)	Lattice parameter (Å)
600°C	TiO_2 Co_3O_4	10 90	29 36	67	a=b= 4.975; c= 2.95 a=b=c= 8.088
900°C	Co_2TiO_4	100	42	10	a=b=c= 8.412

Laser Raman spectroscopy results showed five Raman active modes for the catalyst calcined at 900°C, which is an indication of the formation of an inverse spinel structure. FTIR results showed for the catalyst calcined at 600°C, two strong absorption bands located at 661 and 564 cm^{-1} which is an indication of the formation of Co_3O_4 with a spinel structure. Photocatalytic experiments showed that the concentration of MB did not obviously decrease in the presence of catalyst calcined at 900°C when the suspension was irradiated with UV radiation at wavelength λ = 365 nm. We reach 15 % of degradation after 3 hours of irradiation. But 40 % of degradation was obtained with catalyst calcined at 600°C after 4 hours of irradiation.

4 Conclusion

In this work, a study has been carried out on photocatalytic behavior of cobalt titanate nanoparticles toward a cationic dye such as methylene blue. The obtained results showed a better activity of a mixed phase obtained at 600°C during a period of 3 hours under UV exposure.

Keywords: CO_2 hydrogenation, C_2-C_4 olefins, iron, glycolate, complexes, Fe_3O_4, α-Fe_2O_3

1 Introduction

Lower olefins (C_2-C_4) are the key building blocks of the chemical industry with the largest production volume. These hydrocarbons are traditionally produced by steam cracking of naphtha. However, the strategic determination of several countries to decrease their dependence on imported crude oil, the progressive depletion of known oil sources, and the pressing necessity to minimize the carbon footprint have directed the research efforts into the identification of alternative feedstocks and processes to produce these species. The synthesis of lower olefins from synthesis gas (either directly or via methanol) or via dehydrogenation of lower paraffins have been largely investigated in the last decades. An alternative and sustainable option gaining interests in the latter years is the synthesis of lower olefins through the catalytic hydrogenation of CO_2. To date, however, only a little is known on this process. Potassium promoted iron based catalysts have been reported to be promising for the CO_2 hydrogenation to light hydrocarbons [1]. In fact, even at temperatures higher than 300°C, required to drive the product selectivity towards shorter hydrocarbons chains, iron catalysts have a methanation activity and a secondary olefins hydrogenation activity lower than cobalt [1,2]. It has been shown that the conversion of iron oxide precursor to iron carbide is crucial to achieve high olefins selectivity [3].

In this work, a Fe-based catalyst with high surface area and a spinel structure, easy to be carburized, has been prepared. The catalyst has been tested in the CO_2 hydrogenation and its performance have been compared to those of K-promoted reference model catalysts.

2 Experimental/methodology

Fe-catalysts were prepared by taking the cue from the procedure reported in [3]. Briefly, a $Fe(NO_3)_3$ aqueous solution was mixed at RT with an glycolic acid solution by using a molar ratio glycolic acid/Fe of 1.073. The resulting solution was dried in a rotary evaporator at 60°C for 3 h and then in static air at 45°C overnight. The obtained precursor was calcined at 350°C. Different calcination times (15, 30 and 60 min) were explored in order to identify the best conditions to obtain an iron oxide with a spinel structure and a high surface area. The calcined precursor was subsequently promoted with potassium (K/Fe = 0.02 molar ratio).

Other two catalysts were prepared for comparison purposes by K-IWI of reference model samples of commercial α-Fe_2O_3 (4.6 m^2/g) and Fe_3O_4 (5.2 m^2/g) powders. The obtained samples were named "K-Fe_2O_3" and "K-Fe_3O_4", respectively. All the catalysts were characterized by N_2 adsorption-desorption, X-ray diffraction and H_2 temperature programmed reduction.

Activity tests were carried out in a lab-scale fixed bed reactor operating 24/7. The catalysts were activated in syngas (H_2/CO = 1) at 0 barg for 1h at 300°C. Then the catalysts were tested at 300°C, 5 barg, H_2/CO_2 inlet molar ratio of 3.41 L(STP)/h/m_{cat}^2.

3 Results and discussion

We found that the thermal treatment has a dramatic effect on the morphological proprieties and on the crystal structure of the catalyst. Indeed, the surface area decreases from 66 to 23 m^2/g by increasing the calcination time from 15 min to 60 min, and at the same time the spinel structure (isostructural to Fe_3O_4) is progressively transformed to a corundum-type (isostructural to α-Fe_2O_3). According to our understanding, during the thermal decomposition of the iron glycolate complexes formed from the interaction of the iron salt and the glycolic acid, CO is released so that some Fe(III) is reduced to Fe(II) and the spinel Fe_3O_4 is formed. When the phenomena is complete, the presence of atmospheric O_2 results in the re-oxidation of lower metal valence Fe(II) to the high valences states Fe (III) so that only α-Fe_2O_3 structure is obtained at calcination of 30 or 60 minutes.

The obtained catalyst with the highest surface area and the greatest content of Fe_3O_4 (namely K-Fe15) was tested in CO_2 hydrogenation. In the first 20 h on stream the activity and the selectivity of the catalyst changed from a dominant RWGS regime to a system where both RWGS and the synthesis of hydrocarbons from CO take place. This transient is due to a catalyst reconstruction which involves the transition from Fe_3O_4 to α-Fe and FeC_x. At steady state conditions, measure CO_2 conversion was 45%, while the C_2-C_4 olefins carbon selectivity achieved 40% (Fig. 1). On the opposite, the reference materials, tested at the same flow rate per unit of catalytic surface (41 L(STP)/h/m^2_{cat}), were both characterized by lower activity and light olefins selectivity. We explain this result by considering that the smallest crystallites size and the spinel structure of the home-made sample improve the reducibility and the formation of well dispersed active iron carbide centres.

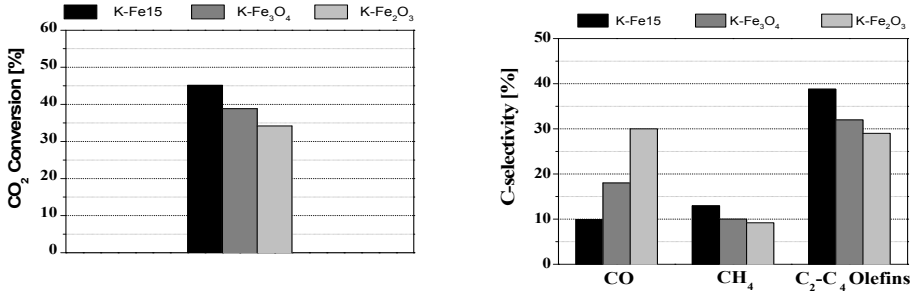

Fig. 1. (left) CO_2 conversion and (right) C-selectivity for K-Fe15, K-Fe_3O_4 and K-Fe_2O_3 (T = 300°C, P = 5 barg, H_2/CO_2 = 3 and GHSV = 41 L(STP)/h/m^2_{cat})

The effect of the process conditions on the CO_2 conversion and on the process selectivity has been also investigated, and the results will be shown during the presentation.

4 Conclusions

A K-promoted bulk iron catalyst with high surface area (66 m^2/g) was prepared by thermal decomposition of iron glycolate complexes. The catalyst was found to be active in the CO_2 hydrogenation, with the C_2-C_4 olefins being the most abundant species in the products pool.

The Analysis of Carbon Dioxide Reforming of Methane (CDRM) Performance of Co-Ce/ZrO_2 System

Paksoy A.I., Aksoylu A.E.*

Bogazici University, Department of Chemical Engineering, Istanbul, Turkey

* aksoylu@boun.edu.tr

Keywords: methane dry reforming, carbon dioxide, utilization, catalytic hydrogen, production

1 Introduction

Carbon dioxide reforming of methane (CDRM), a catalytic process where CO_2 and CH_4 are utilized to produce synthesis gas, has received considerable attention lately. Compared to other routes of indirect utilization of CH_4, such as steam reforming and partial oxidation, the most important advantage of CDRM is the consumption of thermodynamically stable greenhouse gas CO_2. Moreover, the low H_2/CO ratio obtained in CDRM is preferable for further processes like Fischer-Tropsch synthesis. However, due to the endothermic nature of the reaction, high temperatures are required which results in coking and/or metal sintering. Co is an adequate choice as a primary metal with its stable performance, abundance and relatively low cost. A suitable metal(s)-support combination in CDRM can provide resistance to both coke deposition and sintering. Carbon accumulation in CDRM can be controlled by using a support like ZrO_2 which enhances the dissociative adsorption of CO_2 producing CO and surface O, where the latter being responsible for the cleaning of carbon formed from the H_2 producing sites. Additionally, the anti-coking property of the CDRM catalysts can be improved by introducing a second metal, like Ce, that can increase the oxygen storage capacity owing to its redox ability. [1]

The aim of this study is to establish a link between Co:Ce loading ratio and CDRM performance of the catalyst, and to confirm the roles of Co, Ce and ZrO_2 in Co-Ce/ZrO_2 system. The favorable combination(s) of catalyst and reaction condition for stable performance were investigated through following an experimental design involving the Co and Ce loadings, reaction temperature and CH_4/CO_2 feed ratio as parameters. The activity, stability and selectivity profiles of Co-Ce/ZrO_2 catalysts with different Co and Ce loadings were obtained and analyzed. XPS, SEM-EDX and HRTEM-EDX techniques were utilized for further discussion.

2 Experimental

Catalysts with 4 different Co:Ce ratios, 5%Co-2%Ce/ZrO_2, 5%Co-3%Ce/ZrO_2, 10%Co-2%Ce/ZrO_2 and 10%Co-3%Ce/ZrO_2, were prepared by sequential impregnation method. Calcination *in situ* in dry air for 4 h at 773 K and a subsequent reduction *in situ* in H_2 for 2 h at the same temperature were conducted as a pretreatment. The CDRM performance tests were conducted in a quartz microreactor at the space velocity of 20000 mL/h.g catalyst for the temperature interval of 873-973 K and CH_4/CO_2 feed ratios of 1/1, 2/1 and 1/2. All freshly reduced and selected spent samples were characterized by XPS, SEM-EDX and HRTEM-EDX.

3 Results and discussion

The performance of the catalysts is discussed in terms of CH_4 and CO_2 conversion and activity, and H_2 yield. H_2/CO product ratio is used as the measure of selectivity. For all tested catalysts, higher reaction temperatures were found beneficial for both activity and selectivity (Figure 1). However, the activity order of catalysts changes with temperature, which most probably results from the different dynamics of carbon and oxygen forming reactions. The

Co:Ce loading ratio of the samples affects the mechanisms of both processes and changes their relative extent.

For the catalysts with 10% Co loading, high activity losses and more tendency towards H_2 formation were observed indicating the dominant role of Co in CH_4 dehydrogenation. Coke accumulation observed over the catalysts that have high Co:Ce loading ratios indirectly showed that Ce and ZrO_2 are responsible for surface oxygen production and/or transfer; relatively low amount of Ce, ZrO_2 or the combination of both leads to limited surface oxygen and consequently, insufficient carbon removal. This relation was also confirmed by the comparative evaluation of electromicroscopic analysis of freshly reduced and spent samples. It was also noticed that CO_2 conversion profile is more stable than that of CH_4, highlighting the difference between the rates of CO_2 dissociation and CH_4 dehydrogenation. At all tested temperatures, increasing CH_4 source in the feed caused all catalysts to suffer from coke deposition most probably due to higher carbon accumulation rate compared to rate of surface oxygen production. The performance test results indicated that decreasing the CH_4/CO_2 ratio in the feed enhanced the stabilizing effect of Ce in CDRM activity (Figure 1). The changes in Ce^{+3}/Ce^{+4} ratio on freshly reduced and spent catalysts with different Co:Ce loading ratio, measured by XPS, confirmed this effect.

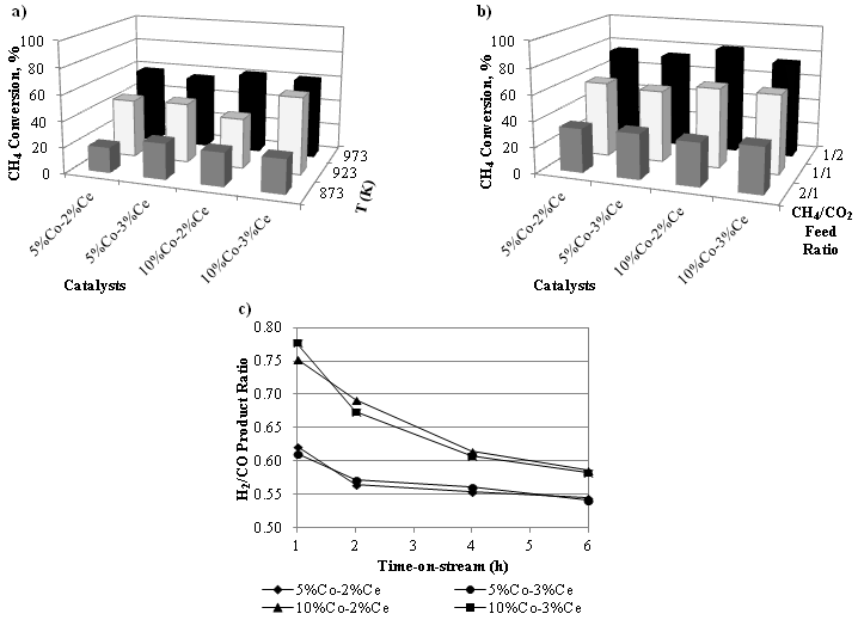

Fig. 1. Activity and selectivity trends of tested catalysts (a) CH_4 conversion (CH_4/CO_2=1/1); (b) CH_4 conversion (T=973 K); (c) H_2/CO product ratio (T=873 K; CH_4/CO_2=2/1).

4 Conclusions

This parametric study concluded that cobalt is dominantly responsible for CH_4 dehydrogenation, which is mostly favored at high temperatures, and both Co loading and Co:Ce loading ratio change product distribution. Ceria limits coke deposition by enhancing surface oxygen transfer, and its activity is limited by the CO_2 concentration in the feed.

Keywords: chemical fixation of carbon dioxide, polyhedral oligomeric silsesquioxane (POSS), ionic liquids, catalysis

1 Introduction

Development of green processes based on chemical fixation of carbon dioxide has attracted the attention in industrial chemistry due to the possibility to transform a waste, such as CO2, into useful products.1 CO2 gas is produced in large amounts from fuel combustion and represents an easy available, inexpensive and abundant carbon source. However, due to its thermodynamic and kinetic stability, its conversion is difficult to achieve and an efficient catalyst is required.2 Cyclic carbonates, synthetized through the reaction between CO2 and epoxides, are interesting compounds that can be used for several applications, such as electrolytes for lithium batteries, polar aprotic solvents, intermediates for organic synthesis and precursor for pharmaceuticals. Various homogeneous and heterogeneous processes have been proposed for this reaction. Recently, ionic liquids have emerged as a novel class of organocatalysts. In particular, imidazolium-based ionic liquids have become very attractive because they are one of the most efficient catalysts for CO2 fixation to produce cyclic carbonate from epoxydes.3

Here the synthesis and applications of a novel class of imidazolium catalyst based on the functionalization of polyhedral oligomeric silsesquioxane (POSS) is presented. The POSS have been functionalized with imidazolium units to obtain an imidazolium-based POSS (POSS-mim-Cl, fig. 1 left). This new material was employed for the reaction of CO2 and epoxides in homogeneous conditions with excellent results. In addition, it was easily recovered from the reaction mixture. To the best of our knowledge, the application of these materials for the fixation of CO2 is a domain still unexplored.

2 Experimental/methodology

The synthesis of POSS-mim-Cl was carried out by means of a synthetic strategy divided in two steps: the first step employed a commercially available octa-vinyl POSS which was reacted with chloropropanethiol, through a thiol-ene reaction. Once the product (POSS-Cl) was obtained, the following step was its functionalization with an excess of 1-methylimidazole to obtain POSS-mim-Cl. The material was extensively characterized by ^{1}H, ^{13}C and ^{29}Si-NMR, and elemental analysis. In order to explore its catalytic activity, styrene oxide was selected as model compound for the chemical fixation of CO_2. In addition, different parameters (solvent, temperature, pressure of CO_2, and mass of the catalyst) were modified to find the best condition for CO_2 fixation.

3 Results and discussion

The POSS-mim-Cl was obtained with high yield. ^{1}H and ^{13}C NMR spectra confirm the

structure of the catalyst and elemental analysis shows a high degree of functionalization. ^{29}Si NMR spectrum displays different signals suggesting the presence of the hepta imidazolium-based POSS. The chemical fixation of CO_2 was performed using styrene oxide as starting material and varying different parameters such of pressure of CO_2, temperature, amount of catalyst and solvent. The catalytic tests were carried out in a batch reactor for 3 h, in homogeneous conditions. The POSS-mim-Cl displayed good catalytic performances. When using water as co-solvent, the material showed good conversion (70 %) and TON (410) with a CO_2 of 40 bar, at 150°C and using 110 mg of catalyst. However, the presence of water decreased the selectivity due to the formation of the styrene glycol as by-product. In order to increase the selectivity, other solvents were also tested. The best results were obtained when using isopropanol. Under these conditions almost quantitative conversion and selectivity > 90% were obtained (TON of 553, fig. 1 right).

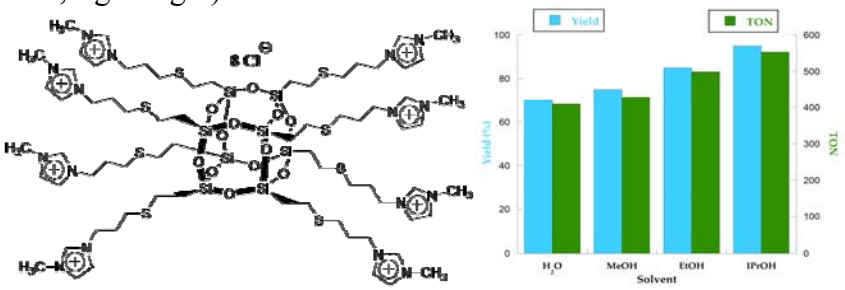

Fig. 1. Structure of the catalyst POSS-mim-Cl (left); Yield and TON of the fixation of CO_2, varying co-solvent at 40 bar, 150°C, using 110 mg of catalyst for 3 h (right).

Additional tests were performed in anhydrous solvents and excellent results in term of both yield and selectivity (> 99 %) were obtained. In order to study the influence of the nano-cage, 1-butyl-3-methyl imidazolium chloride (bmimCl) was also tested as catalyst in the same conditions than POSS-mim-Cl. It is worth to mention that POSS-mim-Cl displayed better performance (TON = 429) than the bmim-Cl (TON = 328). POSS-mim-Cl was also recovered by extraction from the reaction mixture, and its structure was confirmed by ^{1}H and ^{29}Si NMR spectroscopy.

4 Conclusions

A novel class of imidazolium based catalyst was prepared and tested for the reaction of CO_2 with epoxides. The POSS-mim-Cl displayed excellent catalytic performance, especially if anhydrous ethanol was used as co-solvent. The results were compared with those obtained with bmimCl, proving that the nano-cage (POSS) plays a positive role in the reaction probably due to the proximity effect.[4] As far as we know this is the first use of imidazolium-based POSS as catalysts for the chemical fixation of CO_2.

Keywords: environmental TEM, high resolution TEM, ceria, CO_2/O_2, adsorption, surface termination

1 Introduction

Studying functional materials under (quasi) realistic conditions (variable P and T, liquid environment) within the microscope has been a constant concern for scientists since the early days of electron microscopy [1,2]. The advent of Cs-corrected transmission electron microscopes has brought a new impulse to environmental transmission electron microscopy (ETEM) studies [3]. This is particularly true in the field of catalysis in which high resolution imaging of the catalyst surface is required to assess structural/chemical evolutions in presence of controlled gaseous environments. Here we present a study on the adsorption of both O_2 and CO_2 on ceria nanoparticles (NPs) at room temperature. These preliminary steps are part of a global approach aimed at gaining fundamental insights at reactions used for the valorization of CO_2 and the related global warming issues.

2 Experimental/methodology

The studies were performed in the Ly-EtTEM (Lyon Environmental and tomographic Transmission Electron Microscope), a 80-300 kV TITAN objective lens C_s-corrected Environmental TEM from FEI equipped with a GATAN high resolution Imaging Filter (GIF) recently installed in Lyon. The analysis was carried out at room temperature varying the gas pressures from 10^{-6} mbar (vacuum) up to 2 mbar.

3 Results and discussion

It is well-known that under vacuum conditions the incident electron beam induces a partial reduction of ceria [4]. As a consequence cerium surface atoms become highly mobile as it can be readily observed on {100} facets and electron energy-loss spectroscopy (EELS) shows that the characteristic features related with Ce^{4+} species rapidly decrease in intensity both on the O-K and Ce-$M_{4,5}$ edges.

In the presence of dioxygen (O_2 pressure in the mbar range) this beam-induced reduction is "healed" and the surface of ceria NPs is stabilized as it can be confirmed by the absence of mobility of surface cerium atoms on {100} facets as well as by the *in situ* real-time dynamic monitoring of the O-K and C-$M_{4,5}$ edges by EELS that now remain unaltered under irradiation.
Finally, under CO_2 pressure (10^{-2} - 1 mbar), the {100} facets become more stable from both structural and chemical points of view. We notice that the surface terminations of the ceria nanoparticles under vacuum are different from those observed under CO_2. Under vacuum the terminal contrasts observed are strong and clearly correspond to the formation of a terminal cerium plane (Fig.1 left). A different contrast can be noted in the case of the sample exposed to

CO_2 (Fig.1 right) hinting at the presence of stabilized species at the position of oxygen atoms at the surface termination. The stabilization of surface oxygen atoms is likely related to CO_2 adsorption and the formation of carbonate species, as observed by FT-IR spectroscopy under similar temperature and pressure conditions.

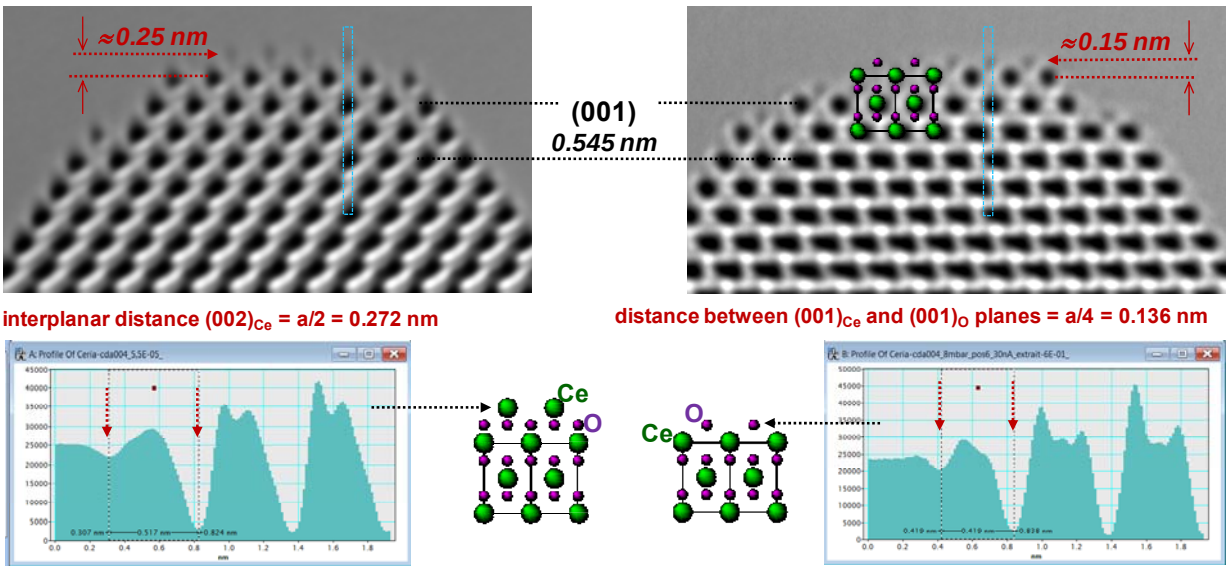

Fig. 1. HRTEM images (top, video frames averaged) and cross-sections of surface contrasts with proposed models (bottom) of CeO_2[110] under vacuum (left) and under 0.8 mbar of CO_2 (right).

4 Conclusions

This high spatial resolution study (structural/chemical) of ceria nanoparticles by environmental TEM not only clearly shows the capability of observing/measuring real-time atom mobility at the surface of nanoparticles and chemical evolution (reduction) but also enables the indirect detection of surface adsorbates (here carbonates due to CO_2 adsorption) by monitoring the surface termination structural evolution.

Keywords: glycerol conversion, gold-supported catalysts, magnesium oxide, macro-mesoporous structure

1 Introduction

The reaction of glycerol with urea to form glycerol carbonate has become a relevant research topic during the last few years. This process utilizes two inexpensive and readily available compounds and additionally provides a route to upgrade the surplus production of glycerol formed in large quantities as byproduct during the production of biodiesel [1]. Although the reaction of glycerol with urea can proceed by increasing the temperature of the system, several heterogeneous catalysts (mostly Zn-based ones) have been found to improve its rate and selectivity to glycerol carbonate [2]. It is accepted that the existence of well-balanced acid-base properties of the catalyst are responsible of the activity and selectivity during the reaction. Hutchings et al. [3] presented a gold supported on magnesia catalyst as a high active and selective system for the glycerolysis of urea. These authors suggest that the combination of the basic properties of the support with the Lewis acidity of the gold-supported nanoparticles results in the improvement of the yield and selectivity. Moreover, the support can also play an additional role concerning to the stabilization of the gold nanoparticles and/or the occurrence of different metal-support interaction effects (e.g. charge withdrawing effects). Thus, the rational design of MgO-type supports (considering parameters such as morphology and porous structure) and the study of the gold-support interactions originated in these types of materials represent a feasible way to improve the catalytic efficiency and stability of Au/MgO-type catalysts.

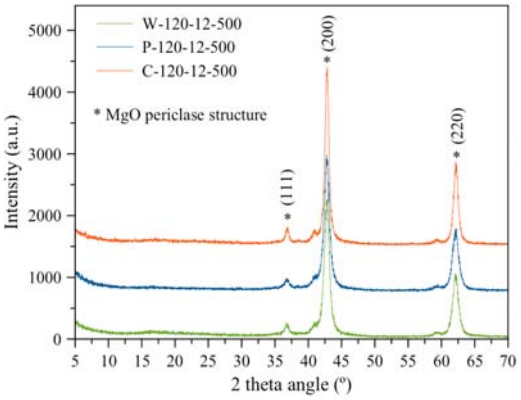
This work describes the synthesis of MgO-type supports by a hydrothermal synthesis route, employing Pluronic P123 block copolymer surfactant or cetyltrimethylammonium bromide (CTAB) as soft-templates. Gold nanoparticles were deposited on the most relevant supports (in terms of surface and morphology) and used as catalysts for the synthesis of glycerol carbonate.

2 Experimental/methodology

In a typical synthesis, P123 or CTAB were dissolved in water at 60 ºC and under vigorous stirring to form a transparent solution. After that, the $Mg(NO_3)_2.6H_2O$ was added to the clear solution (surfactant/Mg molar ratio equal to 0.03). An aqueous ammonia solution (25 wt%) was added dropwise at room temperature to the resulting liquid mixture under stirring until having a final pH close to 10. After precipitation, the slurry was transferred to a 50-mL Teflon-lined stainless steel autoclave for hydrothermal treatment at the selected temperature (120 ºC) for 12 or 24 h. The obtained solid was filtered out and washed three or four times with distilled water and ethanol (for the removal of the majority of the surfactant) and then dried overnight at 100 ºC. MgO was formed by calcination at 500 ºC, 3h, using a very slow calcination program.

3 Results and discussion

Figure 1 shows the XRD patterns of the samples calcined at 500 ºC. All the materials present the reflections characteristic of a pure MgO periclase-phase. Nevertheless, depending on the surfactant used, the MgO particles exhibit a different morphology. The SEM micrographs of the samples prepared with P123, CTAB and without addition of surfactant (denoted as samples P-, C- and W-) are shown in figure 2-a, 2-b and 2-c, respectively. In the absence of surfactant or using CTAB, a similar morphology of hexagonal nanoplates is observed. Higher agglomeration is seen without using surfactant. On the other hand, the presence of P123 provokes the formation of randomly piled aggregates of sheets. Those types of structures allow the formation of flower-like agglomerates with an open macroporous structure. In all the samples, the textural analysis reveals the formation of mesoporous structures (IV-type isotherms). However, the material synthesized in presence of P123 is the one with the highest surface area and pore volume (table 1).



Fig, 1. XRD patterns

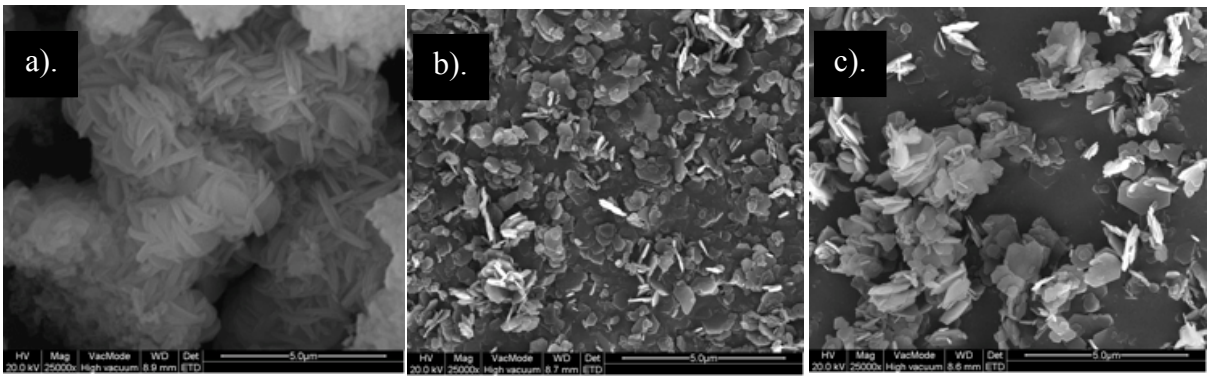


Fig. 2. SEM images of a). P-120-12-500, b). C-120-12-500 and c). W-120-12-500 materials

Table 1. Textural properties of the synthesized materials

Code	S_{BET} (m^2/g)	Pore Vol. (cm^3/g)	Av. Pore size (Å)
W-120-12-500	136	0.22	64
C-120-12-500	97	0.23	96
P-120-12-500	163	0.31	76

4 Conclusions

The combination of an open macro and mesoporous structure and a relevant surface area make the P-120-12-500 solid an interesting material to support gold-nanoparticles. Such textural and morphological properties are expected to influence the stabilization and dispersion of the deposited metallic phase and the diffusional processes involved during the catalytic reaction.

* mohdhasbi@ump.edu.my

Keywords: glycerol, boiler, ash, glycerol, carbonate, organic, carbonates, catalyst

1 Introduction

Over the years production of glycerol as a crude waste from biodiesel making industries has been largely increasing. For every 100 kg of biodiesel produced, 10 kg of glycerol is produced as a by-product which corresponds to 10 weight percentage of biodiesel. It is estimated that by the year 2016, the production of crude glycerol will reach 4 billion gallons.[1] Thus, in order to make this waste a useful substance for future use, the conversion of glycerol to other value added product is suggested.[2] Glycerol carbonate is one of the value added product of glycerol which is important to many industries. Glycerol carbonate has low toxicity, noble biodegradability and high boiling point.[3] There are various methods to produce glycerol carbonate using different sources of starting material. However the method used in this study is the most prominent method of near to a green synthesis approach whereby it uses bio-renewable feedstock. Besides, glycerol and urea are relatively cheaper and readily available.[3,4] On the other hand introducing waste material from local palm oil industry in Malaysia which is boiler ash has certainly raised the benchmark to the synthesis of organic carbonate to another level. This does not only propose a cheaper and economical route of transforming polyols into carbonates but also support proper disposal of waste for the betterment of our environment.

2 Experimental/methodology

Catalyst preparation

Raw boiler ash obtained from palm oil mill in Lepar Hilir, Pahang, Malaysia was dried at 110 ˚C overnight and then powdered using mortar and pestle (denoted as BA 110) and sieved using 200µm sized sieve. Later, 2g of the sieved ash were loaded on the combustion boat and calcined under static air at temperature (500 ^{o}C, 700 ^{o}C, 900 ^{o}C and 1100 ^{o}C respectively) for 4 h. The catalysts were later denoted as BA 500, BA 700, BA 900 and BA 1100, respectively.

Catalytic Testing

The reaction was carried out using a three-neck round bottom flask. Typically, glycerol was allowed to heat up to 150 ^{o}C for under the flow of nitrogen gas. When the temperature reached 150 ^{o}C, urea and 0.25g catalyst was added to the reaction and stirred using magnetic stirrer. The molar ratio of glycerol to urea used was (1:1.5). Sampling was done from 0 h to 4 h. The results were analysed using Gas Chromatography-Flame Ionised Detector (GC-FID) Agilent Technologies 7890A equipped with Varian Capillary Column, CP-ParaBOND Q (25m, 0.53mm, 10µm). Similar method was used to synthesis other organic carbonates (i.e ethylene carbonate and propylene carbonate) using the most effective boiler ash from the study.

3 Results and discussion

Table 1 show that boiler ash calcined at 900 ^{o}C is the most effective catalyst which has significant yield, conversion and selectivity. The yield of glycerol carbonate obtained follows the order of BA 900 > BA 700 > BA 1100 > BA 110 > BA 500. This could have resulted from the influence of basic metal oxides present in the catalyst with almost similar strength even after

different heat pre-treatment was carried out. It is also justified that potassium (K) as the most major metal in the catalyst could have been the target metal that has actively played the role in the catalytic activity of boiler ash.

Table 1: Effect of boiler ash calcination temperature on glycerol conversion, glycerol carbonate selectivity and yield

Keywords: NO and o-DCB, removal, TiO_2-Al_2O_3, support, vanadium

1 Introduction

Titania, typically used as support for the active metals, is known to improve the catalytic activity and to stabilize the structure of active centres [1]. However, its catalytic uses as a bulk material are strongly limited by its poor chemical, mechanical, textural, structural stability and high cost. A way of circumventing some of these limitations might be the dispersion of titania on high surface area oxide supports presenting advantageous properties. Alumina is a good candidate as titania support. In fact, numerous studies are presently available on TiO_2/Al_2O_3 catalytic system. Most of them, however, are devoted to the investigation of the influence of TiO_2 on the catalytic properties of the transition aluminas in various catalytic processes [2].

On the other hand, the simultaneous removal of NO_x and Polychlorodibenzo-*p*-dioxins (PCDD) compounds, produced during Municipal Waste Incineration (MWI), is a process with high environmental interest [3]. Because of their structural similarity to PCDDs, 1,2-Dichlorobenzene (o-DCB) has been frequently used as model compound. VO_x/TiO_2 appears as the most promising catalyst where the redox behavior of V appears to be strongly affected by vanadium-support interactions and additives.

To gain some further insight on the discussed topics, the major objective of this work is the investigation of the textural, structural, surface chemistry, and catalytic behavior, in simultaneous removal of o-DCB and NO, of a series of high surface area V/TiO_2-Al_2O_3 samples.

2 Experimental

The TiO_2-Al_2O_3 support (Ti-Al), with TiO_2 composition equal to 10.6 wt.%, was prepared by impregnation of alumina (saint Gobain SA 63158) with a solution of titanium butoxide (dissolved in butanol-1). The obtained suspension was maintained under stirring at 40 ºC for 3 h. After complete evaporation of the organic solvents under reduced pressure, through a rotary evaporator, the catalysts were dried overnight at 120 ºC and calcined at 600 ºC for 4 h. The Vx/Ti-Al and Vx/Al catalysts (where x indicates the weight percentage of V) were prepared by impregnation where NH_4VO_3 was used as vanadia precursor (diluted in oxalic acid). Their characterization involved mainly N_2 physisorption, XRD, FTIR, UV-Visible, NH_3-TPD, CO_2-TPD and TEM techniques. The catalytic tests were performed, on 1.5 g of catalyst, in a fixed bed reactor operating at atmospheric pressure. The gas mixture corresponding to simulated MWI feed consisted of O_2 (10%), CO_2 (10%), NO (300 ppm), NH_3 (300 ppm), o-DCB (100 ppm) and balanced Ar (total flow of 2 L min^{-1}).

3 Results and discussion

The composition and textural characterization of supports and vanadium catalysts are presented in Table 1. Concerning the Ti-Al support, the incorporation of TiO_2 causes a small decrease in the surface area of the alumina (10%), and in the pore volume, indicating a good distribution of

Ti on the surface. This result was confirmed by TEM.

Table 1. Characterization and activity results of the prepared catalysts

Samples	V, wt.%	S_{BET}, $m^2 g^{-1}$	Pore volume, $cm3\ g^{-1}$	Pore size, nm	H_2/V molar ratio (H_2-TPR)	Activity at 350ºC	
						X_{NO}	$X_{o\text{-}DCB}$
Alumina	-	224	0.58	7.5	-	-	-
V1/Al	0.96	201	0.53	7.5	1.22	0	7
V2/Al	2.10	207	0.53	7.5	0.99	24	4
V4/Al	3.67	196	0.49	7.5	1.07	46	22
Ti-Al	-	201	0.50	7.5	-	-	-
V1/Ti-Al	1.36	202	0.52	7.6	1.08	17	3
V2/Ti-Al	2.35	201	0.50	7.6	1.00	46	20
V4/Ti-Al	3.99	192	0.48	7.6	1.12	70	44

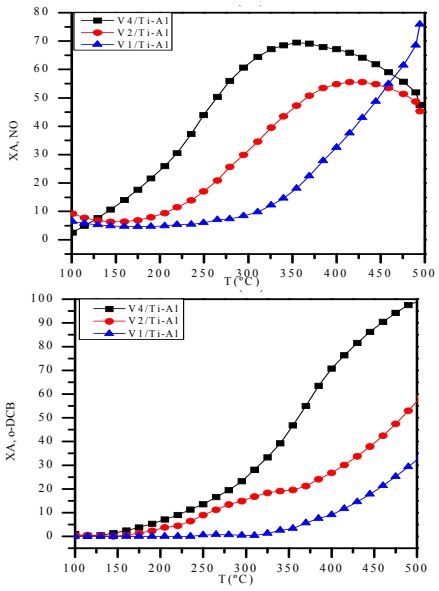

Fig. 1. o-DCB and NO conversions vs. temperature on the Vx/Ti-Al catalysts

The catalytic performances, in term of NO and o-DCB conversions, of the Vx/Ti-Al catalysts are shown in Fig. 1. The results reported in Table 1 also showed that the progressive addition of V improves the activity of the assayed catalysts in both reactions. Moreover, the presence of TiO_2 in the catalysts formulation increases markedly their catalytic activity and selectivity to produce N_2O and CO (not shown). On the most active catalyst (V4/Ti-Al) the NO activation starts around 100 °C. Its conversion increased rapidly to reach about 70% at 350 ºC, and then it decreases with the reaction temperature. Over the same catalyst, the o-DCB conversion presents different trend. The activity increases with the reaction temperature up to 500 ºC when it is close to 100 ºC.

4 Conclusion

Titania was successfully dispersed on the alumina surface. The modification of alumina support by TiO_2 seems to improve the catalytic activity of the Vx/Al catalysts in the simultaneous removal of NO and o-DCB process. In order to explain this effect, a correlation between the catalysts activity and the VO_x species properties was made.

Keywords: Cu species, BETA, FT-IR, NH_3-SCR

1 Introduction

The use of diesel and lean burn gasoline engines in vehicles application is increasing due to their higher fuel efficiency and lower CO_2 emissions compared to stoichiometric gasoline engines. However, the excess of oxygen in the environment makes NO_x reduction a challenging endeavor. SCR technology runs the engine under continuous lean mode and needs an external source of reductant for NO_x elimination, e.g. NH_3 obtained from urea hydrolysis. Cu exchanged ZSM-5 was first reported to be an effective catalyst for NO_x reduction on lean exhaust [1].

This work aims to elucidate the nature and location of Cu species in BETA zeolite catalysts, to be related with NH_3-SCR activity. Thus, a series of prepared catalysts is extensively characterized and the activity for NO_x reduction is tested in reactor experiments.

2 Experimental

Four Cu/BETA catalysts were synthesized by wet-ion exchange using copper acetate as precursor. The as-received BETA zeolite was used in its ammonic or protonic form, resulting in NH_4^+/Cu and H^+/Cu catalysts. Alternatively, an intermediate ion exchange with Na^+ ions was performed over NH_4^+/BETA and H^+/BETA zeolites, afterwards being submitted to copper ion exchange, resulting in NH_4^+/Na/Cu and H^+/Na/Cu catalysts. After ion exchange, catalysts were calcined at 500 ºC during 4 hours. The prepared catalysts were characterized in terms of XRF, N_2 adsorption-desorption, EPR, H_2-TPR, TEM and FT-IR adsorption of NO and CO.

The SCR experiments were performed in a downflow stainless steel reactor with 0.8 g of 0.3-0.5 mm pelletized Cu/BETA catalyst. The composition of the feed gas mixture was 660 ppm NO, 660 ppm NH_3 and 6% O_2 using Ar as balance gas. Total flow rate was set at 2880 ml/min, which corresponded to a space velocity (GHSV) of 86,500 h^{-1}. NO, NO_2, NH_3 and N_2O concentrations at the reactor exit were continuously monitored by online FT-IR multigas analyzer (MKS 2030).

3 Results and discussion

The prepared catalysts presented a Cu loading of 3.3% ± 0.2%. The adsorption of NO and NO_2 over the catalysts was followed by FT-IR, revealing three common IR features for all prepared catalysts: 1575 cm^{-1} which is due to the formation of superficial nitrates, 1622 cm^{-1} ascribed to NO_2 adsorbed on Cu^{2+} and 1908 cm^{-1} which is due to the interaction between NO and Cu^{2+} [2]. Interestingly, only the catalysts prepared by intermediate Na^+ exchange, i.e. NH_4^+/Na/Cu and H^+/Na/Cu, presented an IR feature centered at 1814 cm^{-1}, which is attributed to Cu^+–NO species. Besides, the Cu^+–NO interaction was composed of 3 contributions (1803, 1814 and 1823 cm^{-1}) which suggests the presence of different types of exchanged Cu species.

Figure 1 shows the evolution of H_2 consumption during temperature programmed reduction experiments, presenting two separated peaks representative of CuO aggregates reduction (low temperature) and Cu ions reduction (high temperature) [3]. The H_2 consumption profile was

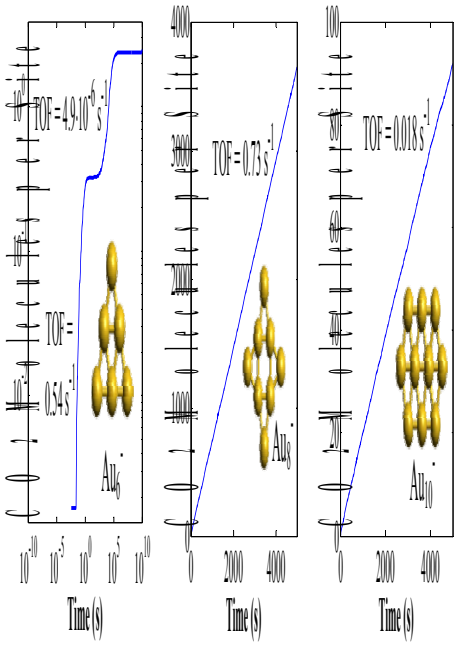

Figure 1. H_2 consumption of prepared catalysts during TPR.

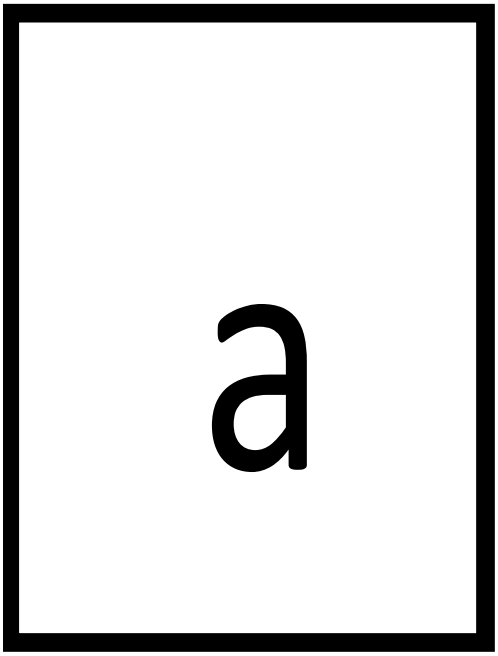

Figure 2. Conversion of NO_x and selectivity to N_2, N_2O and NO_2 for prepared Cu/BETA catalysts.

deconvoluted in five different contributions located at 280, 365, 450, 495 and 545 ºC and assigned to reduction of external CuO clusters, CuO clusters located in the zeolite channels and three different types of copper ions, respectively, related to the contributions observed by FT-IR. The integration of deconvoluted H_2 consumption peaks allows quantifying the nature and location of species. The amount of CuO aggregates, which comprises CuO external clusters and intrachannel nanosized CuO particles with peaks located at 280 and 365 ºC, respectively, accounted for around 45% of the total H_2 consumption disregarded of the catalyst. The reduction temperature of Cu ions increased in the order NH_4^+/Na/Cu < H^+/Na/Cu < NH_4^+/Cu < H^+/Cu, suggesting that the NH_4^+/Na/Cu catalyst contains the easiest reducible ions, located at accessible position of the zeolite framework. Accessibility to Cu ions decreases with temperature.

Figure 2 illustrates the SCR activity of the prepared catalysts. The NO_x conversion followed the trend NH_4^+/Na/Cu > H^+/Na/Cu > NH_4^+/Cu > H^+/Cu in accordance with the accessibility to copper ions determined by H_2-TPR. NH_4^+/Na/Cu resulted in the most active catalyst with maximum NO_x conversion of 87% and 92% of selectivity to N_2 achieved around 350 ºC.

4 Conclusions

The most active catalyst for NH_3-SCR of NO_x was NH_4^+/Na/Cu. The coexistence of Cu^{2+} and Cu^+, and easily reducible copper ions located at accessible exchangeable sites, lead to a highly active and selective NH_3-SCR catalyst for NO_x removal to N_2.

Keywords: Flyash, CO_2 decomposition, spinel structure, Zinc/nickel/manganese, ferrite, nanocatalyst, steel industry wastes, resource recovery

1 Introduction

Recently, over 0.2 million tons per year of flyash hazardous wastes are produced from steel industries in Taiwan and they cause potential environment pollution. The flyashes are ultrafine particles with toxic metals that can be leached out, bioaccumulated, and intaked into body having high risk for human beings or environment [1]. In stainless steel/carbon steel manufacturing plants, the $ZnFe_2O_4$ is major components and can be easily separated/purified using magnetic separation method after ball mill process. The $NiFe_2O_4/ZnFe_2O_4/MnFe_2O_4$ nanocatalysts are used for CO_2 reductive decomposition [2,3]. Carbon dioxide is the main greenhouse gas and play important role in the global warming, Hence its emission from steel companies, powder generation plants, and petrochemical industries has attracted the global attention. Therefore, the structural characterization and CO_2 decomposition efficiencies of $NiFe_2O_4/ZnFe_2O_4$ separated from flyash were studied and compared with as-synthesized ferrites in the present study.

2 Experimental

The metallic ferrite nanocatalysts were obtained by two methods including hydrothermal synthesis from commercial chemicals and magnetic separation from steel industrial flyash. Nickel sulfur and iron nitrite hydrates were stirred for well-dissolved with 1,000 rpm for 30 min. The pH value of solution was adjusted to 8-10 by adding ammonium with stirring for 2 h. Base solution putted into Teflon-lined steel autoclave, and then heated to 180°C for 6 h. After cooling, filtering, washing, and drying, the nickel ferrite nanocatalyst ($NiFe_2O_4$) was synthesized from hydrothermal synthesis. The next method was magnetic separation. The fine-particle flyash was obtained via ball-milling the well-dried flyash. Afterward the magnetic ferrite nanocatalysts were selected by magnetic separation in machine.

3 Results and discussion

The XRD patterns indicated the spinel structures of magnetic flyash after separation shown in Figure 1(a-i). FE-SEM micrographs showed that the flyash were mostly ball-like shape whereas XPS spectra showed that $ZnFe_2O_4$ is main component of the flyash surface. However, the main structures of flyash with weak magnetic or non-magnetic were both spinel and ZnO

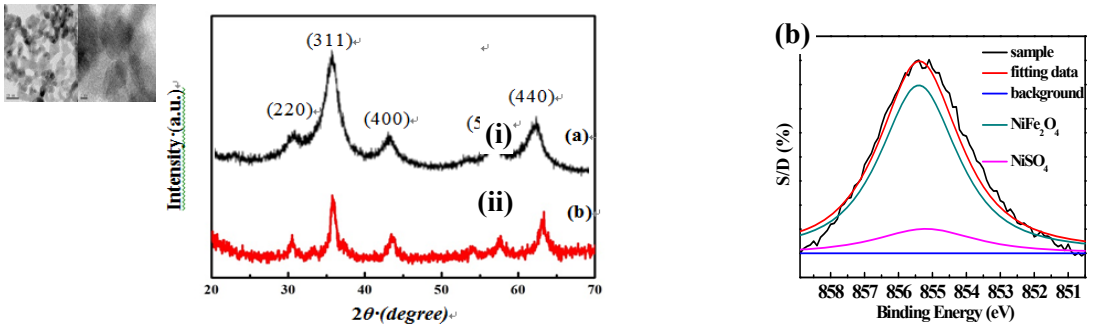

Fig. 1. (a) XRD patterns/HR-TEM micro-images and (b) XPS spectra of $NiFe_2O_4$.

structures. They have ball and bar shapes like morphology. The XPS spectra showed the most of

these flysah possessing ZnO structure. The N_2 adsorption/desorption isotherms of flyash were determined as a Type IV. On the other hand, the XRD patterns of $NiFe_2O_4$/$ZnFe_2O_4$/$MnFe_2O_4$ nanocatalysts prepared from hydrothermal method also have spinel structure shown in Figure 1(a-ii). Based on FE-SEM and HR-TEM micrographs, the particle sizes were ranged from 5-20 nm and uniform nanocatalysts were found. The XPS spectra showed central metals of $NiFe_2O_4$, $ZnFe_2O_4$, and $MnFe_2O_4$ are Ni(II), Zn(II), and Mn(II), respectively (Figure 1b). In addition, N_2 adsorption/desorption isotherms of $NiFe_2O_4$, $ZnFe_2O_4$, and $MnFe_2O_4$ were all Type V. The efficiencies of CO_2 decomposition and methanation processes were measured in response to the different temperatures (Figure 2). Once the reaction temperature increased, more CH_4 was produced. After methanation of CO_2, the surface of flyash was characterized using XPS and Fe_3C structure was observed on the surface. From the GC/TCD analyses, the yields of CH_4 production of as-synthesized $NiFe_2O_4$, $MnFe_2O_4$, and $ZnFe_2O_4$ were 99.8, 89.6 and 22.3%, respectively. In addition, the yield of CH_4 production of flyash was only 6.2%.

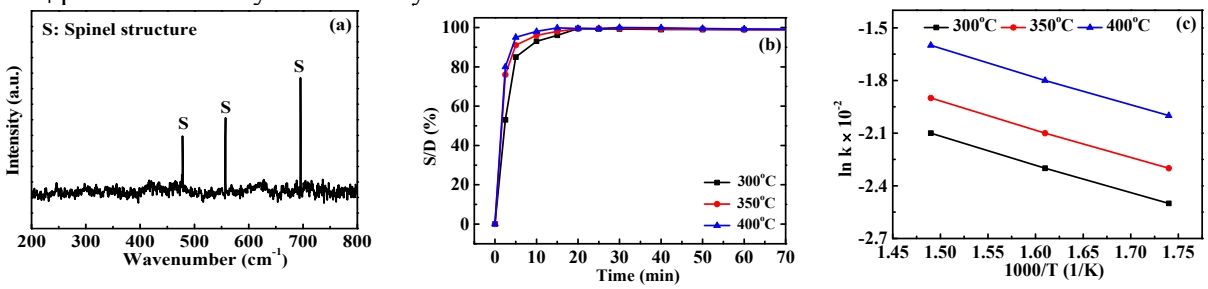

Fig. 2. (a) Raman spectra of $NiFe_2O_4$, (b) S/D values for CO_2 decomposition onto $NiFe_2O_4$ within 70 min, and (c) Arrhenius plot of $NiFe_2O_4$ at various temperatures.

		Flyash	$ZnFe_2O_4$	$NiFe_2O_4$	$MnFe_2O_4$
First order $-\ln\left[\frac{C}{C_0}\right] = K_{SA}\rho_a t$	R-squared (r^2)	0.9896	0.9716	0.999	0.9990
	Rate constant (l/time·m^2)	0.00377	0.00038	0.00049	0.00053

Table 2. Activation energy (E_a) of flyash, $ZnFe_2O_4$, $NiFe_2O_4$ and $MnFe_2O_4$

Sample	E_a (kJ/mol)
Flyash	279
$ZnFe_2O_4$	272
$NiFe_2O_4$	117
$MnFe_2O_4$	139

4 Conclusions

The catalysts prepared from hydrothermal method showed better CO_2 decomposition performance compared to the catalysts separated from the steel industries flyash. Moreover, the yields of CH_4 from synthesized catalysts were more than 90% while only 6% for flyash catalyst.

Keywords: catalyst regeneration, supercritical fluid extraction, co-solvent

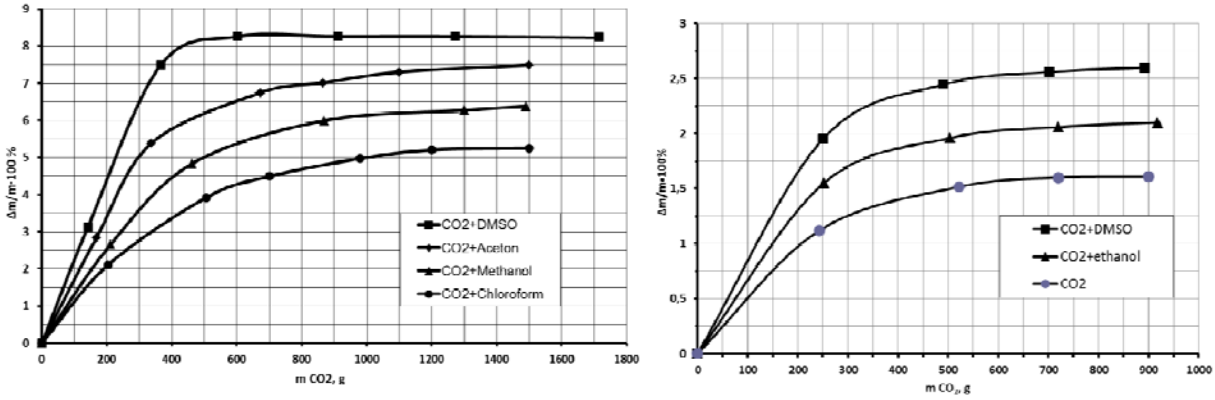
1 Introduction

Catalyst regeneration is one of the main problems in providing technical and economic efficiency of the vast majority of oil refining and petrochemical processes. One of the promising method for catalysts' regenerating is the supercritical fluid extraction (SCFE) process [1].

The aim of the present work is to explore the possibility of regeneration of spent catalyst from the enterprise of "Nizhnekamskneftekhim" (nickel-on-kieselguhr, palladium catalyst LD-265) in a supercritical carbon dioxide (SC-CO_2) medium [2].

2 Results and discussion

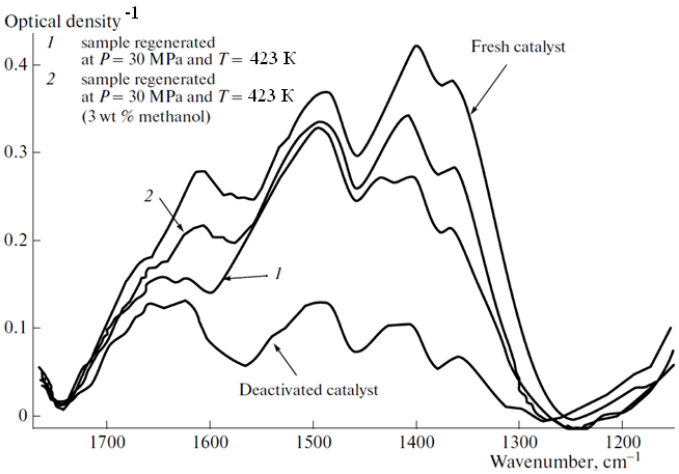
In the first series of experiments, the regeneration of the catalyst was performed by using pure SC-CO_2. For the purpose of the greater effect there was investigated the influence of concentration of different nature co-solvents of (chloroform, dimethylsulfoxide (DMSO), methanol and acetone) on the change in mass of the catalysts in the process of regeneration [3]. The extraction kinetics of catalyst regeneration at T=423 K using modified by various additives SC-CO_2 with an optimal concentration of co-solvents is presented in Fig.1.



a

b

Fig. 1. Change of catalyst's mass in the course of its regeneration
a – nickel-on-kieselguhr *P*=30 MPa,
b – palladium catalyst LD- 265 *P*=20 MPa



The greatest degree of extraction decontamination compounds is provided when used as co-solvent DMSO, which has a high polarity, and allows the most complete extraction of polar compounds.

The IR spectra of the regenerated catalyst samples (Fig. 2) confirm the occurrence of changes, primarily a decrease in the amount of deactivating compounds. The activity of the nickel-on-kieselguhr catalyst was estimated from the extent of hydrogenation of ethylene to ethane (table 1).

Evaluation of the activity of samples of the aluminum-palladium catalyst was carried out on the residual value of diene and bromine numbers in the hydrogenation product (table. 2).

Fig. 2. The IR spectra of the samples of nickel-on-kieselguhr catalyst, regenerated using pure and modified SC CO_2

Table 1. Activity of the samples of nickel-on-kieselguhr catalyst subjected to various treatments in the hydrogenation of ethylene

Product	Samples			
	initial catalyst	spent catalyst	regenerated (SC CO_2+ 3%wt methanol)	regenerated (SC CO_2)
Ethane, vol %	91,5	87,7	92,9	92,3
Ethylene, vol %	8,5	12,3	7,7	7,1

Table 2. Comparative analysis of hydrogenation results of the benzene-toluene-xylene-fractions, obtained on samples of the palladium catalyst LD-265

Activity index	Samples			
	steam-air treatment	regenerated (SC CO_2)	regenerated (SC CO_2+6%wt DMSO)	regenerated (SC CO_2+6%wt ethanol)
Diene number, gJ_2/100g	2,85	2,4	1,5	2,0
Bromine number, gBr_2/100g	20,5	19,0	16,2	17,0

3 Conclusions

Thus, the obtained values of the catalytic activity of the hydrogenation catalyst samples demonstrate the effectiveness of the extraction process, at the level of requirements imposed on the catalysts.

Keywords: activated carbon, adsorbents, CO_2 adsorption, isotherms, CO_2 adsorption kinetics

1 Introduction

CO_2 adsorption capacity of activated carbons at a given temperature and pressure depends the pore structure and the properties of functional groups introduced to the surface by certain pretreatments. CO_2 adsorption capacities of a commercial activated carbon subjected to different treatments such as HNO_3 oxidation, air oxidation, alkali impregnation and heat treatment under helium gas atmosphere were determined by gravimetric analyses for 298-473 K temperature and 0-20 bar pressure range. The experimental details can be found elsewhere [1]. It is possible to fit the kinetic data to both pseudo-first and pseudo-second order models aiming to determine the appropriate reaction order for the adsorption processes based on R^2 correlation coefficient values. Pseudo-first and pseudo-second order kinetic models as well as the intra-particle diffusion model were applied to the experimental kinetic data on the CO_2 adsorbent samples studied for the 1 bar CO_2 pressure.

2 Experimental

The chemically modified activated carbon based adsorbents used in this study are given in Table 1.

Table 1. List of activated carbon based adsorbents.

Name	Treatment
AC1	HCl washed NORIT ROX
AC2	HCl washed and air oxidized NORIT ROX
AC3	HCl washed and HNO_3 oxidized NORIT ROX
AC4-200	Na_2CO_3 impregnated and calcined (200°C) AC2
AC4-250	Na_2CO_3 impregnated and calcined (250°C) AC2
AC4-300	Na_2CO_3 impregnated and calcined (300°C) AC2
AC5-175	Na_2CO_3 impregnated and calcined (175°C) AC3
AC5-200	Na_2CO_3 impregnated and calcined (200°C) AC3
AC5-250	Na_2CO_3 impregnated and calcined (250°C) AC3
AC5-250-400He	Na_2CO_3 impregnated and calcined (250°C) AC3 subjected to He treatment at 400°C
AC4-300-600He	Na_2CO_3 impregnated and calcined (300°C) AC2 subjected to He treatment at 600°C

The adsorption and desorption isotherms of all samples were obtained at 25, 120/180 and 200°C in the 0-20 bar pressure range. Pseudo-first and pseudo-second order kinetic models as well as the intra-particle diffusion model were used to describe the kinetic behavior of the adsorbents.

3 Results and discussion

The CO_2 adsorption kinetic plots revealed a two-step adsorption process for all the adsorbents (Figure 1); a relatively fast kinetic region phase followed by a slow one till reaching the equilibrium. Pseudo-first and pseudo-second order kinetics explain adsorption for the kinetic region for most of the samples. When the whole adsorption data range is considered, the adsorption cannot be explained by any model due to complex nature of the adsorbents, but the adsorption behavior fits rather well to pseudo-first order kinetics at 120°C for the alkali impregnated samples, and at 25°C for non-impregnated samples and the adsorbents subjected to high temperature helium treatment as well.

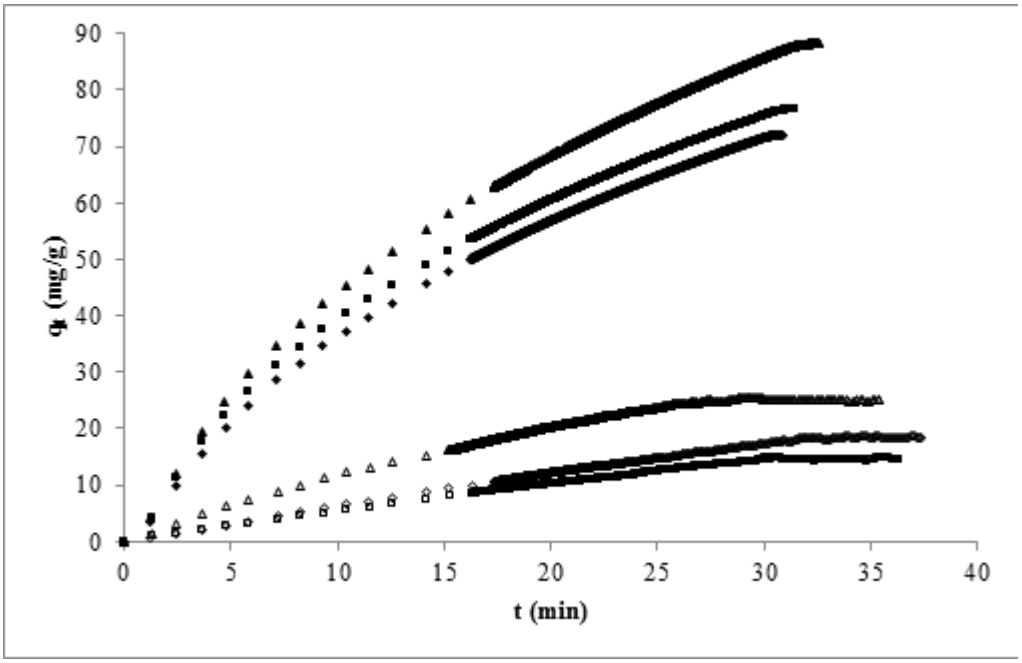

Figure 1. The kinetic plots of AC4 samples: (■) AC4-200, (▲) AC4-250 and (♦) AC4-300 at 25ºC (filled data points) and 120ºC (hollow data points).

Epoxidation of Fatty Acid Methyl Esters of Vegetable Oils by Air

Kulazhskaya A.D., Sapunov V.N., Udaev S.A., Voronov M.S.*

Mendeleev University of Chemical Technology of Russia, Moscow, Russia

* kulazhskaya_92@inbox.ru

Keywords: fatty acid methyl esters, vegetable oils epoxidation, atmospheric, oxygen, hydroperoxide

1 Introduction

The epoxidation of vegetable oils and fatty acid methyl esters of vegetable oils are widely used to produce plasticizers and lubricants now. A number of methods of epoxidation is characterized by using different epoxidizing agents: epoxidation with peroxyacids [1], the epoxidation of organic hydroperoxides [2], epoxidation with hydrogen peroxide [3]. These methods have significant disadvantages. For example, the use of peracid produced *in situ* from the corresponding organic acid and hydrogen peroxide, is always associated with the use of expensive corrosion resistant equipment. Organic hydroperoxides are highly toxic and explosive compounds. A concentrated solution of hydrogen peroxide is also very expensive.

In this paper, it is shown the possibility of obtaining a mixture of epoxy compounds of fatty acid methyl esters of vegetable oils by reacting unsaturated compounds with air oxygen. The purpose of research is definition of the mechanism and kinetics of the process.

2 Experimental/methodology

The process was carried out in a glass column reactor. The mixture of methyl esters of fatty acids of sunflower oil was charged into the reactor, bubble feeding air was started and then mixture was heated up to the target temperature. During the study of the epoxidation the homogeneous metal complex catalyst based on molybdenum was added to the reaction mixture. The course of study of the oxidation reaction was carried out without catalyst. Synthesis was performed for 5 hours. Hydroperoxide content was determined by iodometrically titration, accumulation of epoxides fixed by gas-liquid chromatography.

3 Results and discussion

When the oxidation of mixture of fatty acid methyl esters of sunflower oil with no catalyst was carried out, accumulation of hydroperoxides, epoxides, and weak organic acids was observed. Based on this fact probable mechanism of formation epoxy compounds was supposed [4]: non-catalytic interaction of peroxide radicals with unsaturated compounds (Fig.1.) and classical hydroperoxide epoxidation with metal complex catalyst (Fig.2.).

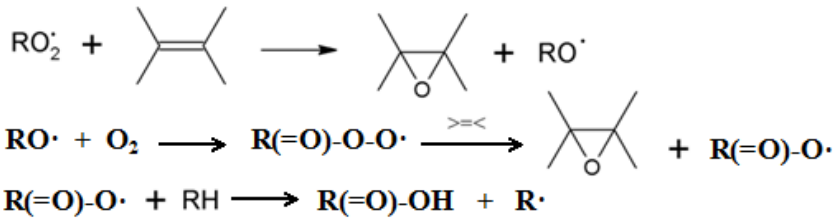

Fig. 1. Non-catalytic route of process of epoxidation.

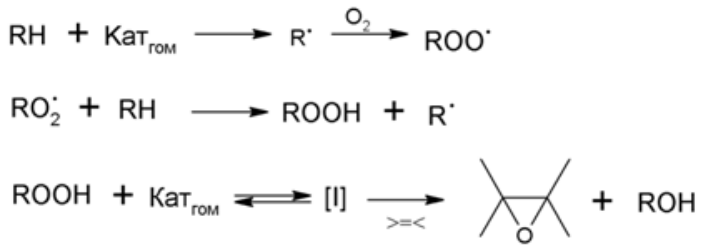

Fig. 2. Catalytic route of process of epoxidation.

4 Conclusions

Kinetic regularities of oxidation and epoxidation of fatty acid methyl esters was studied. Mathematical model based on the proposed mechanisms was composed, it describes the experimental data adequately.

Keywords: TWC, perovskite, postcombustion catalysis, iron copper

1 Introduction

Three-way catalysis (TWC) is an expensive technology due to extensive use of precious metals (Platinum group metal PGM). Previously, perovskite-type materials were developed for three-way applications especially to stabilize PGM from thermal sintering. This strategy led to interesting outcomes with lower PGM contents. In this study, low cost Fe-based perovskites being non-toxic and thermally stable were investigated. However, the main drawback lies in the surface reconstruction and a usual lanthanum enrichment which affects their catalytic properties [2]. A better optimisation of the surface proprieties can be obtained through partial substitution of A- and B-site ($LaFe_{1-x}Cu_xO_3$ and $La_{1-x}Ca_xFe_{1-x}Cu_xO_3$). It was also found that none stoichiometric perovskite especially lanthanum-deficient perovskites leads to significant enhancement of the catalytic performances.

2 Experimental/methodology

The perovskite catalysts were prepared by a conventional citrate method and finally calcined in air at 600 °C. BET, H_2-TPR, Raman spectroscopy, XRD and XPS characterisations were performed before and after catalytic measurements. NO_x and reductants concentrations were measured during temperature-programmed reactions in a fixed bed continuous-flow reactor with WHSV=60,000 $mL.g^{-1}.h^{-1}$ from 110°C to 500°C under stoichiometric, lean, and rich conditions. Realistic feed gas compositions consisted of 0.1% NO, 15 % CO_2, 10 % H_2O, CO (0.5 %; 0.7 %; 0.9 %), CH_4 (150 ppm; 225 ppm; 300 ppm), C_3H_6 (300 ppm; 450 ppm; 600 ppm), C_3H_8 (150 ppm; 225 ppm; 300 ppm), O_2 (0.935 %; 0.777 %; 0.609 %), and H_2 (0.167 %; 0.233 %; 0.3 %).

3 Results and Discussion

Partially substituted $LaFeO_3$ with Cu and Ca were characterized from XRD highlighting an orthorhombic perovskite structure. Surface compositions as well as the reducibility of the solids are strongly influenced by Cu substitution whereas Fe prevents the degradation of the structure in reducing atmosphere.

The conversion profiles of CO, NO and propene vs. T during temperature-programmed reactions are presented in Fig. 1. Temperatures corresponding to 50 % conversion of CO under stoichiometric conditions and NO under rich conditions as well as their surface properties are reported in Table 1. The reference $LaFeO_3$ catalyst exhibits poor catalytic performances. By contrast, a significant enhancement of CO and NO conversion is observed for the La-deficient sample, $La_{0.7}FeO_3$. This enhancement is related to higher Fe surface concentration evidenced by

XPS analysis.

Table 1. Temperatures of 50 % conversion of CO (stoichiometric) and NO (rich) and surface properties of the low-cost Fe-based perovskite catalysts.

Catalyst	T_{50} CO	T_{50} NO	Fe/La	S. S. A. (m^2/g)
$LaFeO_3$	492 °C	*460 °C* (T_{25})	0.41	9.5
$La_{0.7}FeO_3$	382 °C	494 °C	1.47	31.9
$LaFe_{0.9}Cu_{0.1}O_3$	305 °C	489 °C	0.42	18.4
$LaFe_{0.8}Cu_{0.2}O_3$	294 °C	*501 °C* (T_{25})	0.40	13.8
$La_{0.9}Ca_{0.1}Fe_{0.9}Cu_{0.1}O_3$	288 °C	478 °C	-	21.4
$La_{0.8}Ca_{0.2}Fe_{0.8}Cu_{0.2}O_3$	279 °C	469 °C	-	24.0

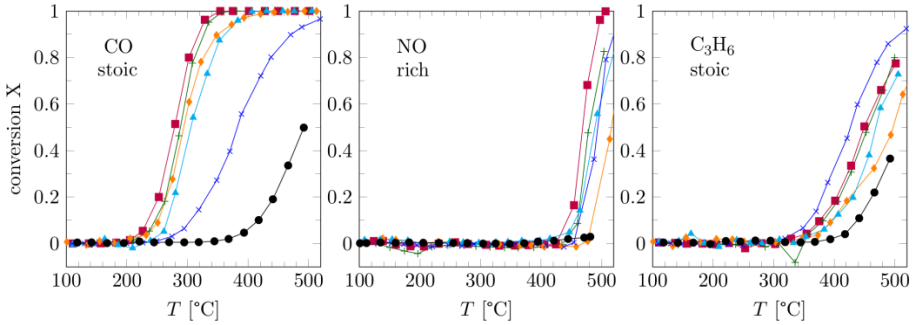

Fig. 1. CO, NO, and C_3H_6 conversions on Fe-based perovskite catalysts: $LaFeO_3$ (●), $La_{0.7}FeO_3$ (x), $LaFe_{0.9}Cu_{0.1}O_3$ (▲), $LaFe_{0.8}Cu_{0.2}O_3$ (♦), $La_{0.9}Ca_{0.1}Fe_{0.9}Cu_{0.1}O_3$ (+), $La_{0.8}Ca_{0.2}Fe_{0.8}Cu_{0.2}O_3$ (■).

The partial substitution of La and Fe by Ca and Cu enhances the catalytic performances (Fig. 1). Copper addition led to a CO activation at much lower temperature ~300 °C whereas NO and propene were converted above 400-450 °C. Replacing part of La by Ca leads to higher activities, with light-off conversion curves shifting more than 200 °C for CO oxidation as compared to $LaFeO_3$. Propene oxidation is enhanced for $La_{1-x}Ca_xFe_{1-x}Cu_xO_3$ perovskites (x = 0.1, 0.2) and $La_{0.7}FeO_3$ catalysts. XRD analysis of used catalysts confirms the stability of the perovskite structure in the presence of steam assigned to the presence of Fe. Low temperature CO conversion is very interesting since CO is known to strongly adsorb on Pt which inhibit NO reduction to N_2 at low temperature. The combination of Cu and Ca doping and surface composition optimisation will also be investigated.

4 Conclusions

Fe-based perovskites are low-cost alternatives to partly replace noble metals in conventional 3-way catalysts. Surface composition optimisation strongly enhances the catalytic activity of the perovskite by increasing the accessibility of the active sites. Cu and Ca doping further increases the catalytic activity especially CO oxidation which can avoid CO inhibition on noble metals. Combination of partial substitution, non-stoichiometric formulation is a first step for further optimisation. Anyway, the presence of low content of noble metals seems to be inevitable for the conversion of NO.

Keywords: desilication, zeolite, polystyrene hydrocracking

1 Introduction

Polystyrene (PS) hydrocracking to fuels is studied as an alternative in plastic recycling, with bifunctional Pt/HY catalysts. Big polymer molecules cannot enter the internal pores of the catalysts[1]. Hierarchical supports with high external surface area have been found suitable for this kind of processes[2]. In this work, a desilication treatment was carried out to increase external surface area of the support, thus improving polymers accessibility to the active sites.

2 Experimental

Bifunctional catalysts: Four supports were prepared from NH_4Y zeolite (Zeolyst Corp., Si:Al = 6). HY was obtained by direct calcination of NH_4Y (1 K min^{-1}, 823 K). The other three supports were obtained by desilication with NaOH: 10 g of NH_4Y zeolite were mixed with 1 L of NaOH solutions of different concentrations (0.1 M: hHY1, 0.2 M: hHY2 and 0.3 M: hHY3) plus 10 g of tetrapropilammonium hydroxide (TPAOH) as pore directing agent to protect the zeolite structure[3].

Four catalysts with nominal 0.5 wt.% Pt were prepared on the supports by ionic exchange[4], using tetraammineplatinum(II) nitrate (Alfa Aesar, 99.99%). 10 g of the support in powder form were slurred in deionised water (1 L) and then heated to 353 K under continuous stirring and reflux at pH=7 for 24 h. Afterwards, the solid was separated, washed, dried (393 K, 12 h), calcined (823 K, 2 h) and reduced in hydrogen flow (800 K, 3 h).

Catalysts were characterized by: XRD, SEM, N_2 physisorption (BET and external surface, 77 K), NH_3-TPD (acid strength), FTIR of adsorbed pyridine (Py) (Brønsted and Lewis acidity[5], 423 K), FTIR of absorbed 2,6-di-*tert*-butylpyridine (DTBPy), (external acidity[6], 423 K), XRF (actual Pt content), TEM and H_2 chemisorption (Pt dispersion, 308 K).

Catalytic activity: PS hydrocracking in the liquid phase was carried out at kinetic regime[1]: 5% PS (M_W = 192,000 g·mol^{-1}, M_n = 120,000 g·mol^{-1}) solved in decahydronapthalene, 623 K, 180 bar of H_2, 1800 rpm, 2.36 $g_{Cat.}·L^{-1}$ in slurry, with an stirred autoclave reactor. PS conversion was evaluated by GPC. Selectivity was analyzed by GC-FID.

3 Results and discussion

Table 1 shows measured catalyst properties. XRD showed no significant change of support relative crystallinity with desilication, although desilicated supports were less crystalline than the original support. Desilication improved external surface area up to 40%. Despite the loss of total acidity and acid strength, Brønsted acid sites, essential for cracking reactions, remain nearly constant with desilication in the studied range. These facts mean that most of silicon removed came from extraframework species related to structural defects, and the accessibility of the acid sites increased slightly, in good agreement with $S_{Ext.}/S_{BET}$. Pt dispersion significantly increased with desilication, as local big Pt particles were found with TEM in untreated Pt/HY.

Table 1. Properties of the catalysts.

Catal.	Crystal.	$S_{Ext.}$	NH_3, μmol·g^{-1}				Py, μmol·g^{-1}		Acces.	Pt[a]	Disp.[b]	d_{Pt}[b]
	%	m^2·g^{-1}	T	W	M	S	B	L	%	%	%	nm

Pt/hHY2	93	156	472	378	61	33	179	118	29.8	0.5	60	1.8
Pt/hHY3	90	161	448	373	48	27	176	113	30.1	0.5	83	1.3

Key to acidity: T, total; W, weak; M, medium; S, strong; B, Brønsted; L, Lewis; Acces., accessible.
[a]Nominal; [b]Estimated by TEM.

Desilicated hierarchical catalysts showed higher PS hydrocracking rates, which improved with desilication, as shown in Figure 1(a). This fact can be attributed to the higher accessibility of PS to the active sites. Apparent activation energy is not significantly affected by desilication. Small differences were found with desilication on the chemical nature of PS hydrocracking products, although products in the diesel range significantly increased at the expense of products in the gasoline range and gases, particularly at low temperature, what is probably related to the lower acid strength of the desilicated catalysts. Figure 1(b) shows TOF values for all the studied catalysts.

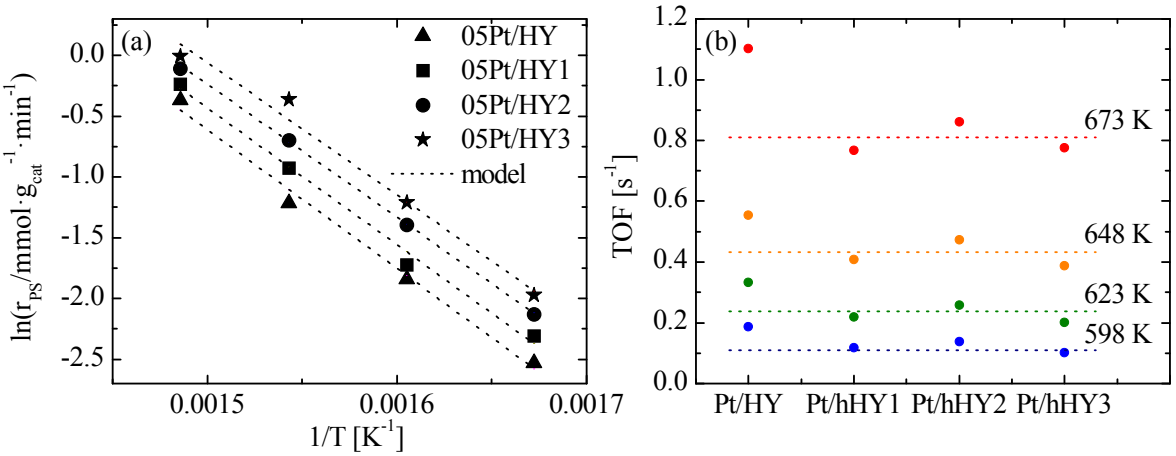

Fig. 1. Experimental rates (a) and TOF values (b) with temperature for the prepared catalysts.

4 Conclusions

Desilication of HY increases mesoporosity with small loss of crystallinity or Brønsted acid sites, decreases acid strength and improves Pt dispersion in the catalysts, thus increasing PS hydrocracking rate and selectivity to diesel range. TOF values of untreated Pt/HY are higher than those of the desilicated catalysts, which could be related to its higher acid strength.

Keywords: CO oxidation, heterogeneous, nanostructured catalysis, noble metal, TiO_2, temperature, hysteresis

1 Introduction

Supported Pt/TiO_2 catalysts are active in the low-temperature CO oxidation, used for the environmental protection. It is known that modifying of this catalyst by the additives of transition metal results in a substantial increase in their activity [1, 2]. The aim of this work is to develop Pt/TiO_2 catalysts, doped by Fe, with enhanced activity in low-temperature CO oxidation.

2 Experimental

Catalysts 1 wt.% Pt/TiO_2 and 1 wt.% Pt, (0.03-0.55) wt. % Fe/TiO_2 were prepared by impregnating of the TiO_2 with iron and platinum nitrate solution followed by drying and heat treatment in air at 500°C. Catalysts were investigated by XRD, HREM, XPS and adsorption methods. Catalytic activity in oxidation of CO was conducted at a flow-circulation installation BI-CATr (oxy) (Russia) with circulation rate of the reaction mixture 1000 liters per hour and increasing and then decreasing the temperature in the range from 25 to 150°C. Composition of the reaction mixtures were analyzed by a chromatograph equipped with a thermocatalytic detector on a column filled with carbon SKT mark. Measurements were carried out on the fraction of catalyst 0.25-0.5 mm at the following reaction mixture: 1 vol. % CO, 10 vol. % O_2, N_2 balance, feed rate was 4.46×10^{-3} mol/min.

3 Results and discussion

According to XRD catalysts 1 wt.% Pt/TiO_2 and 1 wt.% Pt, (0.03-0.55) wt. % Fe/TiO_2, represent the anatase phase for all concentrations of iron. Oxide or metallic platinum reflexes are not detected. It indicates on highly dispersed platinum species.

Investigation of $Pt,Fe/TiO_2$ catalysts with HREM method showed that the real structure of the support is a nanocrystalline, on the surface of the support well crystalline platinum particles with the size of 1.5 - 3.5 nm are observed. At the same time the dimensions of Pt in Pt/TiO_2 catalyst are 1.5 - 6.0 nm. Note that the interplanar distances of the crystal lattice of platinum obtained by HREM showed no apparent changes in compare to standard values of metal platinum. Based on this, it can be assumed that there is no introduction of iron into platinum particles. Probably, Fe^{3+}, Fe^{2+} ions are stabilized either in the lattice of anatase to form a substitution solid solution or in interblock boundaries of nanocrystalline anatase structure.

According to XPS data, both Pt/TiO_2 and $Pt,Fe/TiO_2$ catalysts contain two types of Pt states in different atomic ratios – Pt^0 ($E_b(Pt4f_{7/2})$ = 71.1 eV) and $Pt^{\delta+}$($E_b(Pt4f_{7/2})$ = 72.1 eV) (Tabl. 1). At the similar platinum content the ratio of $Pt^{\delta+}/Pt^0$ grows with an increasing of the iron concentration to 0.28 wt.%, and then it decreases at 0.55 wt% of Fe.

The temperature dependences of CO oxidative conversion in the course of catalyst heating or

cooling in the reaction mixture are compared in Tabl 1. The heating and cooling curves do not coincide. The hysteresis recurred persistently for all studied catalysts (Fig.1). Activity of Pt/TiO_2 catalyst is much lower than that of $Pt,Fe/TiO_2$. The activity of $Pt,Fe/TiO_2$ catalysts increases with an increasing of iron content from 0.03 to 0.28 wt. %: the 50% CO conversion temperature decreases from 127 to 62^{0}C, and the reaction rate rises. But the further increase of iron content to 0.55 wt. % leads to decrease the catalytic activity. The optimum amount of Fe for the most effective CO oxidation was estimated to be 0.28 wt.%.

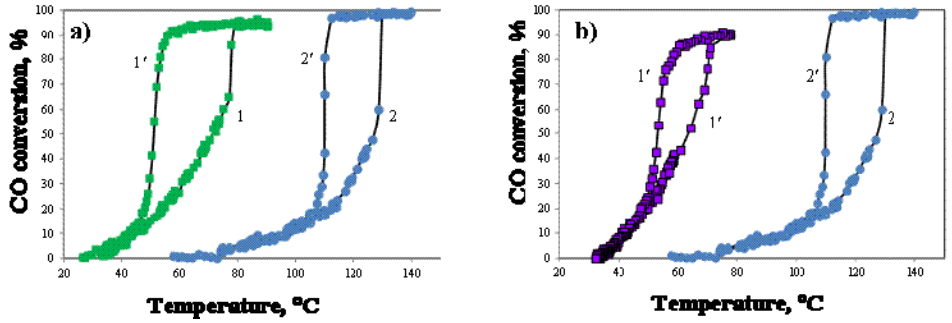

Fig. 1. Temperature dependence of CO oxidative conversion when the reaction system is (1, 2) heated and (1', 2') cooled over different catalysts: **a)** 1 wt.% Pt, 0.03 wt.% Fe/TiO_2 (1', 1'), 1 wt.% Pt/TiO_2 (2, 2'), **b)** 1 wt.% Pt, 0.55 wt.% Fe/TiO_2 (1', 1'), 1 wt.% Pt/TiO_2 (2, 2').

Table 1. Influence of the Fe content on the ratio of $Pt^{\delta+}/Pt^0$ in $Pt,Fe/TiO_2$ catalysts and their catalytic properties when the reaction mixture is heated or cooled.

Composition, wt.%	$T^{heat}_{50\%}$, °C	$T^{cool}_{50\%}$, °C	$W\times10^5$, mol CO g^{-1} min^{-1} at 60^{0}C	$Pt^{\delta+}/Pt^0$
1% Pt/TiO_2	127	109	0	0.44
1% Pt, 0.03 % Fe/TiO_2	71	51	3.2	0.80
1 % Pt, 0.14 % Fe/TiO_2	70	51	3.3	1.34
1% Pt, 0.28 % Fe/TiO_2	62	53	5.1	1.55
1% Pt, 0.55 %Fe/TiO_2	69	62	3.4	1.0

4 Conclusions

Thus, the improvement of the catalytic activity of Pt/TiO_2 catalyst in low-temperature CO oxidation could be achieved by modification of a small amount of iron. The relationship between Pt/TiO_2 and $Pt,Fe/TiO_2$ behaviours depends on the chemical composition and real structure. The introduction of iron additives in Pt/TiO_2 catalyst results in the formation of nanocrystaline structure of support. It leads to increase in platinum dispersion and change in the electronic state. For the optimum amount of Fe in the catalyst 1 wt.% Pt, 0.28 wt.% Fe/TiO_2 the $Pt^{\delta+}/Pt^0$ ratio arises to maximum value of 1.55. It is due to the changes in the interaction of platinum with support because the iron stabilized in nanocrystalline structure of TiO_2. This provide the high catalytic activity $Pt,Fe/TiO_2$ catalysts in low-temperature CO oxidation.

Keywords: composite, carbon, nanomaterials, zeolite, CWPO, phenol

1 Introduction

Catalytic wet peroxide oxidation (CWPO) is one of the most economical and environment-friendly advanced oxidation processes. Previously we have shown that Fe and Cu-containing zeolites with MFI structure possess a high catalytic activity in the CWPO of refractory organic pollutants [1]. A promoting effect of graphite-like carbon in Fenton-like process was also revealed [2]. Hence composite carbon nanostructures/zeolites(porous matrix) materials can be very effective adsorbent-catalysts for organic containing wastewater purification due to high adsorption capacity of carbon nanomaterials, high catalytic activity of Fe and Cu-containing zeolites, and porous structure of composite providing mass transport and filtration.

The aim of this study was the development of preparation mode of the composite adsorbent-catalysts and the testing of the prepared adsorbent-catalysts in a purification of solutions of model organic substrates: formic acid and phenol. Formic acid is an intermediate in deep oxidation of most organic compounds and the main reason for leaching of the active components of the catalysts into the reaction solution. Phenol is a typical wastewater pollutant.

2 Experimental

Two preparation mode were used for the synthesis of composite adsorbent-catalysts.

Method 1 is mechanical mixing of the zeolite H-ZSM-5 with Si/Al= 30 and the content of Fe^{3+} framework ions equal to 0.65 wt.%, with the mesoporous graphite carbon Sibunit. The composites were formed by the pressing. The weight ratio of carbon/zeolite was varied from 75/25 to 0/100.

Method 2 is pyrolysis of carbon compounds supported on the zeolite. Polyvinyl alcohol (PVA) was used as a carbon source. PVA was supported on surface of the zeolites H-ZSM-5 (Si/Al=30, Fe-0.65 wt%) and Cu-ZSM-5 (Si/Al=30, Fe-0.65 wt%, Cu-1 wt%) by impregnation. Composites were heated in inert (N_2) or reducing (H_2) conditions. The carbon content was 12 wt.%.

The catalysts were characterized by ICP-AES, EPR, XRD, DR UV-Vis and tested in CWPO of formic acid and phenol at pH 3 using a batch and a flow reactors. Reaction conditions: 0.1M HCOOH, 7mM PhOH, 1M H_2O_2, 3 gL^{-1} catalyst, 30-50ºC. The concentration of formic acid and phenol in solutions was determined by HPLC in a Phemomenex Synergi 4u Hydro-RP 80A column using a Shimadzu LC-20A chromatograph with a diode array detector.

3 Results and discussion

Composites prepared by method 1 showed the catalytic performance in phenol oxidation;

it increased proportional to the amount of Fe^{3+} ions in them. Their adsorption capacity appeared to be on the proportional rise with the content of the carbon material.

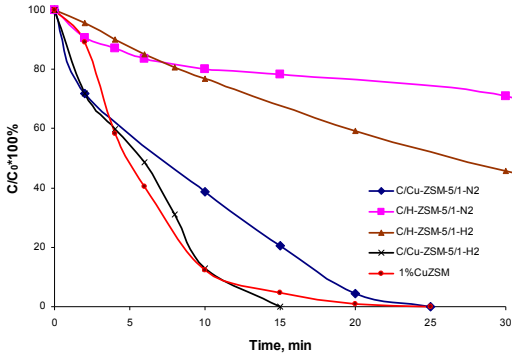

Figure. Kinetics of phenol peroxide oxidation over the zeolite 1% Cu-ZSM-5-30 and the composite catalysts prepared by the method 2 (7 mM PhOH, 1 M H_2O_2, 3 g·L^{-1} catalyst, 50 ºC).

The carbon composites prepared by method 2 and contained Cu-zeolite exhibited higher catalytic activity in the oxidation of phenol compared to composites based on copper-free zeolite H-ZSM-5 (Figure) and composites prepared by method 1. The phenol oxidation rate over the reduced composites was higher than that over the zeolites treated in inert atmosphere. Reduction treatment allows removal of O-containing surface species which inhibit peroxide oxidation [3].

Moreover, initial catalytic activity was higher for carbon-containing composites than one of zeolite catalysts. The last observation can not be explained by phenol adsorption, such as the reaction was started after the achievement of the adsorption equilibrium. One possible reason for increase of phenol oxidation rate is a change of reaction mechanism in the presence of carbon materials. Probably, oxidation proceeds on the surface of the graphite-like carbon, and electronic and conductive properties of carbon are particularly important. We believed the heterogeneous reaction steps involve the electrons transfer through the graphite π-π system from adsorbed substrate to the oxidant. Such relationships have been described for other reactions [3-5].

In the case of the formic acid oxidation, on the contrary the composite was less active on the initial step of reaction than zeolites. This result can be attributed to the hydrophobicity of the carbon surface and a peculiarity to the nature of the substrate.

4 Conclusions

The carbon/zeolites composite absorbent-catalysts were prepared by two preparation modes and tested in CWPO of phenol and formic acid. The obtained results testify that the combination of carbon and the zeolite can improve the adsorption capacity as well as the catalytic activity in the CWPO of organic substrates. However, the catalytic activity depends on the substrate nature and the mechanism of its interaction with the surface of the solid catalyst.

Keywords: N_2O decomposition, iridium, alumina, ceria, SO_2

1 Introduction

Nitrous oxide (N_2O) has recently attracted great attention, due to its deleterious environmental impact. N_2O is a powerful greenhouse gas with a global warming potential (GWP) about 300 times higher than that of CO_2, while at the same time it notably contributes to stratospheric ozone depletion [1]. Therefore, the abatement of N_2O emissions from combustion and chemical processes is of significant importance. Among the different remediation methods, the catalytic decomposition of N_2O to N_2 seems to represent the most promising approach. Up to date several catalytic systems have been evaluated for N_2O decomposition. Among them, noble metal-based catalysts exhibit satisfactory performance at low temperatures. Additionally, the use of structural and/or surface modifiers seems to enhance further their intrinsic activity [2]. Except N_2O, other components that typically exist in flue gas are O_2, SO_2, H_2O, etc. The effect of SO_2 and/or O_2 on the activity of Ir catalysts for the N_2O decomposition is investigated in the present study.

2 Experimental/methodology

A series of Ir catalysts supported either on bare alumina (Al_2O_3) or CeO_2-modified alumina (AlCe: 80 wt. % Al_2O_3 and 20 wt. % CeO_2) were investigated for N_2O decomposition, in the presence of SO_2 and/or O_2. Supporting materials were synthesized *via* the co-precipitation method, while incorporation of the active phase (0.5 wt. % Ir) was carried out through the impregnation method, using $IrCl_3 \cdot H_2O$ as precursor salt. The catalysts were characterized by means of N_2 physisorption (BET), H_2-TPR, XRD and TEM techniques and evaluated for N_2O decomposition in a bench-scale, fixed bed reactor unit, in the temperature range of 200°C to 600°C. Selected catalytic samples were also characterized in "used" state to explore the impact of reaction conditions on catalyst's characteristics.

3 Results and discussion

N_2O conversion values as high as 99.0% and 96.9% were obtained over Ir/AlCe sample, during the N_2O decomposition in the absence and in the presence of O_2, respectively, compared to 98.0% and 66.4% achieved over the Ir/Al_2O_3 sample (Table 1). In the presence of SO_2 under oxygen deficient conditions (N_2O+SO_2 reaction) the N_2O conversion is decreased to 82.2% over Ir/Al_2O_3 catalyst, whereas the de-N_2O performance of Ir/AlCe sample remained almost unaffected (93.6%). However, in the co-presence of SO_2 and O_2 ($N_2O+O_2+SO_2$), the N_2O conversion over Ir/Al_2O_3 and Ir/AlCe catalysts is notably decreased to 61.6 and 39.2% respectively. Most interestingly, the N_2O conversion increases from 66.4% over the fresh

Ir/Al_2O_3 sample to 78.2% over the sulphated catalyst (i.e. catalyst after the corresponding reaction, in which 50 ppm SO_2 was co-present), implying the beneficial effect of sulfidation (Table 1).

Table 1. N_2O conversion (%) of Ir-based catalysts under various feed composition. Reaction conditions: 1000ppm N_2O, 50ppm SO_2, (2 % O_2), Ft=900 cm^3/min, W_{cat}=0.6 g, GHSV=40000 h^{-1}.

Feed	% N_2O Conversion	
	0.5 wt.% Ir/Al_2O_3	0.5 wt. % Ir/AlCe
N_2O	98.0	99.0
N_2O+SO_2	82.2	93.6
N_2O (Sulphated Catalyst)	74.4	58.4
N_2O+O_2	66.4	96.9
$N_2O+O_2+SO_2$	61.6	39.2
N_2O+O_2 (Sulphated Catalyst)	78.2	45.7

4 Conclusions

The effect of SO_2 and/or O_2 on the decomposition of N_2O over Ir catalysts supported either on bare Al_2O_3 or CeO_2-promoted Al_2O_3 was investigated. The superior performance of CeO_2-promoted catalysts under oxygen excess conditions was clearly revealed. However, the co-presence of O_2 and SO_2 in the feed stream resulted in a decrease of N_2O conversion, being more intense over Ir/AlCe catalyst. Interestingly, the de-N_2O performance of Ir/Al_2O_3 catalyst was notably enhanced upon sulfidation, which is not the case for Ir/AlCe catalyst. The obtained results are interpreted on the basis of characterization studies, which reveal the impact of CeO_2 modification in conjunction with the reaction conditions on the physicochemical characteristics and de-N_2O performance.

Keywords: ion, bombardment, surface, treatment, nanocatalyst, cerium, oxide, Pt, nanoparticles

1 Introduction

Interface science is at the forefront in the development of new materials for advanced technological applications [1]. In particular, surface properties strongly influence catalysis which is essentially a surface phenomenon. One of the novel applications of ion beam irradiation includes the modification of the catalytic activity of solid catalysts [2]. In this study we evaluated the effect of ion irradiation on the catalytic properties of $Ce_{0.7}Zr_{0.3}O_2$ and the supported noble metal catalyst Pt/ $Ce_{0.7}Zr_{0.3}O_2$, which plays an important role in automotive exhaust control applications, among others.

2 Experimental/methodology

Industrial catalysts $Ce_{0.7}Zr_{0.3}O_2$ and Pt (1%w/w) /$Ce_{0.7}Zr_{0.3}O_2$ were bombarded with N^+ ions with a current density of 3.75 μA/cm^2. The effect on the catalytic properties is analyzed by Temperature Programmed Oxidation (TPO) and Reduction (TPR) experiments which were carried out on catalyst wafers (50-60 m3 $kg^{-1}h^{-1}$) in a flow infrared cell (293-823 K, 2000 ppm CO, CH_4, C_3H_6, C_6H_{14}, H_2 and 10% v/v O_2) connected to a quadrupole mass spectrometer (Omnistar, Pfeiffer) to detect both the adsorbed and gas species. High Resolution Transmission Electron Microscopy (HRTEM, TECNAI 30G^2) and X-Ray Photoelectron Spectroscopy (XPS, k-alpha ThermoScientific) were used for microstructural analyses.

3 Results and discussion

The differences in the catalytic activity of $Ce_{0.7}Zr_{0.3}O_2$ and Pt/ $Ce_{0.7}Zr_{0.3}O_2$ before and after the ion irradiation were evaluated performing TPO experiments of 2000 ppm CO, CH_4, C_3H_6, C_6H_{14} in 10 % O_2 in the range 293-823 K. It was noticed that $Ce_{0.7}Zr_{0.3}O_2$ bombarded catalyst achieved the 50% of conversion of the different species at temperatures (T50) which were roughly 20 K lower than the correspondent T50 values measured before ion bombardment. The Pt/ $Ce_{0.7}Zr_{0.3}O_2$ catalytic system showed as expected higher activity respect to the unmodified $Ce_{0.7}Zr_{0.3}O_2$ with significantly lower T_{50} values (70-90 K) due to the presence of the noble metal. The ion bombardment induced a further decrement of the T50 values of about 40 K. The T_{50} values of the representative pollutants are reported in details in Table 1 for both catalysts.

The higher catalytic activity of $Ce_{0.7}Zr_{0.3}O_2$ and Pt/$Ce_{0.7}Zr_{0.3}O_2$ catalysts after ion bombardment is strictly related to their enhanced reducibility, as shown by TPR experiments carried out using H_2 as a reductant. It was observed that $Ce_{0.7}Zr_{0.3}O_2$ catalyst treated with ion irradiation presents a remarkably higher reducibility respect to the unmodified catalyst. As a result, the peak of H_2 consumption was measured at 585 K, a temperature roughly 100 K lower than that reported for the corresponding non bombarded catalyst. In the presence of Pt, the

reduction was achieved at lower temperature (520 K) than on the bare support and the ion bombardment lead to a further decrement of the temperature linked with the maximum of the reduction peak to 340 K.

Table1 T_{50} values of representative pollutants combustion measurements

	$Ce_{0.7}Zr_{0.3}O_2$		$Pt/Ce_{0.7}Zr_{0.3}O_2$	
	non treated	bombarded	non treated	bombarded
T_{50} CO (K)	739	696	640	579
T_{50} C_3H_6 (K)	756	738	682	645
T_{50} C_6H_{14} (K)	764	754	693	660

The higher reducibility of both $Ce_{0.7}Zr_{0.3}O_2$ and Pt/ $Ce_{0.7}Zr_{0.3}O_2$ bombarded catalysts was also confirmed by FTIR study of H_2 reduction between 373 and 773 K. The evolution of surface hydroxyl species vibrational modes ν(OH) was used as probe of the surface oxidation state [3]. In particular, the band assigned to the hydroxyl group coordinated to two cations in close proximity with an oxygen vacancy (~3630 cm^{-1}) was observed to increase in intensity with the reduction temperature until 673 K and to be always more intense for the bombarded catalysts respect to the corresponding untreated ones. The results are in line with HRTEM analysis (Fig. 1) which revealed that the sample, after ion bombardment, is characterized by a uniform distribution of nanoparticles on the catalytic surface, as well as by the formation of atom vacancies and incomplete terraces. XPS clearly shows that the spectra, thus the associated microstructures, are modified after the bombardment. Local charges seem to be created, in line with the enhanced catalytic properties.

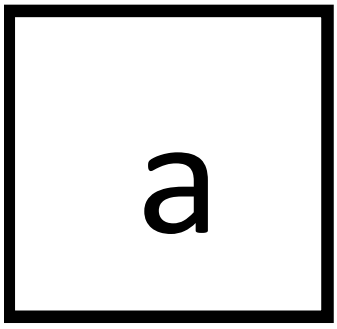

Fig.1 HRTEM characterization of Pt nanoparticles supported on $Ce_{0.7}Zr_{0.3}O_2$

Analogous results have been obtained from the study of alternative catalytic systems such as Pd/Al_2O_3 treated with the same ion bombardment protocol, which provokes a remarkable change in the particle morphology, as highlighted by both XPS and IR studies.

4 Conclusions

The present study revealed that ion irradiation significantly enhanced the catalytic activity and the stability of both $Ce_{0.7}Zr_{0.3}O_2$ and the $Pt/Ce_{0.7}Zr_{0.32}O_2$ catalysts and it suggests the feasibility of this method for the effective and controlled surface modification of several catalytic materials.

Keywords: platinum zeolite catalyst, polystyrene hydrocracking

1 Introduction

Diffusion limitations are common when working with polymers. In particular, we have shown that external mass-transfer can be controlled in catalytic polystyrene (PS) hydrocracking in the liquid phase to fuels, but the big size of polymer molecules limits their accessibility to the external catalytic surface[1]. Optimizing catalysts for this process, besides maximizing external surface[2], involves minimizing platinum content while maintaining enough hydrogenation activity. Thus, we studied in this work the effect of platinum content in Pt/Hβ catalysts on the catalytic performance in the process.

2 Experimental

Bifunctional catalysts: Five catalysts with nominal platinum content of: 0.1, 0.3, 0.5, 0.7 and 1 wt.% were prepared by ionic exchange[3] of tetraammineplatinum (II) nitrate (Alfa Aesar, 99.99%) on a Hβ zeolite (Zeolyst Corp. SiO_2:Al_2O_3 ratio of 25). 10 g of the powdered support were slurred in deionised water (1 L) and then heated to 353 K under continuous stirring and reflux, at pH=7, for 24 h. Afterwards, the solid was filtered, washed, dried (393 K, 12 h), calcined (823 K, 2 h) and reduced in hydrogen flow (800 K, 3 h). Characteristics of the catalysts such as: BET and external surface (N_2 physisorption, 77 K), acid strength (NH_3-TPD), Brønsted and Lewis acidity[4] (FTIR of absorbed pyridine (Py), 423 K), external acidity[5] (FTIR of adsorbed 2,6-di-*tert*-butylpyridine (DTBPy), 423 K), metallic content (ICP) and Pt dispersion (H_2 chemisorption and TEM), were measured.

Catalytic activity: PS hydrocracking in the liquid phase was studied, and the optimized operational conditions for a kinetic regime[1] were: 5% PS (M_W = 192,000 g·mol^{-1}, M_n = 120,000 g·mol^{-1}) solved in decahydronapthalene, 623 K, 180 bar of H_2, 1800 rpm, 2.36 g·L^{-1} of catalyst (average particle size 230 μm) in slurry, with an stirred autoclave reactor. PS conversion was evaluated by gel permeation chromatography (GPC) and the evolution was followed by assuming continuous distribution kinetics. Liquid and gas product selectivity was analyzed by gas chromatography with flame ionization detector (GC-FID)[2].

3 Results and discussion

The main properties of the catalysts are shown in Table 1. External surface area is around 200 m^2·g^{-1}, relatively independent of metallic content, as expected. Total acidity (NH_3-TPD) is nearly constant up to 0.7 wt.% Pt, acid strength slightly increasing with Pt loading. Higher Pt content produces a moderate decrease in total acidity and acid strength. Brønsted sites are majority up to 0.5 wt.% Pt, Brønsted to Lewis ratio increasing with Pt loading. Above 0.7 wt.% Pt, however, Lewis sites are majority and independent of Pt content. Probably, for high Pt loading, metal particles partially block pyridine access to micropores.

DTBPy molecule cannot enter small pores, and was used to estimate external acidity of the

catalysts. Hβ support with no metal was used as a reference with 100% accessibility[5]. Table 1 shows a significant decrease of accessible acidity with metal loading. Regarding metal dispersion, values around 60% were obtained, with relatively small values of Pt particle size in all the range (around 2 nm).

Table 1. Properties of the catalysts.

Catalyst	S, $m^2 \cdot g^{-1}$		NH_3, $\mu mol \cdot g^{-1}$				Py, $\mu mol \cdot g^{-1}$		Acces.	Pt	Disp.	d_{Pt}
	BET	Ext.	T	W	M	S	B	L	%	%	%	nm
01PtHB	425	172	463	183	224	56	284	204	67	0.1	58	1.9
03PtHB	468	198	461	182	229	50	249	172	41	0.23	36	3.0

Key to acidity: T, total; W, weak; M, medium; S, strong; B, Brønsted; L, Lewis; Acces., accessible.

Figure 1(a) shows initial reaction rate for PS hydrocracking with temperature for the different catalysts. Although higher metal loading produces higher rates, Figure 1(b) shows that TOF decreases with Pt loading, what is probably related to the higher accessibility of the acidic sites. Selectivity was checked to be hardly affected by Pt loading in the studied range.

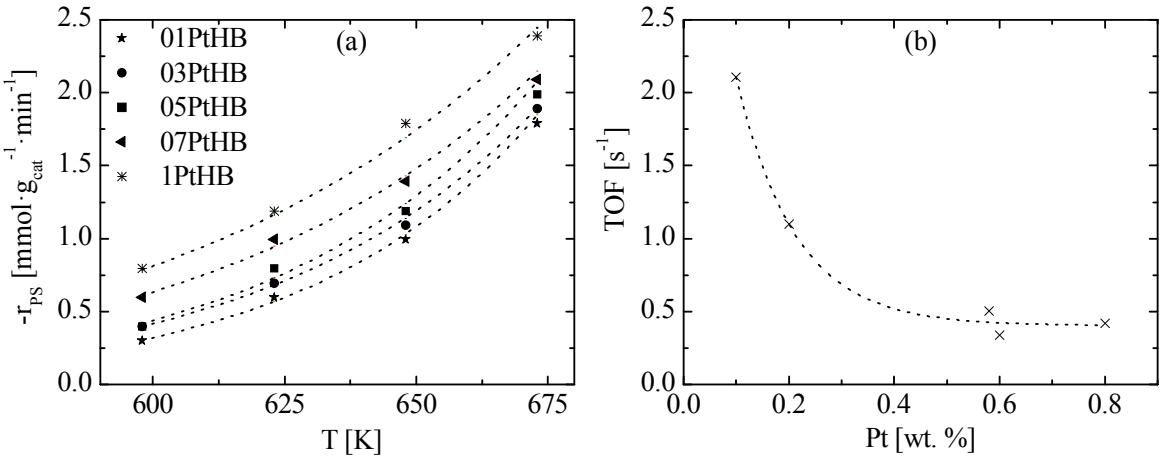

Fig. 1. Initial PS hydrocracking rate with temperature (a) and TOF values at 598 K (b).

4 Conclusions

PS hydrocracking to liquid fuels has been studied as a model reaction for plastic recycling, in the kinetic regime. A bifunctional 0.1 wt.% Pt/Hβ catalyst prepared by ionic exchange has proven to be adequate for this process: it produces good yields, with higher TOF and no relevant variation on the selectivity to the desired products.

Insights into the Elementary Kinetics of the Low-Temperature NO_x Reduction by H_2 on $Pt/WO_3/ZrO_2$ under Lean Conditions

Hahn C.*, Endisch M., Kureti S.

Technical University of Freiberg, Institute of Energy Process Engineering and Chemical Engineering, Chair of Reaction Engineering, Freiberg, Germany

Keywords: NO_x reduction by H_2, Pt catalyst, kinetic modelling, thermodynamic consistency

1 Introduction

For the removal of NO_x from the oxygen-rich exhaust of diesel engines, catalytic abatement technologies are applied since a couple of years implying the selective catalytic reduction by NH_3 and NO_x storage reduction catalysts. However, a constraint of these techniques is their limited efficiency below 175°C. For the NO_x reduction at low temperatures, the H_2-deNO_x reaction has been shown to reveal promising potential. But, classical Pt/Al_2O_3 catalysts perform in a narrow range from 50 to 150 °C only and they include considerable N_2O selectivity of about 80% [1]. Contrary, we recently reported on an advanced $Pt/WO_3/ZrO_2$ catalyst exhibiting high practical relevance. This catalyst showed marked efficiency between 50 and 450 °C and very low N_2O selectivity of about 10% [2].

2 Modelling

To unravel the improved performance of $Pt/WO_3/ZrO_2$ in the lean H_2-deNO_x this work addresses the elementary kinetic modelling. The model was developed based on a detailed reaction mechanism [2] as well as kinetic examinations conducted in a gradient-free loop reactor and implied a network of 48 elementary reaction described by Arrhenius-based rate expressions. Kinetic parameters were taken from literature [3] and were determined by fitting calculations and thermodynamic constraints. Pre-exponential factors of adsorption were estimated from the kinetic gas theory. Also, the kinetic parameters for adsorption and desorption of O_2 were deduced from independent TPD study [4].

3 Results and discussion

Selected fits of NO traces and calculated H_2O proportions are demonstrated in Figure 1 (left) showing satisfactory agreement with the experimental data. The kinetic model also provided simulation of the coverage of the Pt surface (Figure 1, right) showing that the active sites are predominantly covered by NO in the temperature range from 80 to 200°C. These results are in line with in situ DRIFTS studies previously reported [2]. The simulations additionally evidenced that the rate determining step of NO reduction is the dissociation of chemisorbed NO forming N and O surface species. The improved N_2 selectivity of $Pt/WO_3/ZrO_2$ was found to be associated with the relatively high surface coverage by N, which combines to yield N_2. As another consequence, the production of N_2O originated from the reaction of chemisorbed N and NO is suppressed. Furthermore, above 200°C, chemisorbed oxygen becomes the dominating surface species thus strongly inhibiting the NO dissociation resulting in drastic decrease in catalytic H_2-deNO_x performance.

The developed kinetic model was validated by simulating experiments with various feed contents. Additionally, the thermodynamic consistency of the model and the implemented kinetic parameters was proven by checking Gibbs free enthalpy of the surface reactions (Figure

2) [4].

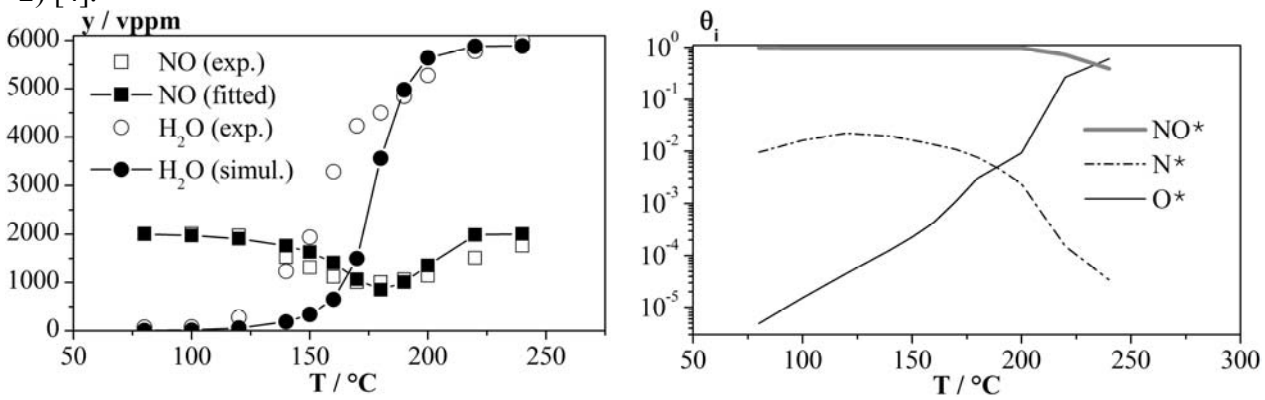

Fig. 1. Left: Fractions of NO and H_2O in H_2-O_2-NO_x reaction on $Pt/WO_3/ZrO_2$; right: simulated surface coverages. Conditions: $y(NO_x)$ = 2000 vpm, $y(H_2)$ = 6000 vpm, $y(O_2)$ = 6%, N_2 balance, SV = 77000/h.

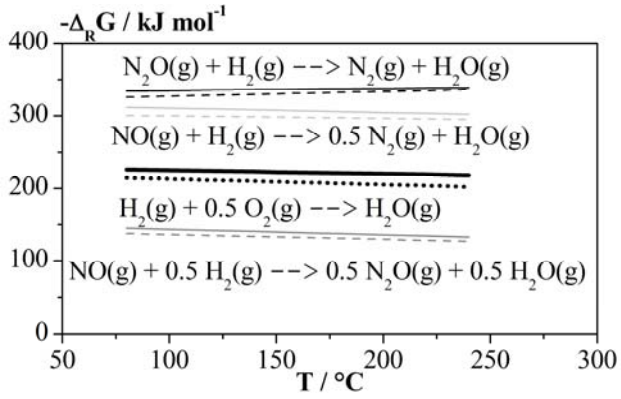

Fig. 2. Gibbs free enthalpy calculated with thermo-chemical data (solid lines) and kinetic parameters of the surface reaction on $Pt/WO_3/ZrO_2$ (dashed lines).

4 Conclusions

As a result of the elementary kinetic model, we conclude that the marked H_2-deNO_x performance and high N_2 selectivity of $Pt/WO_3/ZrO_2$ is related to the significantly lower energy barrier of the dissociation of chemisorbed NO as compared to Pt/Al_2O_3 [3]. This results in increased Pt coverage by N predominately evoking N_2 instead of N_2O [4]. These findings are in line with our recent in situ DRIFT spectroscopic studies [2] and allow the rational catalyst design in future work.

$VO_x/TiO_2/ZSM5$ Catalysts Activity for the Simultaneous Abatement of NO_x and PCDDs for MWI Plants

Gallastegi-Villa M.*, Aranzabal A., González Marcos J.A., González-Velasco J.R.

Department of Chemical Engineering, Faculty of Science and Technology, University of Basque Country, Bilbao, Spain

Keywords: NO_x, PCDDs, catalytic removal, VO_x, species, titania, zeolites

1 Introduction

VO_x/TiO_2 catalysts, specially ungraded with W or Mo oxides, have been developed for the NO_x selective catalytic reduction (SCR) with ammonia. They have also been reported to be efficient in the total oxidation abatement of dioxins (PCDDs).Therefore, the simultaneous removal of NO_x and PCDDs in the municipal solid waste incineration plants (MSW) by the catalytic technology is a highly interesting alternative to current non destructive methods.

The TiO_2 is reported to be the most active support due to the best dispersion of VO_x monolayer [1]. However TiO_2 shows low surface area, low resistance to sintering and high cost. Therefore, other supports are widely analyzed in the literature. Metal exchanged zeolites show high SCR activity and has recently gained interest as potential catalyst for the oxidation of chlorinated volatile organic compounds, due to their high selectivity towards total oxidation products [2]. Therefore, zeolites may be a suitable catalyst for the simultaneous removal of NO_x and PCDDs. Then, the present work is essentially devoted to the determination of $VO_x/TiO_2/ZSM5$ catalysts activity in the simultaneous removal of NO and 1,2-dichlorobenzene (o-DCB, taken as a model molecule for PCDDs). Moreover, the TiO_2 effect was analyzed by varying from 0 to 100%.

2 Experimental/methodology

$VO_x/TiO_2/ZSM5$ (V/xTi/Z, being x the TiO_2 mass fraction) catalysts were prepared by the wet impregnation method in two steps. Firstly, the desired quantity of Ti(V)butoxy dissolved on butanol was added to H-ZSM5. Them, after dried overnight at 110 ºC and calcined at 520 ºC for 3 h the desired amount of NH_4VO_3 to obtained 3% of V complexed with 2 moles of oxalic acid for 1 mole of V was impregnated. Finally, the samples were dried and calcined at 500 °C for 3 h (1 ºC·min-1). The catalysts were characterized by ICP, N_2 physisorption, XRD, UV-vis-NIR, NH_3-TPD and H_2-TPR. Catalytic tests were performed as light-off curve on fixed bed reactor (1.5 g) by feeding constant total flow of 2 $L_N \cdot min^{-1}$of simulated gas mixture representative of a MSW incinerator flue gas (100 ppm o-DCB, 300 ppm NO, 300 ppm NH_3, 10 % O_2, 10 % CO_2 and balance Ar).

3 Results and discussion

Fig. 1. shows o-DCB and NO conversions as a function of reaction temperature. V/Ti shows the highest conversion at lower temperature on both reactions, being T_{50} values 260 ºC and 150

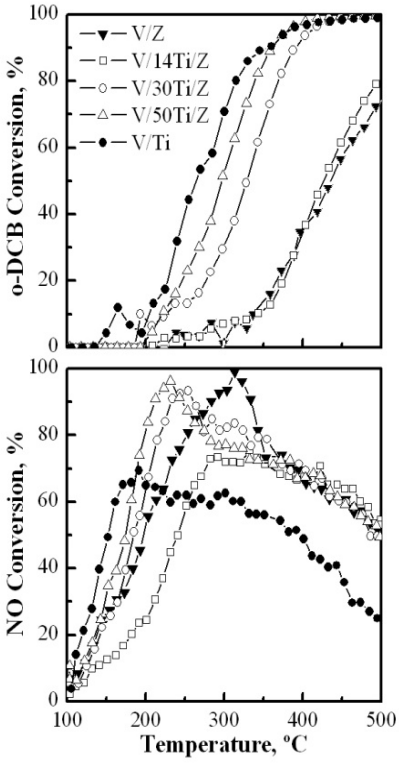

Fig. 1. Catalytic activity

ºC for o-DCB oxidation and NO reduction, respectively. The performance of V/Z catalyst is improved by the addition of more than 14 wt. % of TiO_2, by shifting the light-off curves to lower temperatures, and reaching higher NO conversion (>90%) in the range of temperature between 200 and 300 ºC, in comparison to the 70% conversion obtained by the V/Ti catalyst.

The better SCR performance of zeolites is due to their high surface acidity [3]. NH_3-TPD results show that the addition of TiO_2 to V/Z catalyst, reduce its surface acidity (0.79 mmol NH_3/g) about 21% (V/14Ti/Z), 30% (V/30Ti/Z) and 42% (V/50Ti/Z). Thus, the maximum NO conversion is also reduced as TiO_2 concentration increases.

Catalysts characterisation results suggest that the catalytic activity is related to the VO_x species. Fig. 2. shows UV-Vis spectra and their corresponding first-derivative curves to identify more easily the UV-Vis bands. The anatase (330 nm) and isolated VO_x species (370-410 nm) bands are observed over all the catalysts. However, V/14Ti/Z and V/Z catalysts also show a little band at 470 nm associated to d-d transition of V^{+5} ions in distorted octahedral symmetry. Moreover, V/T, V/50T/Z and V/30T/Z show a band centered at 668 nm related to the d-d transitions of V^{+4} in square pyramidal coordination.

H_2-TPR profiles confirm the formation of crystalline V_2O_5 over V/Z and V/14Ti/Z catalysts. Both show two reduction peaks whereas a unique reduction peak related to isolated VO_x species is obtained with V/T, V/50Ti/Z and V/30Ti/Z catalysts. However, XRD patterns show no diffraction peaks assigned to V_2O_5 species, evidencing its high dispersion and small particle size. XRD analyses confirm the addition of TiO_2 as anatase crystalline structure and the intensity of its diffraction peaks increase while the intensity of H-ZSM5 peaks decrease drastically as TiO_2 content increases. On the other hand, the reducibility of the V/Z is slightly improved by the TiO_2 addition and may be therefore is improve the catalytic performance [1]. Finally, the increase of the TiO_2 loading leads to a gradual decrease in BET surface area.

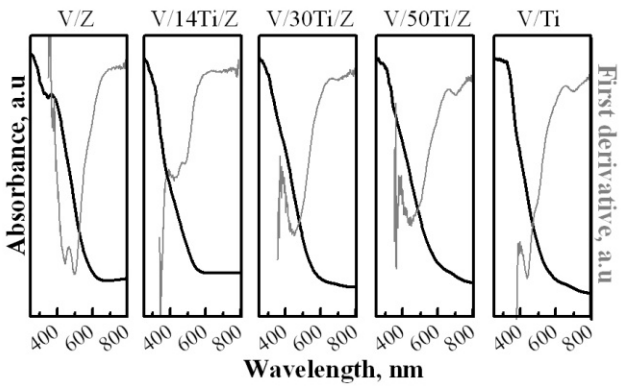

Fig.2. UV-vis spectra and the first derivative

4 Conclusions

It has been found that V/Ti/Z catalyst is valid for the simultaneous removal of NO and o-DCB. More than 14% of TiO_2 is necessary to avoid the formation of small V_2O_5 crystallites and thus obtain similar catalytic activity to V/Ti catalyst. Furthermore, the use of zeolite improves the SCR performance at high temperature.

Selective Oxidation and Hydrogenation of CO over Precious Metal Catalysts for Fuel Cell Applications

Mohamed Z.*, Singh S., Friedrich H.

School of Chemistry and Physics, University of KwaZulu-Natal, Durban, South Africa

* chemcatm@gmail.com

Keywords: PEMFC, WGS, PROX and SMET

1 Introduction

Increased attention has now turned to the development of fuel cell powered systems, because of their expectedly low environmental impact. Proton-exchange membrane fuel cells (PEMFCs) are, at this moment, the most studied type of hydrogen-based electrical power sources, both for static and mobile power applications [1]. PEMFCs use either hydrocarbons or hydrogen, which offers maximum power density, as the fuel.

The production of H_2 is usually accomplished by a series of catalytic reactions such as; steam reforming, partial oxidation and auto-thermal reforming which is followed by the water-gas shift (WGS) reaction [2]. Following the WGS reaction, however, the amount of CO generated is still too high, and it can be removed by the preferential oxidation (PROX) and/or by selective methanation (SMET) of CO to sub-ppm levels [3]. Catalysts for these reactions are usually noble based metals (Au, Pt, Pd, Ru, Rh and Ir). South Africa on the other hand possesses rich amounts of some of these noble metals including Pt, which will be focused on in this study.

2 Experimental/methodology

Pt supported on TiO_2 and ZrO_2 catalysts were synthesized using the wet-impregnation and deposition precipitation methods. These catalysts were characterized by; BET surface area and pore volume, inductively-coupled plasma optical emission spectroscopy (ICP-OES), powder X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX), HR transmission electron microscopy (TEM), temperature programmed techniques (TPR,TPO and TPD), and chemisorption analysis (CO, H_2 and O_2).The synthesized catalysts were tested using a custom built reactor for both PROX and SMET activity, within the stipulated PROX and SMET temperature ranges, with varying GHSVs. The effect of CO_2 and stability of the catalyst for these reactions were also investigated.

3 Results and discussion

Table 1. shows the surface characteristics of the supports and the deposited Pt catalysts. Following the deposition of Pt on both the supports a decrease in surface area and pore volume is observed. This suggests that the Pt particles are situated on the surface of these supports, but due to the low metal loadings these cannot be seen in XRD. This result is also evident that the Pt particles are well dispersed over the supports, which is usually a characteristic for materials prepared by this method of synthesis. SEM-EDS shown in Figure 1. confirms the uniform dispersion of these Pt particles over the supports and are confirmed by line scans . HRTEM results indicated particle sizes ranging from 10-15nm. Temperature programmed studies conducted showed that the materials are reduced at temperatures below 100 °C, and can be readily oxidized following their reductions.

Table 1. Surface characterization of Pt samples

Catalyst	BET surface area (m2/g)	Pore Volume(cm3/g)	Nominal wt% (%)	ICP wt% (%)
TiO_2	156	0.63	-	-
Pt-TiO_2	84	0.26	1	1
ZrO_2	97	0.32	-	-
Pt-ZrO_2	51	0.24	1	0.7

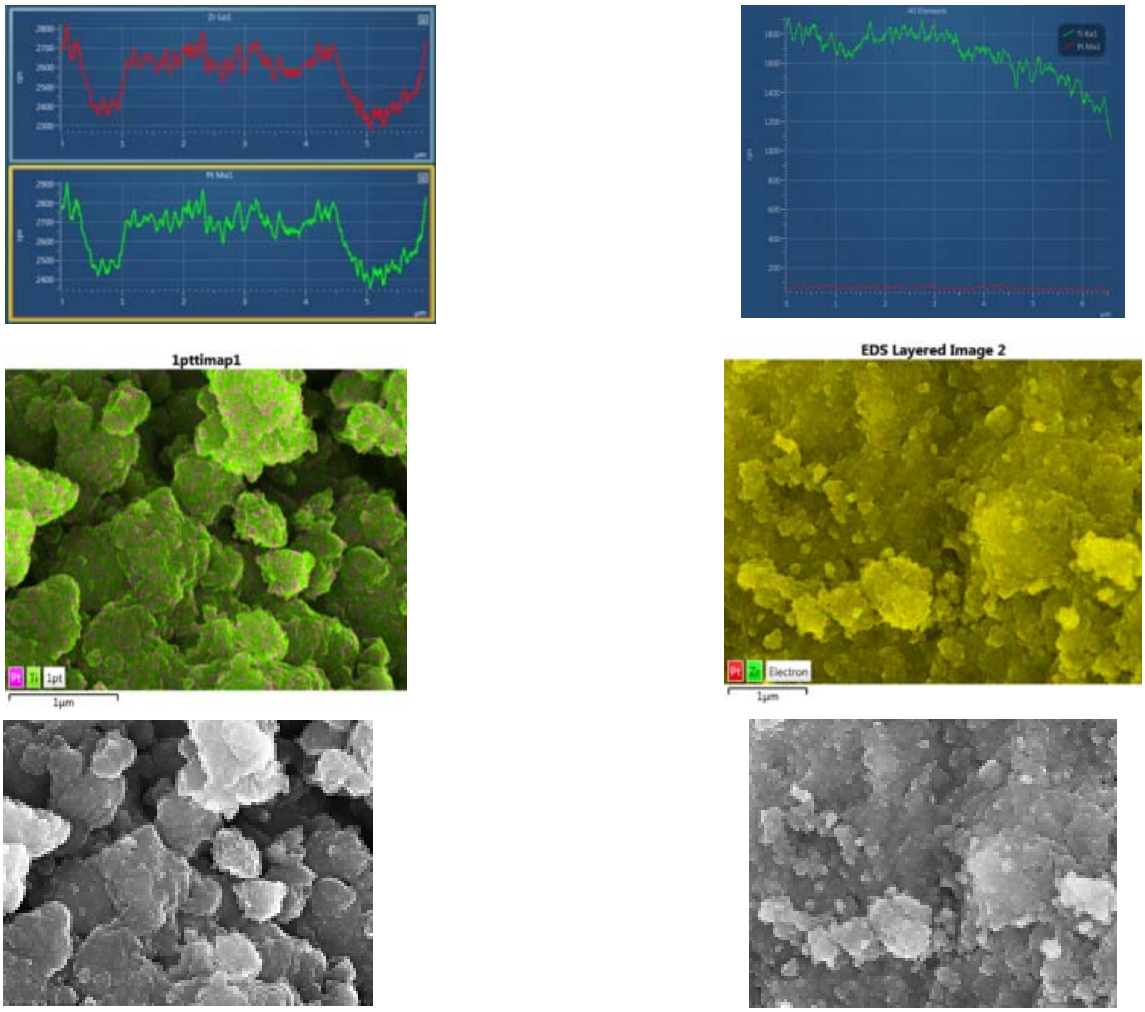

Fig. 1. SEM images of (A) Pt-TiO_2 and (B) Pt-ZrO_2 showing the metal dispersions using EDS mapping and line scans

4 Conclusions

Synthesis of these materials using different preparation methods gives rise to catalysts with varying metal dispersions and particles sizes. These could either enhance or retard their activity during the catalytic reactions.

Enhanced-SCR Reaction over a Commercial Fe-Zeolite Catalyst: Activity and Mechanism

Marchitti F., Nova I., Tronconi E.*

Dip.Energia, Politecnico di Milano, Milan, Italy

* enrico.tronconi@polimi.it

Keywords: ammonium, nitrate, DeNOx, Urea/NH_3-SCR, Fe-zeolite catalyst

1 Introduction

The new generation of Diesel engines, optimized for reduced fuel consumption, release exhaust gases at lower temperatures. In addition to the tightening emissions regulations, this demands for more effective aftertreatment systems in the 180-250°C T-window. Typically, a certain amount of NO is oxidized to NO_2 upstream of the SCR converter in order to enable the Fast-SCR reaction, i.e. the most effective NOx + NH_3 reaction. It is well known however that NO oxidation calls for a noble metal catalyst (DOC), which is costly and also prone to deactivation [1]. In order to overcome the DOC issues, an alternative solution is represented by the Enhanced-SCR (E-SCR) reaction, which involves spraying a NH_4NO_3 (AN) aqueous solution into the feed stream to the SCR converter. Promising results have been reported over commercial V_2O_5–WO_3/TiO_2 and Fe-zeolite catalysts [2-4]. The aim of this work is to elucidate the Enhanced-SCR mechanism, with a particular focus on the key steps responsible for the improvement of the DeNOx activity.

2 Experimental/methodology

Both the NH_3-SCR and E-SCR reactions were investigated over core samples (about 6 cm^3) drilled from a commercial Fe-Zeolite washcoated monolith catalyst supplied by Umicore. Isothermal steady-state and transient runs were carried out in the T=150–500°C and GHSV = 35000-100000 h^{-1} ranges. Typical feed concentrations of NOx (NO_2/NOx = 0-0.5) and NH_3 were 500 ppm, with 8 % O_2, 5 % H_2O v/v and N_2 as balance gas. In E-SCR runs an aqueous solution of AN was also dosed upstream of the SCR catalyst. The solution concentrations and the pump flow rates were selected to result in AN feed concentrations of 100-350 ppm. The concentrations of NO, NH_3, NO_2, and of N_2O in the outlet gases were continuously monitored by a UV-analyzer (ABB Limas 11HV) and a ND-IR-analyzer (ABB Uras 26).

3 Results and discussion

The potential of AN to improve the low temperature SCR activity was first investigated in steady state runs. Over the tested Fe-Zeolite the NO conversion at Standard SCR conditions (NO_2/NOx = 0) was definitely boosted by AN injection in the low-T range, with a maximum 80% improvement at 180°C upon addition of 250 ppm of AN, which resulted in a DeNOx activity very close to the Fast-SCR activity. A set of transient response (TRM) runs was then performed to address the mechanistic aspects of E-SCR. Figure 1A shows a transient run at 190°C: initially 500ppm of NO were fed to the reactor, and a steady state was reached after 500s. After 1175s from the NO feed, the pump was switched on to feed 5% H_2O + about 200ppm AN: the NO outlet concentration dropped suddenly to roughly 320ppm and, at the same time, NO_2 was formed, its outlet concentration increasing up to an average value of 180ppm. This clearly indicates that AN was able to oxidize NO to NO_2 quantitatively according to reaction (1). In a subsequent step the NH_3 feed was started and correspondingly all the NO_2 was consumed according to the Fast-SCR reaction (2). Figure 1A clarifies therefore that the

Enhanced-SCR reaction (3) results from the combination of reactions (1) and (2):

$$NO + NH_4NO_3 \rightarrow NO_2 + N_2 + 2H_2O \quad (1)$$
$$2NH_3 + NO + NO_2 \rightarrow 2N_2 + 3H_2O \quad (2)$$
$$2NH_3 + 2NO + NH_4NO_3 \rightarrow 3N_2 + 5H_2O \quad (3)$$

Accordingly, the AN promoting effect of E-SCR derives from the in situ generation of a stoichiometric amount of NO_2 via the very fast, direct oxidation of NO by AN, reaction (1). Figure 1B shows another transient run in which AN and ammonia were co-fed to the Fe-zeolite catalyst. In stage (1) the feed composition (AN + NO + NH_3) enabled the occurrence of the Enhanced-SCR reaction; at a given point (t = 9270s) NO was removed from the feed (stage (2)). In the absence of NO, after a transient, NH_3 recovered its feed level and was no longer consumed. Stage (2) in Figure 1B indicates that, at least under the tested conditions, there is no direct reaction between AN and NH_3. These results were confirmed at other operating conditions.

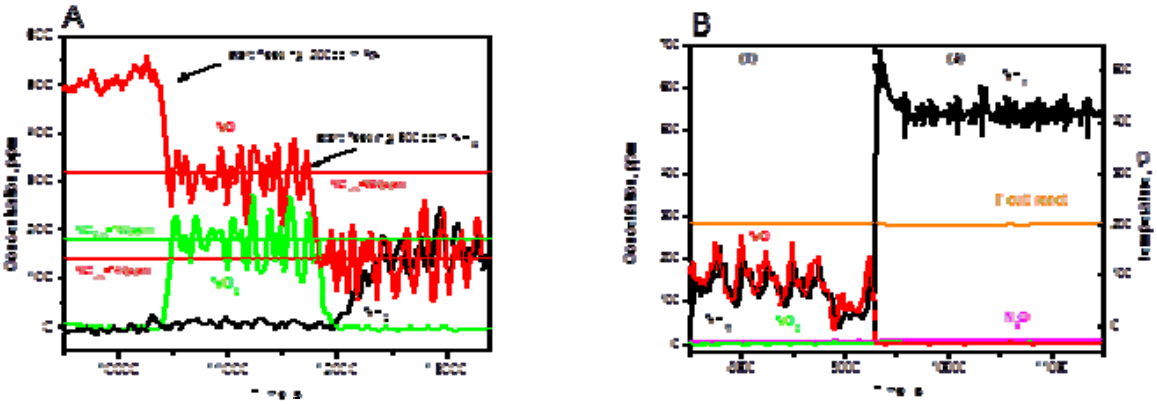

Fig. 1 A-B. Transient runs: A) T = 190°C, GHSV = 75,000 h^{-1}. Feed: AN = 0-200ppm, NH_3 = 0-500ppm, NO = 500ppm, H_2O = 5%(v/v), O_2 = 0%(v/v). B) T = 200°C, GHSV = 100,000 h^{-1}. Feed: AN = 200ppm NH_3 = 500ppm, NO = 0-500ppm, H_2O = 5%(v/v), O_2 = 8%(v/v).

4 Conclusions

Both transient and steady state runs confirm that AN injection can greatly improve the low-T deNOx activity of a Fe-Zeolite catalyst via the E-SCR reaction. Essentially, the promoting role of ammonium nitrate consists in generating NO_2 *in situ* via reaction (1). In presence of NH_3 such NO_2 can further react according to the very effective Fast-SCR reaction (2): this explains the greatly enhanced SCR activity. We show also that at low temperatures AN is preferably reduced by NO rather than by NH_3, and that N_2O formation is not incremented by AN injection.

Keywords: hybrid magnetic nanocomposites, catalytic wet peroxide oxidation (CWPO), 4-Nitrophenol

1 Introduction

Catalytic wet peroxide oxidation (CWPO) is a well-known advanced oxidation process for the removal of organic pollutants from industrial process waters and wastewater. Specifically, CWPO employs hydrogen peroxide (H_2O_2) as oxidation source and a suitable catalyst to promote its decomposition via formation of hydroxyl radicals ($HO^{\bullet}$), which exhibit high oxidizing potential and serve as effective species in the destruction of a huge range of organic pollutants . When an iron salt is used in CWPO, through the so-called Fenton process , high degradation rates of organic pollutants are obtained. However, the Fenton process usually requires a final separation step for Fe ions present in the treated water, increasing the treatment costs. More recently, carbon materials have been shown as active metal-free catalysts for the CWPO of organic pollutants in aqueous solutions; nevertheless carbon materials still show low catalytic activity in comparison with metal-based catalysts .

In the present work, nanostructured hybrid composites containing iron magnetic species and carbon xerogels materials are synthesized and tested as catalysts in the CPWO of highly concentrated 4-nitrophenol solutions (5 g L^{-1}). In this way, the synergistic effects that can arise from the combination of the high catalytic activity of iron oxide species with the flexibility for tuning the textural properties of carbon-based materials are explored. In addition, *in-situ* magnetic separation of the catalysts at the end of the treatment process is a further advantage.

2 Materials and methods

A carbon xerogel (CX) was prepared by polycondensation of resorcinol with formaldehyde (with a molar ratio of 1:2), following the procedure described elsewhere : 9.91 g of resorcinol were dissolved in 18.8 mL of deionised water, 13.5 mL of formaldehyde solution being then added and the pH adjusted to 6.1. The gelation step was allowed to proceed at 85 ^{o}C during 3 days, the recovered gel being afterwards grounded (particle sizes in the range 0.106-0.250 mm), dried in an oven (from 60 ^{o}C to 150 ^{o}C, defining a heating ramp of 20 ^{o}C day^{-1}) and pyrolyzed at 800 ^{o}C under a N_2 flow (100 mL min^{-1}) in a tubular vertical oven, resulting in CX materials. $CX/Fe_{0.05}$ was synthesized using the same procedure, except that iron (III) chloride hexahydrate was added to the resorcinol solution (considering a Fe/resorcinol molar ratio of 0.05) prior to formaldehyde. The solids recovered from pyrolysis were then washed with 1 L of an HCl solution (pH = 3) at 50 ^{o}C and dried overnight at 60 ^{o}C, resulting in the $CX/Fe_{0.05}$ materials.

CWPO experiments were conducted in a 250 mL well-stirred (600 rpm) glass reactor loaded with 50 mL of a 4-NP aqueous solution (5.0 g L^{-1}), during 24 h at T = 50 ^{o}C, considering a catalyst load = 2.5 g L^{-1}, and using the stoichiometric amount of H_2O_2 needed to completely

mineralize 4-NP (17.8 g L^{-1}). Pure adsorption runs and blank experiments, without catalyst, were also performed in order to discriminate the adsorption and non-catalytic components of 4-NP removal by CWPO, respectively.

3 Results and discussion

The ability of the magnetic composites to act as catalysts in the CWPO of 4-NP was evaluated. Comparisons between the removal of 4-NP by CWPO in the presence of CX and in a series of three consecutive runs using $CX/Fe_{0.05}$ are shown in Figure 1a. Non-catalytic removal of 4-NP is also shown for comparison. As observed, a marked increase in the removal of 4-NP is observed when using $CX/Fe_{0.05}$ as catalyst, even in its third consecutive reuse. In addition, adsorption of 4-NP on $CX/Fe_{0.05}$ was found negligible (ca. 9%). Therefore, $CX/Fe_{0.05}$ is univocally an active catalyst for CWPO of highly concentrated 4-NP solutions. Nevertheless, some Fe leaching was observed even at the end of the third run (4.8 mg L^{-1}). Bearing this in mind, the effect of the initial pH on the 4-NP removals and Fe leaching was assessed through an additional CWPO run performed without any pH adjustment. As observed in Figure 1b, the 4-NP removal decreased from 77% to 45% when the initial pH was not adjusted, whereas the Fe leaching dropped from 10.4 mg L^{-1} (at pH = 3) to 2.5 mg L^{-1}. In this way, further studies are now being conducted in order to maximize catalyst activity and minimize Fe leaching levels, through the synthesis of magnetic carbon xerogels with improved Fe dispersion and stability.

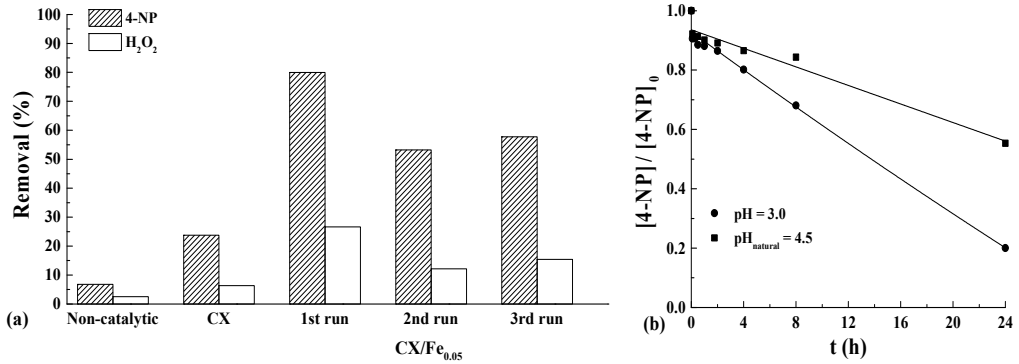

Fig. 1. (a) 4-NP and H_2O_2 removals obtained after 24 h in CWPO runs performed at pH = 3; (b) effect of the initial pH on the 4-NP removal by CWPO when using $CX/Fe_{0.05}$ as catalyst.

4 Conclusions

High catalytic activity is obtained when magnetic carbon xerogels are used in the CWPO of highly concentrated 4-NP solutions. Nevertheless, further studies are required in order to increase the catalytic stability of these materials.

Acceleration of Catalytic Ozonation of Ammonium Ion in Water over Cobalt Oxide Catalyst by Repeated Use

Mahardiani L.[1], Kamiya Y.[2*]

1 - Graduate School of Environmental Science, Hokkaido University, Sapporo, Japan
2 - Research Faculty of Environmental Earth Science, Hokkaido University, Sapporo, Japan

Keywords: ammonium ion, cobalt oxide, catalytic ozonation, wastewater treatment, repeated use

1 Introduction

Ammonium nitrogen (NH_3 and NH_4^+) in industrial effluent and household sewage and generated by intensive agricultural activities can cause eutrophication for aquatic ecosystem with serious consequences for drinking water sources and fisheries. Therefore, it is necessary to remove the ammonium nitrogen from water and preferably to decompose it into harmless compounds like di-nitrogen (N_2). Catalytic ozonation is an attractive method, in which ozone is utilized as an oxidant to decompose the ammonium nitrogen, because the reaction proceeds at ordinary temperature and pressure.

We have previously reported that Co_3O_4 was highly active and selective catalyst with low solubility for the catalytic ozonation of NH_4^+ in water [1]. Here we report on acceleration of the catalytic ozonation of NH_4^+ in water over Co_3O_4 catalyst by repeated use.

2 Experimental

Co_3O_4 was prepared from $Co(NO_3)_2$ by a precipitation method and calcined at 450°C for 3 h. Catalytic ozonation of NH_4^+ in water (NH_4Cl, 10 mmol L^{-1}) was carried out in a batch reactor at 60°C with vigorous stirring in a stream of O_2/O_3. For some experiments, an aqueous solution with high NH_4^+concentration (30 mmol L^{-1}) was used as a reaction solution. Concentration of NH_4^+ and NO_3^- were determined by using ion chromatographs. After the reaction, the catalyst was separated by filtration, washed with distilled water and dried overnight at 100°C. The spent catalyst was then reused for the catalytic ozonation of NH_4^+ under the reaction conditions similar to those for the first run. The reactions were repeated for several times.

3 Results and discussion

The conversion and selectivity to gaseous compounds for the catalytic ozonation of NH_4^+ over Co_3O_4 at 6 h for its repeated use are shown in Fig. 1. For comparison, the reaction over Al_2O_3, Mn_5O_8 and SnO_2, which also have low solubility for the reaction [1], were also carried out. The conversion of NH_4^+ for Co_3O_4 was increased by the repeated use with slight change in the high selectivity to gaseous compounds. Ammonium ion was completely decomposed after the second reuse of Co_3O_4. Meanwhile, for Al_2O_3 and Mn_5O_8, the acceleration was not observed by their repeated uses. As for SnO_2, the acceleration was observed for the repeated use but only little. Namely, enhancement of the catalytic activity by the repeated use was specific for Co_3O_4.

To investigate how far the catalytic activity of Co_3O_4 was enhanced by repeated use, the reaction over Co_3O_4 with high NH_4^+ concentration was repeatedly conducted. The conversion was increased from 31% for fresh catalyst to 81% for 9 time-reused catalyst. The selectivity was basically unchanged by the repeated use.

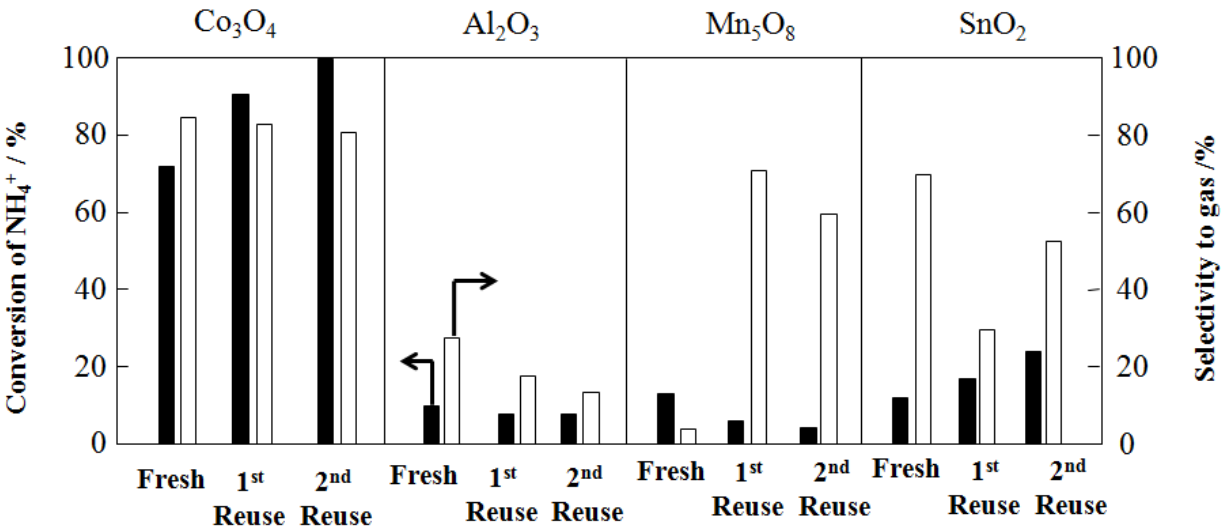

Fig. 1 Repeated uses of oxide catalysts for catalytic ozonation of NH_4^+ in water.

Characterization of physical and chemical properties for the fresh and spent Co_3O_4 catalyst was conducted to investigate what caused the acceleration effect. Surface area of catalyst was decreased by repeated use, and there was no difference in the crystalline structure between fresh and spent catalyst. However, there was a significant difference in NH_3-TPD profiles for the fresh and spent catalyst, where large peak was observed for the spent catalyst while fresh one gave only a small one. The formation of acid sites on the spent catalyst may be caused by the oxidation of catalyst surface with O_3 under the reaction conditions. Thus, we speculated that the formation of the acid sites, maybe Lewis acid site, lead to the acceleration of the reaction over Co_3O_4 by the repeated use due to effective activation of O_3 and/or NH_4^+ on them.

4 Conclusions

Catalytic activity of Co_3O_4 for catalytic ozonation of NH_4^+ was significantly enhanced by the repeated use of the catalyst even after 9 times-reuses. Crystalline structure and degradation of surface area of spent catalyst were not the reason for acceleration. The formation of acid sites by oxidation of catalyst with O_3 may lead to the enhancement activity of Co_3O_4.

Keywords: $DeNO_x$, $LaCoO_3$, $LaMnO_3$, $LaCo_xMn_{1-x}O_3$, perovskite

1 Introduction

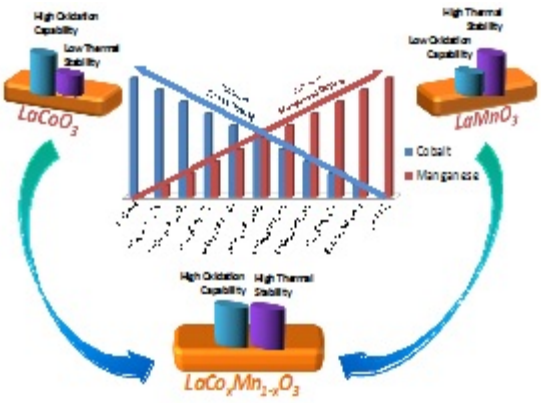
Air pollution due to the emission of toxic gases has serious adverse effects on human health. Recent studies point out that perovskite-based $DeNO_x$ catalysts can be considered as potential candidates that can create alternatives for high-cost Pt-based conventional NO oxidation catalysts [1]. In one of our recent studies, we reported that $LaMnO_3$ has much higher NOx adsorption capacity and higher structural stability as compared to $LaCoO_3$ [2]. La-based simple perovskites such as $LaMnO_3$ and $LaCoO_3$ can reveal either high thermal stability or high NO oxidation capability but do not possess both of these merits at the same time [1,2]. Along these lines, catalytic activity and thermal stability of La-based perovskites can be fine-tuned via designing hybrid $LaCo_xMn_{1-x}O_3$ perovskite structures (Figure 1). In the current work, hybrid perovskite structures were synthesized by varying Co and Mn loadings (x=0.1-0.9) and the structural characterization of these catalysts were carried out via XPS, XRD, ex-situ FTIR, BET and TEM techniques. In addition, the interaction of NO_x and SO_x species with the surface of the hybrid perovskite structures was also comprehensively elucidated at the molecular level by means of in-situ FTIR and TPD techniques.

2 Experimental/methodology

Detailed description of the synthesis protocol of the conventional $LaCoO_3$, $LaMnO_3$ catalysts has been reported in a former report of GM company [1]. The synthesis of the hybrid perovskites in the current work was carried out by co-precipitation of La, Mn and Co-based nitrate precursors via citrate method in the form of $LaCo_xMn_{1-x}O_3$ (x=0.1-0.9).

3 Results and Discussion

Figure 1 represents the schematic illustration of the synthesis protocol. Greater oxidation capability of $LaCoO_3$ perovskites are synergistically combined with the thermally stable $LaMnO_3$ perovskites through the formation of hybrid perovskites in the form of $LaCo_xMn_{1-x}O_3$. NOx adsorption and release properties of hybrid perovskites were analyzed via TPD. NO(g) desorption channels of the investigated materials during nitrate decomposition is shown in Figure 2. These TPD results indicate that NO desorption characteristics are strongly influenced by Mn/Co ratio in the catalytic formulation. Figure 2 suggest that Co-rich hybrid perovskites can store and release a significantly higher amount of NOx species where $LaCo_{0.8}Mn_{0.2}O_3$ catalyst seems to store the greatest amount of NOx as compared to all of the other hybrid and simple perovskites. The superior NOx oxidation and storage capability of the $LaCo_{0.8}Mn_{0.2}O_3$ system can be associated with the particular relative populations of mixed-valence Co and Mn sites (i.e. Co^{2+}/ Co^{3+} and Mn^{2+}/ Mn^{3+}) in the hybrid perovskite unit cell, presence of substitutional and/or interstitial defects as well as relative density of oxygen vacancies on the hybrid perovskite surface.



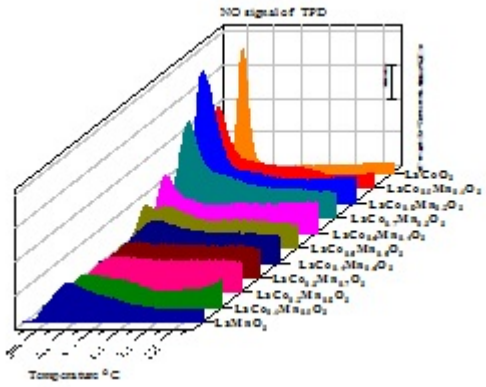


Figure 1: Material design strategy for the synthesis of hybrid perovskites.
Figure 2: NO(g) TPD profiles of H_2 pre-treated perovskites.

Furthermore, nature of the NOx (i.e. nitrite, nitrate) or SOx (sulfite, sulfate) species formed during the adsorption of NO_2 or SO_2+O_2 on the hybrid perovskites were investigated via in-situ FTIR in comparison to the conventional perovskites (i.e. $LaCoO_3$ and $LaMnO_3$). The interaction of the adsorbed NOx and SOx species with H_2 and their corresponding resistances against reduction was also studied via in-situ FTIR. Thermal sulfur regeneration of the hybrid perovskites after sulfur-poisoning was also investigated via TPD experiments.

4 Conclusions

In the current work, a novel synthesis strategy has been utilized in order to design novel hybrid perovskite structures that can combine unique functional characteristics of different conventional perovskite structures within a single catalytic architecture. Our results indicate that through this novel approach, NOx/SOx oxidation, adsorption, storage and release properties of hybrid perovskite architectures can be fine-tuned in an attempt to obtain next generation Pt-free DeNOx catalysts not only revealing superior activity but also possessing enhanced stability.

Keywords: V_2O_5-WO_3/TiO_2 catalyst, NH_3-SCR, NH_3-oxidation, indirect kinetic scheme, kinetic analysis

1 Introduction

NH_3-SCR is the state of art technology for NO_X abatement from power plant flue gases. The reaction (NH_3+NO+1/4 O_2→N_2+3/2H_2O) involves a 1 to 1 consumption ratio, but full-scale reactors typically operate at NH_3/NO inlet ratios of 0.8, in order to keep NH_3 slip below 2 ppm. Increasing the NH_3/NO inlet ratio (High Efficiency SCR process) and adding an extra catalyst layer able to efficiently convert the unreacted NH_3 to N_2 could be a strategy to enhance the NO_X abatement while maintaining NH_3 slip under this limit. This configuration is successfully applied in automotive SCR after-treatment systems [1]. In this work, the kinetics of the NH_3/NO/O_2 reacting system over V_2O_5-WO_3/TiO_2 catalysts was studied under conditions of NH_3/NO ratio ≥ 1 and temperature up to 400°C, where some ammonia oxidation is expected.

2 Experimental/methodology

A high vanadia load (3% w/w) catalyst was prepared and tested in fine powders in a quartz-diluted fixed-bed microreactor. NH_3-SCR tests were carried out on a catalyst bed of 30 mg, a total flow rate of 650 cm^3/min (NTP), a gas mixture consisting of 30 ppm NO, 2% H_2O, 3.5% O_2, in He; NH_3 concentration was set at 33 or 150 ppm. NH_3 oxidation was also tested under the same operating conditions, but in the absence of NO, at varying NH_3 concentration. Data were quantitatively analyzed by a pseudo-homogeneous 1D reactor model accounting for the possible impact of intraporous mass transfer limitations within the catalyst particles

3 Results and discussion

Figure 1 shows in symbols the experimental NO (panel a) and NH_3 conversion (panel b) obtained in NH_3-SCR tests performed over the home-made catalyst. In the low temperature window, where the process was uniquely controlled by the kinetics of the SCR reaction, NO conversion increased with increasing NH_3 inlet concentration. Despite the excess of NH_3, the low concentration of reactants exalted the kinetic dependence on NH_3 surface coverage. The data collected at temperatures below 300°C were used to fit the parameters of an Eley-Rideal rate expression ($r_{SCR} = k_{SCR}C_{NO}\theta_{NH3}$), wherein ammonia adsorption was described by adopting the same coverage dependent heat of adsorption of ammonia, independently estimated by Lietti et al. [2] in previous studies. Above 325°C, NO conversion passed through a maximum at increasing temperature (also observed in [3]), as commonly observed in SCR tests at the onset of ammonia oxidation; however, since the experiments were performed under excess ammonia, the high temperature decrease of NO conversion could not be attributed to a lack of surface NH_3. The experiments were thus interpreted as the evidence of an unselective NH_3-oxidation route, giving rise to some NO production (NH_3+5/4O_2→NO+3/2H_2O).

NH_3 oxidation was then studied by dedicated tests; Figure 2 reports in symbols the

measured conversion of NH_3 (panel a) and the corresponding outlet concentration of NO (panel b). NH_3 conversion decreased with increasing inlet concentration: data were in fact well described by a simple rate expression of the form: $r_{Ox\text{-}NH3} = k_{Ox}\theta_{NH3}$, which again incorporated the same coverage-dependent heat of adsorption derived in [2].

However, by assuming an indirect reaction scheme, wherein NH_3 oxidation leads to the formation of NO which in turn prompts the NH_3-SCR reaction, a very nice description of the results (conversion and product distribution) was obtained, as shown by the solid lines in Figure 2). The scheme proposed was validated by simulating the SCR tests over the entire temperature range. As shown in Figure 1 by the solid lines, a very satisfactory match was found; notably, the calculated treads in Figure 1 are pure predictions at temperatures above 300°C.

The kinetic investigation was extended to commercial catalysts with low and medium V-loads. On these catalysts the NH_3-SCR tests did not show provide clear evidence for NH_3-oxidation and NH_3-oxidation tests showed above 95% selectivity to N_2. However, a quantitative analysis based on the independent estimate of the intrinsic rate of NH_3-SCR, showed that the two-step kinetic scheme is fully in line with the observation of only few ppm NO slip in the NH_3-oxidation tests.

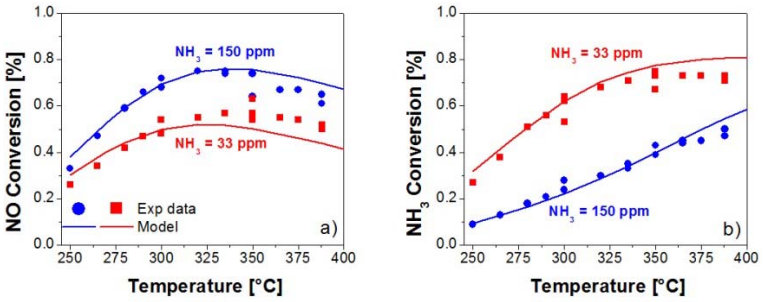

Fig. 1. Measured and calculated NO conversion (panel a) and NH_3 conversion (panel b) in SCR tests

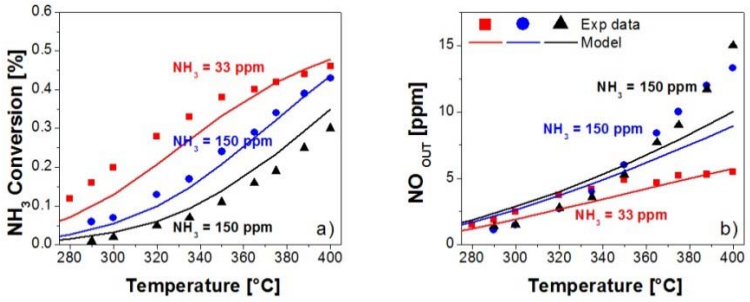

Fig. 2. Measured and calculated NH_3 conversion (panel a) and outlet NO concentration (panel b) in NH_3-ox tests.

4 Conclusions

The results of this study give new perspectives to the design of High Efficiency SCR reactors, operating at NH_3/NO close to 1. The impact of the rate and stoichiometry of NH_3 oxidation herein developed could be crucial on the final performance of the reactor (NO conversion and NH_3 slip); its accurate description is a pre-requisite for correctly estimating the final composition of the gas stream, and thus addressing on a truthful basis the design of an additional NH_3-SCO (Selective Catalytic Oxidation) bed layer.

Synthesis and Properties of Silver-Containing Photocatalytic Systems on the Base of Titania

Vodyankin A.A.*, Nikitich M.P., Pasalskaya K.O., Vodyankina O.V.

Tomsk State University, Tomsk, Russia

* orzie@mail.ru

Keywords: photocatalysis, titania, silica, photoreduction, silver

1 Introduction

Photocatalytic processes have become quite actual in the recent time due to the increased interest in energy-saving technologies and effective oxidation of organic pollutants. Titania is generally considered the most popular material for photocatalysts due to its high stability, relatively cheap price and noticeably higher photoactivity [1]. Besides, the addition of small-sized silver particles to titania surface has been found to improve the photocatalytic properties of samples due to the formation of Schottky barrier responsible for lowering the rate of exciton recombination, influence on the band gap characteristics and general affinity of silver to oxidation processes [2, 3]. Moreover, the addition of silver particles to small clusters of anatase can induct a notable sensitizing effect, increasing the radiation absorbance in the visible spectrum. The purpose of the present work is to create silica-supported catalysts with anatase clusters and silver nanoparticles and to investigate the influence of the Schottky barrier on the photocatalytic properties of the prepared samples due to the electron-hole separation on the border between the metal particle and semiconductor.

2 Experimental

In the following study the samples used represent pure titania (Degussa P25), modified titania/silica and titania/alumina, with all of them also promoted with silver nanoparticles. The supported TiO_2 silica-based samples were prepared by grafting technique using tetraisopropylorthotitanate (TTIP) as a precursor, while the addition of silver was made by photoreduction [4] and impregnation methods. The amount of titania was varied approximately from 1 to 6% for the supported samples. The SiO_2 support prepared by sol-gel method was used according to [5]. All of the prepared catalysts were examined by XRD, FTIR, UV-Vis spectroscopy, TEM, AES, and Brunauer–Emmett–Teller method, also being tested in a model photocatalytic reaction, namely the degradation of methylene blue.

3 Results and discussion

The supported TiO_2/SiO_2 samples prepared by grafting have shown the presence of both anatase and amorphous titania as it is demonstrated by the results of XRD analysis. According to the FTIR data, the titanium atoms are chemically bound to the silica surface via Si-O-Ti groups. UV-Vis spectroscopy has also demonstrated a peak of plasmon resonance at ~535 nm in the silver-containing catalysts prepared by photoreduction method and a notable absorbance shift towards the UV region most probably due to the increase of the titania band gap length after the addition of silver.

The relative photocatalytic constants of the model photocatalytic reaction of methylene blue decomposition for all samples are shown in Fig. The highest photoactivity is demonstrated by the sample containing 6% wt. titania and 0.5% wt. silver added via photoreduction, most likely due to the expected effects of silver influencing on the properties of titania being an active component in the reaction. It should be also noted that unlike the $Ag/TiO_2/SiO_2$ series, the

titania-silica samples without Ag don't show the same correlation of the amount of active component and photocatalytic activity. This indicates the specific behaviour of the support (silica) depending on the properties of the loaded titania and photodeposited silver particles as well. Besides, a considerably high activity is shown by one of supported silver-titania samples with the lowest amount of silver. This can be due to the specific properties of dispersed silver, like both the particle size and their shape.

It should be noted that the activity increase is observed both for unsupported and supported TiO_2 catalysts with addition of Ag. One of the reasons of this is the O^- anion radical formation on the Ag particle – TiO_2 interface border. Further work is in progress to clarify this matter.

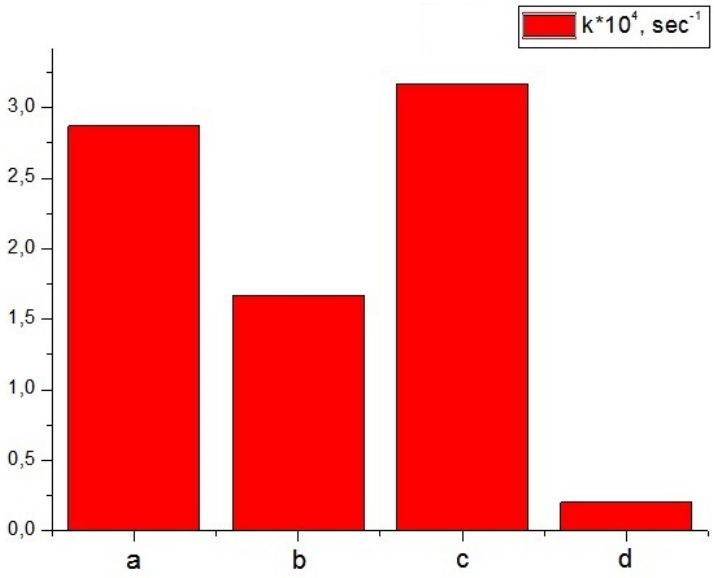

Fig. Relative constants of photocatalytic degradation of methylene blue for the tested samples: a) 0,5% Ag/TiO_2, b) 6% TiO_2/SiO_2, c) 0,5% Ag / 6% TiO_2 / SiO_2, d) TiO_2 Degussa P25.

4 Conclusions

The silver particles dispersed on the surface of both pure titania and titania/silica grafted systems do increase the photocatalytic activity of the samples, not influencing on the relative surface area.

The grafting technique responsible for the preparation of titania/silica systems also seem to increase the photocatalytic activity of the samples in the model reaction. The best photoactivity in the testing reaction is shown by **0.5 % Ag / 6% TiO_2 / SiO_2** catalyst.

Epoxidation of Fatty Acid Methyl Esters of Plant Oils with Hydrogen Peroxide

Voronov M.S., Sapunov V.N., Alexandrova J.V., Kulazhskaya A.D.*

Mendeleev University of Chemical Technology of Russia, Moscow, Russia

* vms90@rambler.ru

Keywords: epoxidation, ion exchange resin, fatty acid methyl esters, peracetic acid, hydrogen peroxide

1 Introduction

Currently epoxidation of vegetable oils and their derivatives is carried out with solutions of peracetic acid generated *in situ* from an aqueous solution of acetic acid and hydrogen peroxide in the presence of acidic catalysts such as ion exchange resins [1, 2, 3, 4]. However, the presence of the three-phase system complicates the mathematical description of the epoxidation process, and reduces the lifetime of the catalyst due to mechanical damage.

The aim of this study was to simplify the epoxidation process by separate production a solution of peracetic acid flowing solutions of acetic acid and hydrogen peroxide through a fixed bed of catalyst (*ex situ*), and following epoxidation of fatty acid methyl esters. A further object is to compare the efficiency of two processes epoxidation.

2 Experimental procedure

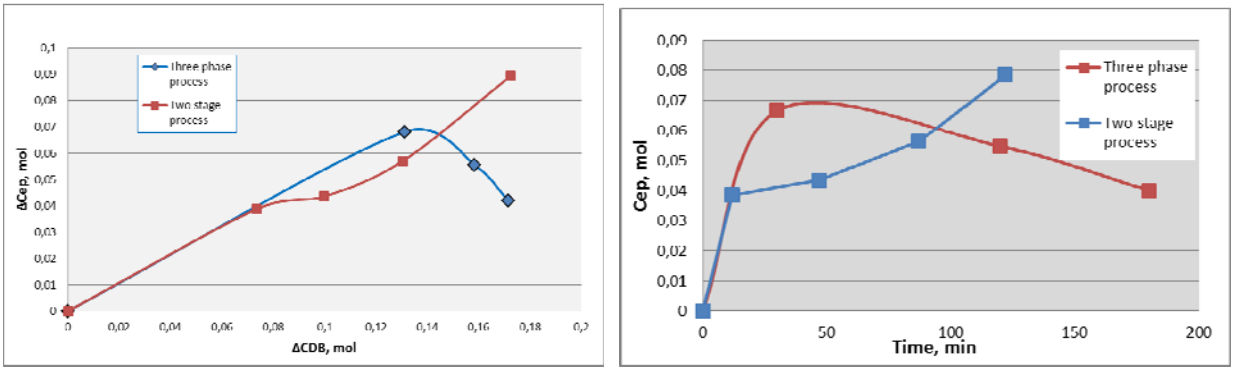
Epoxidation *in situ* is carried out in a glass reactor in the presence of cation exchange resins Amberlyst 15 Dry. The reactor is charged fatty acid methyl esters, the catalyst and acetic acid, and then with stirring is added dropwise an aqueous solution of 37 wt% hydrogen peroxide during 2 minutes. The reaction time was 3 hours.

In a two-stage process, at first, the solutions of hydrogen peroxide and acetic acid is passed through a fixed bed of the catalyst at 50 ° C and then prepared solution is added into a glass reactor with previously loaded fatty acid methyl esters, equipped with a jacket and a reflux condenser. Epoxidation process carried out in thermostatically controlled conditions (50 ° C). Further, separation of layers was carried out, and the aqueous phase was again passed through a fixed catalyst bed. There were four such cycles with different times of reaction epoxidation.

The concentration of peracetic acid and hydrogen peroxide was determined by the method described in [5]. The content of epoxides was determined by gas-liquid chromatography.

3 Results and discussion

Comparative characteristics of the two methods is shown in the example of the epoxidation reaction of methyl esters of fatty acids of rapeseed oil at molar ratio double bonds: acetic acid: hydrogen peroxide = 1 : 4.7 : 1.7, with 10 % by weight of aqueous phase ion-exchange resin Amberlyst 15 Dry.



(a) (b)

Fig. 1. The dependence of selectivity of epoxides (a) and time dependence of the yield of epoxides (b) in comparison of two methods of epoxidation.

Two stage process shows greater selectivity of epoxides compared with a batch process. Reuse of the aqueous phase in the process reduces the actual time the epoxidation, catalyst does not reduce its activity and does not wear out.

4 Conclusions

Thus, comparison of the two methods of epoxidation of the fatty acid methyl esters of vegetable oils with peracetic acid showed the greatest selectivity for the process related to reusing the aqueous phase. The method of separate preparation of epoxidizing agent can significantly reduce the overall process time and simplify its modeling.

Mesoporous Nanomaterials Based on Ceria: Synthesis and Catalytic Application

Zagaynov I.V.[1*], Liberman E.Yu.[2]

1 - A.A. Baikov Institute of Metallurgy and Materials Science, Moscow, Russia
2 - D. Mendeleev University of Chemical Technology of Russia, Moscow, Russia

* igorscience@gmail.com

Keywords: ceria, mesopores, solid solution, CO oxidation

1 Introduction

Nanoscale ceria is very attractive for TWC, SOFC, etc. Doped CeO_2-materials are considered as more promising solid solutions for use in these goals. The introduction of smaller isovalent non-reducible cations like Zr^{4+} and Ti^{4+} into the ceria lattice enhances OSC by creating intrinsic oxygen vacancies thereby increasing the oxygen mobility by facilitating the Ce^{3+}/Ce^{4+} redox process. Whereas doping of aliovalent non-reducible cations (Gd^{3+}) into the ceria lattice enhances oxygen storage capacity (OSC) mainly through the extrinsic oxygen vacancies. Recently, the use of variable valence dopants into ceria lattice has attracted much attention. It is known that the properties of ceria materials are dependent on the initial powder properties such as homogeneity, particle size, porous structure, and phase purity. It is clear that the quality of the synthesized powder changes with the preparation method. However, the simplest method for production of nanoscale ceria, especially for catalytic applications, is necessary to be used for obtaining a large quantity of intermediates. Among them, the most suitable and simplest method is co-precipitation with ultrasonic treatment (sonochemical method). Ultrasound irradiation can induce the formation of particles with a much smaller size and higher surface area than those reported by other methods and this technique has good reproducibility.

2 Experimental/methodology

Cerium (III) nitrate, zyrconyl nitrate, gadolinium nitrate, and titanium (IV) chloride were used as metal precursors. Appropriate amounts of salts were dissolved into 500 mL distilled water containing of nitric acid (pH=2) to give final concentrations of 0.04 M. Then, deposition was carried out by addition of aqueous ammonia at 30°C under stirring to reach pH 10. Sonication was used during dissolution of salts in distilled water (10 min), and after receiving the sediment (10 min). The resulting precipitate was filtered, washed with distilled water, dried at 150°C for 12 h, and calcined in static air at 500°C for 1 h in a muffle furnace. To study the composition, structure, and morphology of the samples a range of modern instrumental techniques was used [1].

3 Results and discussion

Single-phase material having the fluorite structure solid solution of CeO_2 ($Gd_xZr_yTi_zCe_{1-x-y-z}O_2$), wherein the cation-dopants (Gd^{3+}, Zr^{4+}, Ti^{4+}) is distributed throughout ceria, was obtained. Zr enters deep into the crystal lattice of ceria, Gd and Ti largely located in the surface planes of the crystal lattice. Thus, a substitutional solid solution with selective cation-dopants position was synthesized.

It has been found that the crystallite size was not dependent on the type and quantity of dopant and was 9-10 nm, and specific surface was about 85 m^2/g.

Obtained catalysts were investigated in CO oxidation reaction, using modeling mixture consisted of a) $CO-O_2-N_2$, b) $CH_4-CO-O_2-N_2$. It was shown that these composites are highly efficient catalysts for the oxidation of CO and preferential oxidation of CO [2].

4 Conclusions

Therefore, using such mesoporous system in the oxidation processes, would eliminate a number of problems: 1) The high temperature conversion; 2) Low stability and short lifetime of the catalyst; 3) Low amount of active surface oxygen and oxygen storage capacity (OSC).

Keywords: benzene, ruthenium, hydrogenation selectivity, benzoperene, hydrogen

1 Introduction

Creation of new catalysts for selective hydrogenation of benzene stood before us with the problem of complete removal of benzene from gasoline. It is known that the incomplete burn of gasoline containing benzene form a strong carcinogen benzopyrene in the exhaust gases, therefore, on the Euro standard, its content should not exceed 1%. For the adoption of the new requirements to reduce the benzene content of 0.1% is no technology to achieve them. Creating the selective hydrogenation catalysts of small amounts of benzene conversion can fully open towards this condition. Despite numerous studies of the hydrogenation of benzene, is still not established a selective hydrogenation catalyst in the presence of other aromatic compounds. We have previously [1] have been developed rhodium catalysts on carbon (sibunite, CAU, BAU) which spend small amounts of selective hydrogenation of benzene with full conversion. In [2] were obtained bimetallic Rh-Au catalysts siral synthetic aluminosilicate-40. As carriers there were tested activated carbons were prepared from apricot kernels and rice husk [3].

In the present report are available ruthenium catalysts on birch charcoal (BAU), which has a large surface area and high mechanical strength.

2 Experimental/methodology

Experiments were carried out in an autoclave, which allows maintaining a constant temperature and hydrogen pressure of 5 to 100 bar, equipped with a turbine agitator and sampler inlet of the reaction, and also allows to measure the amount of hydrogen absorbed. Catalysts were prepared by tank water metal carrier after necessary processing reduced in a stream of hydrogen in the temperature range 250-300^{0}C. The reaction products and starting compounds were analyzed by GLC. Catalysts have been verified by complexes of physico-chemical methods.

3 Results and discussion

Ruthenium has been applied to the activated carbon BAU (birch activated carbon), with a surface area up to 1000 m^2/g. Figure 1 shows the kinetic curves of Comparative hydrogenation of benzene, toluene, and cumene. If the hydrogenation of benzene is at 8-0 ml/min and the absorbed hydrogen amount, calculated on the H_2 uptake 1200 ml, when introducing the hydrogenation of toluene and cumene practically do not react. Absorbed no more than 50 ml of hydrogen 3% Ru / BAU is exceptional hydrogenation of benzene and toluene and cumene are not hydrogenated. At 1% Ru / BAU observed several different picture hydrogenation of toluene at speeds three times lower than that of benzene, and cumene in these conditions, virtually no hydrogenated. The selectivity of the hydrogenation of benzene to 3% Ru / RAU is 98%, 1% Ru / RAU does not exceed 70%. Determined by the order of the reaction by reacting components and other kinetic parameters.

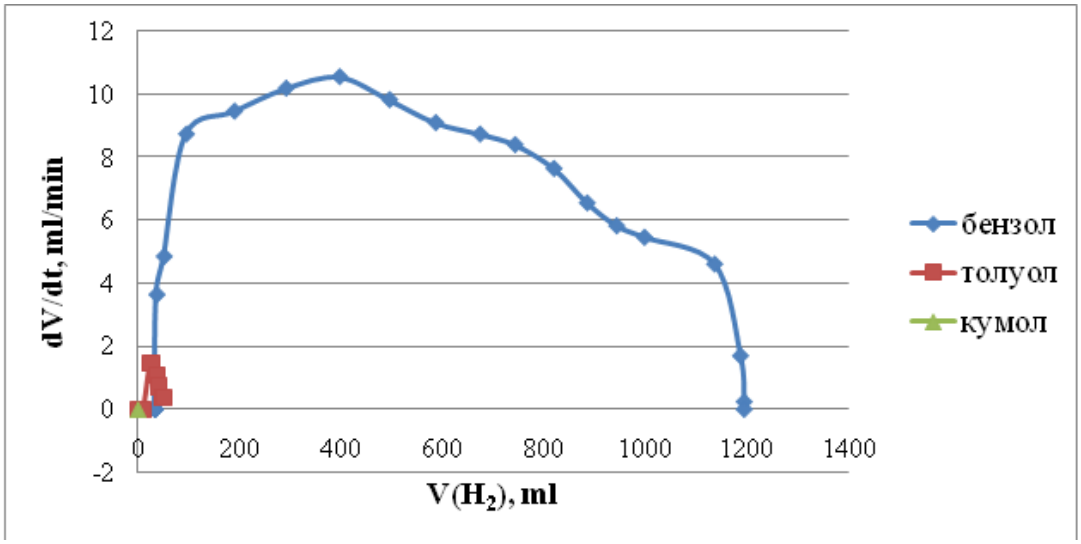

Fig. 1. Hydrogenation of aromatic compounds of 3% Ru / RAU in ethanol at 80° C and 4.0 MPa.

The selective effect of the catalyst is an unknown function, as different content ruthenium catalyst has a strong influence on the selectivity. We have previously shown [1-4] that the selectivity of the hydrogenation of benzene on a rhodium catalyst has an exceptional impact on the presence of the surface of the charged form of rhodium metal that was shown by XPS. Effect of ruthenium on the surface of BAU gives grounds to assert that there is a more subtle and unidentified law.

Utilizing Water as the Oxygen Atom Source: Catalytic Formation of Lactams From Amines

Khusnutdinova J.R.[1], Gellrich U.[2], Milstein D.[2*]

1 - Okinawa Institute of Science and Technology Graduate University, Okinawa, Japan
2 - Department of Organic Chemistry, Weizmann Institute of Science, Rehovot, Israel

Keywords: pincer, ruthenium, water, lactams, amines, dehydrogenation

1 Introduction

Utilizing water as an inexpensive and "green" reagent and solvent is of high practical importance for developing new environmentally friendly transformations in organic synthesis. This work will focus on developing a new atom-economical approach to dehydrogenative transformations in water catalyzed by the Ru pincer complex. In particular, we were able to develop a novel method for the synthesis of lactams directly from amines in the absence of oxidants, using water as the only reagent and a source of oxygen atom in the amide group [1]. This transformations is accompanied by the formation of H_2 gas as the only by-product, thus providing an ultimately atom economical and "wasteless" way for lactam synthesis. This is advantageous compared to other existing methods for lactam formation that typically involve the use of strong oxidants such as PhIO [2], ^{t}BuOOH [3], $RuO_2/NaIO_4$ [4] that also lead to the formation of stoichiometric waste products. In this report, we will focus on the mechanistic studies of the catalytic system through a combined experimental and DFT study.

2 Experimental

All operations were performed in a nitrogen-filled glove box or using Schlenk technique. The complex **1** was prepared as described previously [5]. General procedure for catalytic reactions: a 50 mL pressure tube was charged with pyrrolidine (1 mmol), **1** (10 μmol) in combination with NaOH (15 μmol) or catalyst **2** (10 μmol), 1.5 mL of dioxane and 1.5 mL of water. The reaction mixture was heated at 135-150 ^{o}C for 48h. After 48h, the reaction mixtures were cooled down in ice bath, H_2 pressure was released. Pyridine (20 μL) was added as an internal standard, and the reaction samples were analyzed by NMR in D_2O solution. The yields of products and conversion were determined by NMR integration vs. pyridine as an internal standard. The products were identified by GC-MS and by comparison with authentic samples.

3 Results and discussion

Complex **1** in combination with NaOH shows catalytic activity in the conversion of pyrrolidine to 2-pyrrolidone in dioxane-water mixture at 150 ^{o}C (Figure 1). Similar reactivity was observed with other cyclic amines [1]. In this work, we established that **1** acts as a pre-catalyst for the formation of catalytically active "dearomatized" species **2** under the reaction conditions. The species **2** is responsible for the observed catalytic activity and shows superior activity at lower temperatures as compared to our previously reported results. We will discuss possible pathways for the formation of a catalytically active dearomatized species under the reaction conditions.

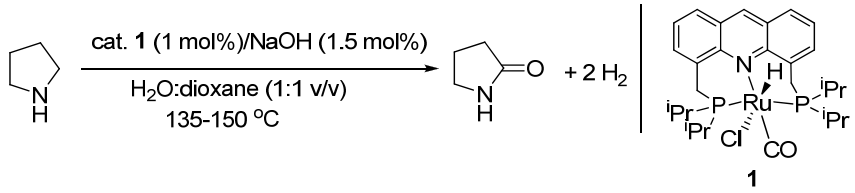

Fig. 1. Ru-catalyzed cyclic amine-to-lactam conversion with water.

The combined experimental study of the reaction intermediates and isotopic exchange experiments are consistent with the proposed pathway of this transformation shown in Figure 2 that involves imine and hemiaminal intermediates. The DFT study shed light on the mechanism of each of these steps. The possibility of the reverse reaction, hydrogenation of lactams to amines, was also considered and tested experimentally.

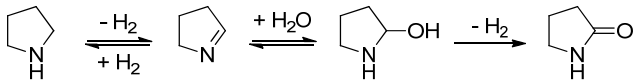

Fig. 2. Proposed pathway for cyclic amine-to-lactam conversion.

4 Conclusions

We have developed an atom ecomonical way of lactam synthesis by reaction of amines with water with liberation of H_2 gas, in the absence of added oxidants. This transformation is a rare example of a reaction in which water is used directly for oxygenation of a CH_2 group of organic substrates [6-7]. The mechanistic studies of this reaction suggest that water plays an important role in this transformation as the oxygen atom source and also facilitates other steps in the proposed mechanism. The acridine-based pincer ligand provides a unique scaffold that allows for facile dehydrogenation steps in this system.

Effects of La and Ce Promotion on CDRM Performance of Co-Ni/ZrO_2 Catalysts

Bal H., Demirhan C.D., Aksoylu A.E.*

Department of Chemical Engineering, Boğaziçi University, Istanbul, Turkey

* aksoylu@boun.edu.tr

Keywords: catalytic hydrogen production, dry reforming, heterogeneous catalysis, carbondioxide, utilization

1 Introduction

Carbon dioxide reforming of methane (CDRM) is a catalytic process where CH_4 and CO_2 are utilized to produce valuable synthesis gas. Compared to other methods, such as steam reforming and partial oxidation, the most important advantage of CDRM is the consumption of CO_2 which is one of the most abundant greenhouse gases whose concentration rise in the atmosphere has been considered as the most common reason for the abrupt climatic changes. The low H_2/CO ratio obtained in CDRM is preferable to be used both in Fischer-Tropsch synthesis and in the production of formaldehyde, polycarbonates or methanol. The main drawbacks of this process are coking and metal sintering, which are the results of the need for high reaction temperatures due to endothermicity of the reaction. ZrO_2 is an appropriate support for reducing carbon accumulation during CDRM, since it enhances dissociative adsorption of CO_2 and migration of the produced O on the catalyst surface to oxidize and gasify the coke formed on catalytic sites. Introducing a promoter (e.g. Ce and La) to form a bimetallic catalyst system also improves the anti-coking property. Preliminary studies of our group have shown that Ce-doped Co/ZrO_2 displays high activity and has a very limited activity loss [1,2]. Additionally, presence of Ni proved to increase CDRM activity [3].

The aim of this study was to design and develop effective Co-La bimetallic, and Co-Ni-La and Co-Ni-Ce trimetallic CDRM catalysts supported on ZrO_2. The favorable reaction conditions for stable performance were investigated through following an experimental design involving the reaction temperature, CH_4/CO_2 feed ratio and space velocity as the parameters. The activity, selectivity and stability of the catalyst as well as the type of carbon deposited on it during reactions performed under various reaction conditions were observed.

2 Experimental

Co-La catalyst was prepared by sequential impregnation, whereas Co-Ni-La and Co-Ni-Ce catalysts were prepared by co-impregnation. The catalysts were calcined *in situ* in dry air for 4 h at 773 K and subsequently reduced *in situ* in H_2 for 2 h at the same temperature. The performance tests were conducted in a quartz micro reactor for the temperature interval of 873-973 K with CH_4/CO_2 feed ratios of 1/1, 2/1, 1/2, and space velocities of 20000 and 60000 mL/h g-catalyst. Agilent Technologies 6850 gas chromatograph (GC) equipped with a Thermal Conductivity Detector (TCD) and a HayeSep D column was used to analyze feed and product compositions. SEM and Energy Dispersive X-Ray (EDX) tests were performed on freshly reduced and spent Co-Ni-Ce/ZrO_2 catalyst samples in order to elucidate their micro-structural properties, and to observe the morphology and localization of the deposited carbon.

3 Results and discussion

The results of the metal mapping studies confirmed well dispersion of Co, Ni and, Ce over

ZrO_2, and SEM results indicated that deposited carbon has both filamentous and graphitic structures. It was observed in performance tests that higher reaction temperatures were beneficial for both increased activity and selectivity, i.e. obtaining H_2/CO product ratio values close to 1. The decrease in space velocity resulted in an increase in CH_4 and CO_2 conversions and H_2/CO ratio in product stream. The effect of CH_4/CO_2 feed ratio on CH_4 conversion at 923 K for all catalysts tested are presented in Figure 1 as an example. 5Co5Ni2La catalyst experienced more activity loss compared to 5Co3Ni2La when CH_4/CO_2 feed ratio is 2/1. Addition of Ni to Co-based catalysts improved activity. However, on La promoted catalysts, increasing Ni-loading caused increased coke formation for CH_4-rich feeds; whereas coke formation was suppressed when Ce was used as the promoter. It was also seen that increasing space velocity led to a decrease in the conversion values and selectivity towards CO without affecting the stability profile.

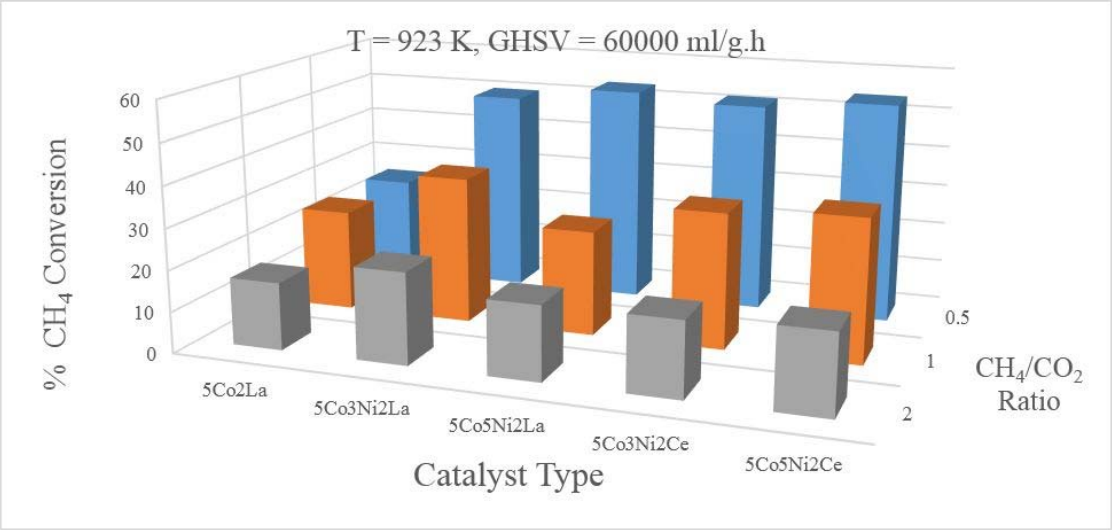

Fig. 1. The effect of CH_4/CO_2 feed ratio on CH_4 conversion at 923 K.

4 Conclusions

La and, more successfully, Ce were proven to be suitable promoters for enhancing the stability of Co- and Ni-based CDRM catalysts. Ce dominantly participated in carbon removal process through forming an additional oxygen storage capacity and regulating surface oxygen transfer. For optimum activity and stability, small amount of Ni addition was found sufficient. Co-Ni-Ce trimetallic system was shown to be the most active and stable catalyst at all reaction conditions. 5Co5Ni2Ce configuration was found to give the optimum performance.

Keywords: photocatalysis, titania, activated carbon, silica, composite photocatalyst, diethyl sulfide

1 Introduction

Volatile organic compounds containing N, S, P or Cl heteroatoms are often highly toxic and very dangerous for human health [1], and some of them could be used as chemical warfare agents (CWA) [2]. One of the best known CWAs is bis(2-chloroethyl) sulfide or mustard gas (HD). This species is a highly toxic vesicant which causes destruction of cell membranes and nucleic acids. In this way the development of effective methods for HD neutralization is an important task to ensure human safety.

The method of photocatalytic oxidation (PCO) using TiO_2-based photocatalysts is regarded as one of the promising methods of CWA disposal due to the high oxidative ability of TiO_2 under UV irradiation. The main objective of the current study was to investigate the PCO of diethyl sulfide (DES) as one of the HD simulants in the gas-phase over composite photocatalysts in which TiO_2 was deposited onto activated carbon (AC) or SiO_2 surfaces [3].

2 Experimental/methodology

Composite photocatalysts were synthesized by thermal hydrolysis of $TiOSO_4$. Typically, a certain amount of activated carbon or silica powder was suspended in a titanyl sulfate water solution (300 mL) and boiled for 5 hours under constant mixing. The calculated TiO_2 content in the sample was varied in the range of 65-80 wt. % for AC-containing samples and 10-80 wt. % for SiO_2-containing samples. The reference TiO_2 sample was synthesized by the same procedure without addition of support (AC or silica). The photocatalysts synthesized were characterized by atomic emission spectroscopy, nitrogen adsorption at 77 K, X-ray diffraction, FT-IR analysis.

Oxidation of the DES vapor was investigated in a 0.3 L static reactor installed in the cell compartment of a Nicolet 380 FT-IR spectrometer (Thermo Fisher Scientific Inc., USA) under UV irradiation produced by a UV LED (Nichia, Japan) with λ_{max} ~373 nm. Concentrations of DES and other oxidation products in the gas phase were calculated using the Beer-Lambert law.

3 Results and discussion

Composite TiO_2/activated carbon (TiO_2/AC) and TiO_2/SiO_2 photocatalysts with TiO_2 contents in the 10 to 80 wt. % range were synthesized. All TiO_2-based samples were in the anatase form, with a primary crystallite size of about 11 nm. It was demonstrated that the specific surface area and pore volume of the composite photocatalyst are slightly lower than the algebraic sum of the corresponding values of TiO_2 and adsorbent (AC or SiO_2). This means that a partial blocking of the support surface by TiO_2 nanoparticles occurs.

The main purpose of our work was to study the PCO of diethyl sulfide with the composite photocatalysts and to investigate their stability in long-term experiments. In this connection in the beginning we optimized the quantity of the photocatalyst in the reactor. It was demonstrated that studies of long-term photocatalyst use should be done using a relatively low TiO_2 quantity

(0.5 mg/cm^2) because in this case we can assume that the entire photocatalyst surface is irradiated and is involved in the reaction process. Then we chose the photocatalyst with good proportions of adsorptivity and photocatalytic activity in each series. There were 70%TiO_2/AC, 40%TiO_2/SiO_2 and reference TiO_2 sample.

Finally, we investigated DES PCO over chosen photocatalysts. Acetaldehyde, formic acid, ethylene and SO_2 were registered as the intermediate products of DES PCO which were completely oxidized to the final oxidation products – H_2O, CO_2, CO and SO_4^{2-} ions.

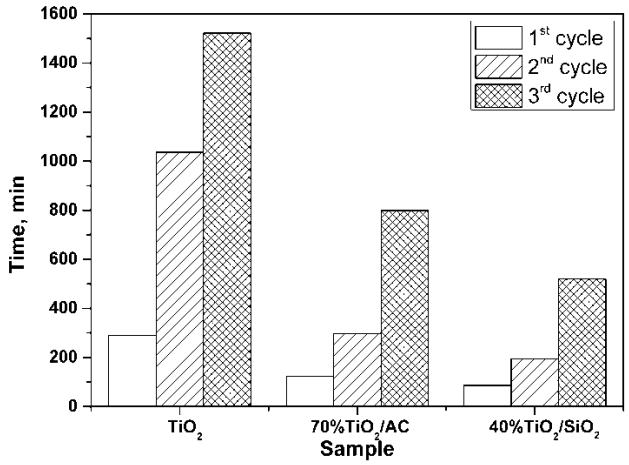

Fig. 1. Time values of 90% DES conversion into CO_2 in three oxidation cycles for pure TiO_2 and TiO_2/adsorbent composite photocatalysts

The influence of the support on the kinetics of DES PCO and on the TiO_2/AC and TiO_2/SiO_2 samples' stability during three long-term DES PCO cycles was investigated. In each subsequent oxidation cycle over the same sample a decrease of DES PCO rate was observed. This means that a strong deactivation of the samples occurs. To estimate the extent of photocatalyst deactivation the time of 90% DES mineralization was calculated in each cycle. Calculated times for all samples in each oxidation cycle are presented in Figure 1. The highest PCO rate was observed for TiO_2/SiO_2 photocatalyst for all three cycles.

To evaluate the activity of photocatalysts the turnover frequency values (TOF) were calculated for three photocatalysts (TiO_2, TiO_2/AC and TiO_2/SiO_2) for the same amount of mineralized DES. It was demonstrated that the TOF value for composite TiO_2/SiO_2 photocatalysts was 3.5 times higher than for pure TiO_2.

4 Conclusions

The usage of composite photocatalyst results in up to an 8-fold decrease of DES removal time if compared with pure unmodified TiO_2. This could be explained by an increase of the available surface area in the case of composite photocatalyst and reversible transfer of non-volatile intermediates from TiO_2 surface to the support surface thus keeping the photocatalyst surface available for further interaction with substrate. Additionally the removal of intermediates – acetaldehyde and formic acid – occurs faster over composite photocatalyst.

The long-term oxidation of DES leads to a strong deactivation of the photocatalyst. The deactivation decreases in the following sequence: TiO_2>TiO_2/AC>TiO_2/SiO_2. The most active and stable catalyst is the TiO_2/SiO_2 one which contains 40 wt. % of TiO_2. The calculated TOF number for this sample is 3.5 times higher than for pure TiO_2.

Keywords: N_2O decomposition, oxygen, exchange, perovskite, fluorite

1 Introduction

Possibility to abate N_2O formed during nitric acid production immediately downstream of the ammonia combustion Pt-Rh gauzes aroused interest in the reaction of its catalytic decomposition at high temperatures. Numerous systems including both bulk and supported oxides of transition metals and lanthanides were tested in this reaction. Our studies of La-Sr-Mn-O composites showed that their catalytic activity of N_2O decomposition at T>600^{0}C correlated with the coefficient of lattice oxygen self-diffusion [1]. We checked in this study whether following increase of activity was possible by using the materials with *a fortiori* higher lattice oxygen mobility—La-Sr-Fe-O and CeO_2.

2 Experimental/methodology

Several types of catalytic systems were prepared: 1) La-(Sr-)Fe mixed oxides, 2) their composites with CeO_2 – by mechanochemical method, 3) supported $MeOx/Al_2O_3(CeO_2)$ (Me = Fe, Co, Ni, Cu) – by impregnation through Pechini route, and characterized by means of XRD, XPS, HRTEM, EDX, UV–Vis DRS, TPD O_2. The kinetics of $^{18}O/^{16}O$ oxygen exchange have been analyzed both in the isothermal (SSITKA, 800^{0}C) and temperature programmed (TPIE, 100^{0}C÷900^{0}C) modes at 0.005 atm oxygen partial pressure, and the rates of surface oxygen exchange (R_s) and lattice oxygen diffusion (R_{bulk}) have been evaluated. Activity in the reaction of N_2O decomposition was tested in the temperature interval 700-900^{0}C and characterized by R_{N2O} value.

3 Results and discussion

Replacement of Fe for Mn in perovskite lattice resulted in increase of the rates of both bulk oxygen exchange and N_2O decomposition. However, following rise of R_{bulk} at partial Sr replacement for La ($La_{0.4}Sr_{0.6}FeO_3$) from $6\cdot10^{-3}$ s^{-1} to $2.5\cdot10^{-2}$ s^{-1} as calculated for 800^{0}C was accompanied by decrease of R_s value from 8 s^{-1} to 3 s^{-1}, thus hindering following rise of activity. Non-additively high R_{N2O} was measured for $LaSrFeO_4$(surface)–$La_{0.4}Sr_{0.6}FeO_3$ composite that exhibited increased rate of surface oxygen exchange compared with that for the individual $LaSrFeO_4$ phase (R_s = 13 s^{-1} and 8 s^{-1}, respectively), on retention of high lattice oxygen mobility characterizing $La_{0.4}Sr_{0.6}FeO_3$ sample. Such synergetic effect was attributed to heterostructured interfaces formed at intergrowing of perovskite lattices.

The same principle of activity regulation was checked for CeO_2 based samples prepared by different manners. CeO_2 itself revealed the highest bulk oxygen mobility (R_{bulk} >0.1 s^{-1}), but negligible activity due to extremely low R_s value around 1 s^{-1}. First, it was shown that at the same surface concentration of supported Me, substantially higher R_{N2O} and general rates of oxygen exchange values characterized $MeOx/CeO_2$ samples compared with corresponding $MeOx/Al_2O_3$ ones (Fig.1A) that undoubtedly pointed to importance of bulk oxygen mobility.

TPIE and SSITKA measurements revealed possible effect of CeO_2 lattice modification by Me^{n+} on the rate of oxygen transfer both in the bulk and in the near subsurface layers correlating well with samples activity.

For $LaFeO_3$(surface)–CeO_2 composites both the rate of oxygen exchange in the subsurface layer and R_{N2O} increased non-additively in a comparison to $LaFeO_3$ and CeO_2 used for their preparation (Fig.1B). It was proved that decoration of ceria surface by finely dispersed LaOx, FeOx and $LaFeO_3$ species was accompanied by accumulation of oxygen vacancies or extended defects arisen after modification of near subsurface layers of fluorite lattice by inserted Fe^{3+} ions.

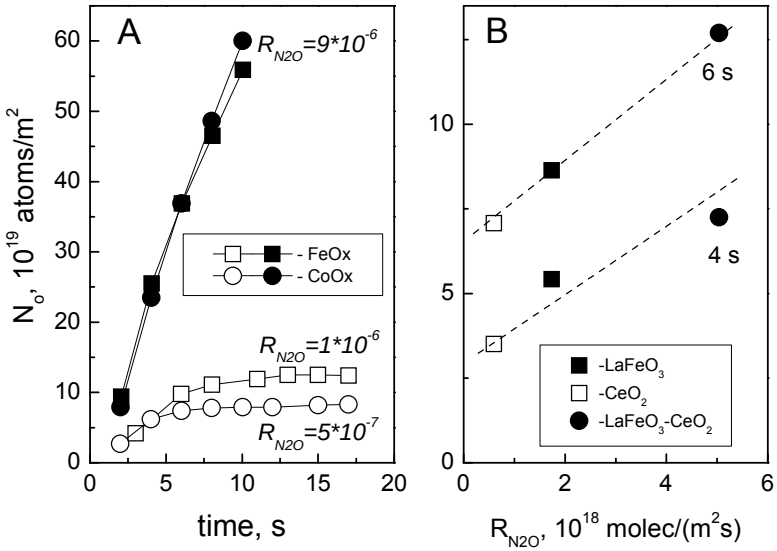

Fig. 1. A) Time dependencies of exchanged oxygen N_0 for Fe(Co)Ox/Al_2O_3 (□,○) and Fe(Co)Ox/CeO_2 (■,●) samples characterized by different R_{N2O} (mole/(m^{2}s)) values. B) R_{N2O} *versus* N_o as calculated for different periods of time (4 and 6 s) for $LaFeO_3$-CeO_2 based samples.

4 Conclusions

For all types of studied oxide systems high bulk oxygen mobility opens additional pathway of oxygen supply from the near subsurface layers to adsorbed species formed after N_2O decomposition on the active surface sites. Formation of heterostructured interfaces on the surface of intergrown composites or mixed solutions enriched by oxygen vacancies promotes oxygen exchange in the surface and near subsurface layers thus hastening O_2 desorption.

Keywords: air purification, CWA, adsorption, oxidation, metal oxides, Fe-ZSM-5

1 Introduction

In today's world there is a high probability of terrorist attacks and technological disasters. The result is a deadly emission of volatile organic compounds or its aerosols. If this happens indoors a lot of victims could occur. Sad examples are the attack in the Tokyo subway in March 20, 1995 and the accident at a chemical factory Union Carbide, which occurred in December 3, 1984 in Bhopal (India). In this way the fast air purification method from the dangerous contaminants is of interest.

Common method of man's protection against CWA is the using of special isolating cloths which is preventing the contact of CWAs vapors and aerosols with the human body. At the same time, many of the CWAs can be absorbed on the surfaces and the risk of danger will remain. In this regard, the development of the method for the fast air and surface purification becomes important. In addition, this method will allow rapid degassing in the places where it is impossible to use personal protective clothes, such as in the subway and other crowded places [1].

The indoor air and surfaces purification can be achieved by adsorption of contaminants on the surface of various sorbents, as has been shown previously by J. Romano et al. [2]. Most CWAs are compounds with branched structure and high molecular weight, and therefore can be easily adsorbed on a solid surface [3]. CWAs adsorption on the adsorbents requires further neutralization. Suitable method for CWAs degradation is photocatalytic oxidation when used the titanium dioxide as an adsorbent. But the complete oxidation is achieved within about ten hours or more [4].

The army decontamination solutions (DS2 or 'MAKS') could not purify the air from CWAs vapors. In this way we need the universal technique for fast air and surfaces purification from CWAs vapors and aerosols. Fast means less than 5 minutes.

In our study, we propose the method which includes fast adsorption step and subsequent degradation of adsorbed CWA by the Fenton system.

2 Experimental/methodology

Since the CWA are highly toxic compounds it is safe tu use less toxic simulants in the research of new decontamination methods. Such substances were butyl-β-chloroethylsulfide (BCES), dimethyl methylphosphonate (DMMP) and O,O-diethyl-O-3,4,5-trichlorophenylphosphate (DETCPP), which are conventional imitators of mustard and organophosphorus CWAs. In the current work were used nanosized samples of TiO_2, AlOOH, SiO_2, MgO, Fe_2O_3 as the adsorbent.

Adsorption experiments were conducted in the isolated 11 l glass cylinder or in the 3.6 m^3 cubic plastic chamber.

The concentration of gaseous organic compounds and CO_2 in the chamber's air was measured by means of the FT-IR spectrometer Vector-22 (Bruker) equipped with a long path gas cell G-3-8-H (Infrared Analysis Inc.).

3 Results and discussion

All volatile CWA's simulants could be removed from the gas phase by TiO_2, AlOOH, SiO_2, MgO, Fe_2O_3 aerosols with different efficiencies. SiO_2 and AlOOH aerosols demonstrated the highest rates of CWA's simulant removal. Fig. 1 (**a**) demonstrates the BCES concentration profile during its adsorption with the SiO_2 aerosol.

The dependence of the characteristic removal time on the specific surface area of adsorbent materials was studied. Optimum sorbent surface area should be higher than 200 m^2/g (Fig. 1. **b**).

Purification of the surfaces from the non-volatile simulants also takes less than 5 minutes due to its absorption by nanosized oxide aerosols.

The subsequent decontamination of oxide aerosols could be provided by the heterogeneous Fenton system.

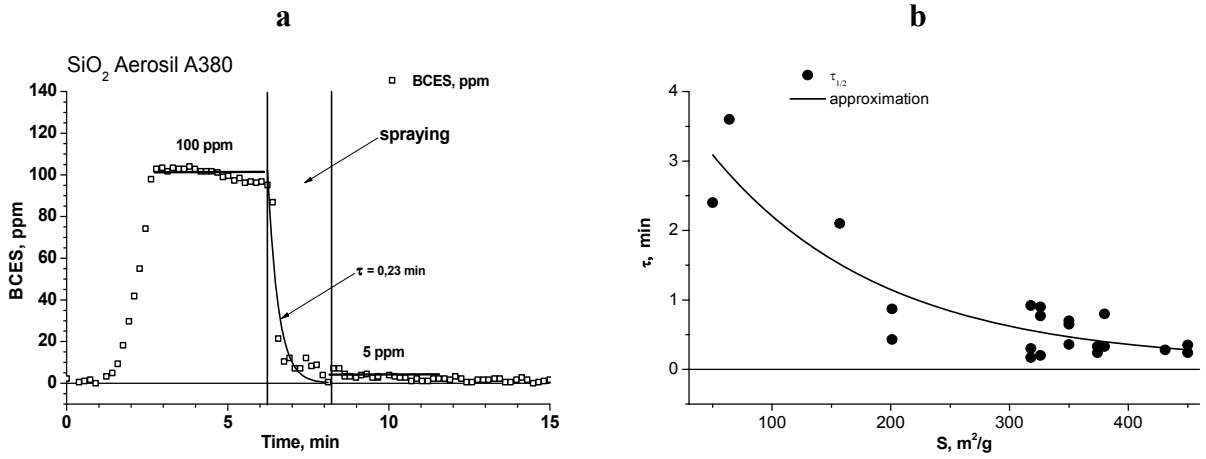

Fig. 1. (**a**) Kinetic curves of air purification from BCES in the static reactor (V = 11 l); (**b**) The dependence of the characteristic time (τ) of vapors removal from the specific surface area of adsorbent being aerosolized.

4 Conclusions

Vapours of simulant CWA can be fast removed from air and surface via adsorption and catalytic oxidation over metal oxide nanosized aerosol particles. It is possible to perform the air and surface purification in practically any place.

Keywords: alloyed Pd–Rh catalysts stabilization, donor sites, exhaust gas neutralization

1 Introduction

Three-way catalysts are well known systems used for neutralization of gasoline automotive emissions. As a rule they contain palladium and rhodium as active components providing the conversion of pollutants via a number of oxidation and reduction reactions. The catalysts with atomically dispersed or sub-nanometer sized ionic clusters of precious metals have been recently shown to have the highest activity in these reactions. In our previous study [1], we have observed that alumina donor sites play defining role in stabilization of atomically dispersed forms of supported Pd. Original catalytic and spectroscopic methods were developed for characterization of active sites responsible for high activity of these catalysts in the CO oxidation reaction. The present study is focused on the activity and stability of bimetallic Pd–Rh catalysts obtained from heterometallic complexes and supported on γ-Al_2O_3. The total precious metal loading in the synthesized samples was as low as 0.2 wt. % that complicated the use of the most of conventional physical and chemical methods of characterization.

2 Experimental/methodology

γ-Al_2O_3 was used as a support for all prepared catalysts. The support was obtained by calcination of commercial $Al(OH)_3$ hydroxide (Condea) at 700°C for 12 h. Incipient wetness impregnation of the support with double complex salt $[Pd(NH_3)_4]_3[Rh(NO_2)_6]_2$ was applied to synthesize the bimetallic Pd–Rh catalysts. The atomic Pd/Rh ratio in the impregnation solution was 3/2. The concentrations of the complexes were selected to obtain the total metals loading of 0.2 wt. %. Mechanical mixture of monometallic Pd- and Rh-containing catalysts with similar metals loading was used as a reference sample. Electron paramagnetic resonance (spin probe method), luminescence spectroscopy, UV-Vis spectroscopy, and testing reaction of ethane hydrogenolysis used for characterization of active sites of the catalysts are described elsewhere [1-2]. Catalytic testing conditions as well as so-called prompt thermal aging (PTA) procedure are reported in [3, 4].

3 Results and discussion

It was found by the spin probe method that both mono- and bimetallic Pd-containing complexes are stabilized on the same donor sites of the alumina surface. Bimetallic-alloyed state of prepared Pd-Rh catalysts was also confirmed by results of ethane hydrogenolysis reaction (Fig.1). As it could be clearly seen from the graph, the state of rhodium in mechanical mixture is equal to that of monometallic Rh sample. In this case, one can conclude that there is no Pd-Rh interaction. At the same time, the light-off curve for bimetallic Pd-Rh sample is shifted into the high temperature region thus indicating the formation of alloyed nanoparticles. The presented data are of great agreement with the catalyst behavior in CO oxidation and NO_x reduction reactions.

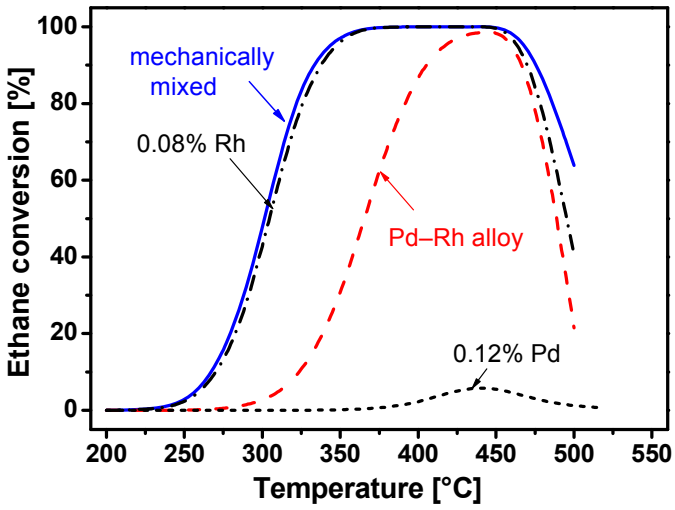

Fig.1. Experimental light-off curves of ethane hydrogenolysis testing reaction for bimetallic (0.12% Pd – 0.08% Rh)/alumina, mechanically mixed (0.12% Pd/alumina + 0.08% Rh/alumina), monometallic 0.12% Pd/alumina, and 0.08% Rh/alumina samples.

Using the UV-Vis and luminescence spectroscopies it was shown that bimetallic Pd-Rh system is characterized by the highest stability in oxidative conditions at temperatures as high as 1000°C. The stabilization effect of alloyed Pd-Rh particles related to both bulk diffusion of rhodium ions into support and surface diffusion of palladium followed by its sintering will be discussed.

4 Conclusions

The main problem of monometallic Pd and Rh catalysts application consists in their rapid deactivation at elevated temperatures. In case of Pd/alumina catalysts, the mentioned loss in catalytic activity is stipulated by the palladium surface diffusion, sintering, and partial covering by support. Bulk diffusion of Rh^{3+} into support followed by its irreversible encapsulation in corundum phase seems to be the predominant reason for deactivation of Rh-containing systems. The experimental data observed in present work indicated the reciprocal stabilization effect of these metals being in alloyed state. It should be also noted that low precious metals loading used in this study allowed us to synthesize the catalysts with active sites in the form of isolated ionic clusters.

Keywords: methane, catalytic, partial oxidation, Ni catalysts, CeO_2

1 Introduction

The production of synthesis gas from natural gas is an important step in the gas to liquid (GTL) technology. The syngas is actually produced by methane reforming processes which are highly energetic and capital intensive and are based on the endothermic steam and dry reforming reactions. A promising alternative to these processes is the partial oxidation of methane (POM) represented by the following reaction

$2\ CH_4 + 1/2\ O_2 \rightarrow CO + 2H_2 \qquad \Delta H°\ 298\ K = -35.5 kJmol\text{-}1$

The products H_2 and CO are in a ratio of 2, appropriate for methanol or Fischer-Tropsch synthesis [1]. The Ni based catalysts are the most suitable for the process, however they generally suffer from deactivation by Ni sintering and by coke formation [2]. The aim of the present study is to investigate the effect of different synthesis procedures of Ni-CeO_2 catalysts on their performance in the methane partial oxidation reaction, aiming to achieve an active and stable catalytic material.

2 Experimental/methodology

Ni-CeO_2 catalysts were prepared by conventional co-precipitation (CP), by wet impregnation (WI), by microwave assisted CP and WI (mw-CP) and (mw-WI) and by hydrothermal (HT) procedures. The effect of the different syntheses on the catalyst structural properties was investigated by XRD, TPR, TGA, TEM and XPS. The catalytic behavior of the catalysts was tested in the methane partial oxidation reaction carried out at 1 atm in a temperature range of 400 °C – 800 °C using He diluted feed gas mixture with $CH_4/O_2 = 2$, WHSV=60000 $mLg^{-1}h^{-1}$. On stream stability tests were also performed.

3 Results and discussion

As shown in Fig.1a and Fig. 1b, total methane combustion occurred within the 450 °C < T< 650 °C temperature range. At around 650 °C partial oxidation of methane started, reaching total methane conversion at 700°C - 800 °C with CO selectivity close to thermodynamic limit. Differences were observed in the POM light off temperatures. The catalyst prepared by hydrothermal treatment was the most active and stable followed by the catalyst prepared by microwave assisted co-precipitation. During the stability test at high temperature, as shown in Fig. 2 the catalysts exhibited different behavior.

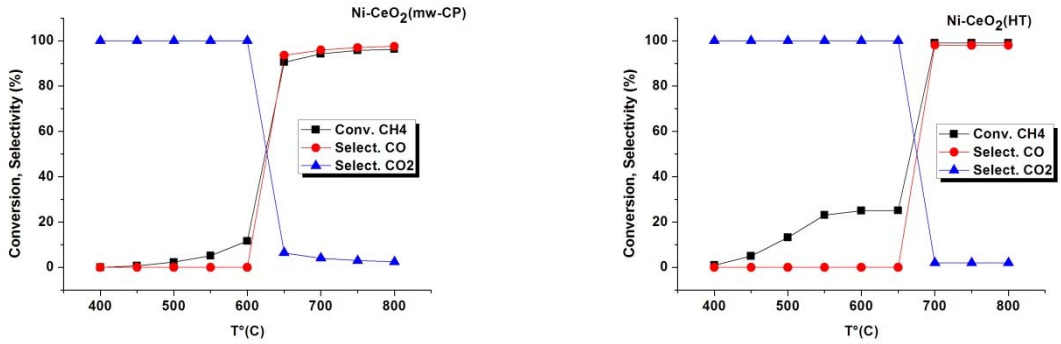

Fig.1a. CH_4 conversion and CO and CO_2 selectivity as a function of temperature in partial oxidation of methane.

Fig.1b CH_4 conversion and CO and CO_2 selectivity as a function of temperature in partial oxidation of methane.

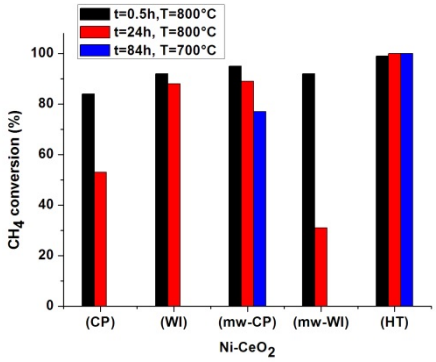

Fig. 2 Methane conversion, after different time on stream at the indicated temperatures, for the differently prepared catalysts.

As derived from the TGA results no significant amount of carbon formed during the reaction. According to the XRD analyses, nickel particle sintering occurred to an extent depending on the preparation procedure.

4 Conclusions

The catalyst preparation procedure affected the catalytic performance of the Ni-CeO_2 catalysts. The main differences were observed in the on stream stability. As arisen from the structural results, the deactivation was largely due to the nickel particle sintering related to the Ni-support interaction modulated by the synthesis.

Keywords: diesel soot, perovskites, oxidation, catalyst, $SrFeO_{2.83}$, Mn-substitution

1 Introduction

Diesel engines are superior to the gasoline engines in terms of fuel consumption with lesser CO_2-emission, higher energy efficiency etc. [1]. Although, diesel engines have several advantages than that of gasoline engines, however, it emits particulate matter (PM), commonly known as soot due to the incomplete combustion of diesel fuel. The size of PM varies in the range between 1 and1000 nm that can be easily inhaled by human and attributed for several respiratory diseases. Diesel particulate matter consists of both organic (benzene, xylene, toluene etc.) and inorganic moieties (ash, trace amounts of phosphorous, chromium, zinc, silicon, iron and calcium) [2]. Recently, diesel engine emission norms were tightened further due to the severe adverse effects not only on health but also on environment. It has been proved that after-treatment technologies, for instance diesel oxidation catalysts (DOC) and diesel particulate filters (DPF) are efficient to reduce the emissions of CO, HC and PM. However, most of the diesel oxidation catalysts require platinum group metals (PGM) (Pt, Pd, Rh, etc.)[3]. Therefore, there is an essential need to search the alternatives to PGM due to their not only high cost but also their localized availability. Perovskites among the various mixed oxide type materials may be anticipated to partly replace the current PGM catalysts due to their thermal stability at elevated temperatures, flexibility in tailoring of structures as well as physiochemical properties, and comparable catalytic activity [4]. In this study, we successfully prepared the pure phase of strontium ferrite ($SrFeO_{2.83}$) and manganese (Mn) substituted strontium ferrite $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) through co-precipitation method, followed by step-wise calcination at 900 ºC for various duration. Our results inferred that Mn-substitution enhances significantly the catalytic activity for soot oxidation by about 125 ºC.

2 Experimental

The pure perovskite phase of $SrFeO_{2.83}$ [5] and Mn-substitutes $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) were prepared by co-precipitation method followed by calcination at 900 °C. The aqueous solution of nitrate precursors ($Sr(NO_3)_2$, $Fe(NO_3)_3.9H_2O$) and $Mn(NO_3)_2.4H_2O$)with intended stoichiometry were co-precipitated using the aqueous solution of NaOH. The co-precipitate mass was then calcined step-wise at 900 °C for 8, 24 and 8 h, respectively. $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) were characterized by powder X-ray diffraction (pXRD), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The redox properties of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) were examined by temperature programmed desorption (TPD) and temperature programmed reduction (TPR). Thermal stability of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) was examined under harsh oxidation conditions at 700 ºC for 2 h. The catalytic activity of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) was evaluated using state-of-the-art fixed-bed flow reactor.

3 Results and discussion

Figure 1*a* shows the pXRD profiles of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$(x = 5, 10), confirming the formation of pure perovskite phase of both $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10). The 2θ values of $SrFeO_{2.83}$ shifted to lower 2θ values with increasing of Mn-substitution, indicating that the lattice of $SrFeO_{2.83}$ is most likely altered upon Mn-substitution. The particles of both $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) were agglomerated due to the alcinations temperature of 900 ºC, as shown in the Figures 1b and 1c. The pure phase of $SrFeO_{2.83}$ showed the catalytic activity for the oxidation of soot, which is further increased significantly with increasing of Mn-substitution, as shown in Figure 2. The maximum soot oxidation temperature observed for $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) is 425 ºC, which is significantly lower (125 ºC) than that for the oxidation temperature bare soot (550 ºC).

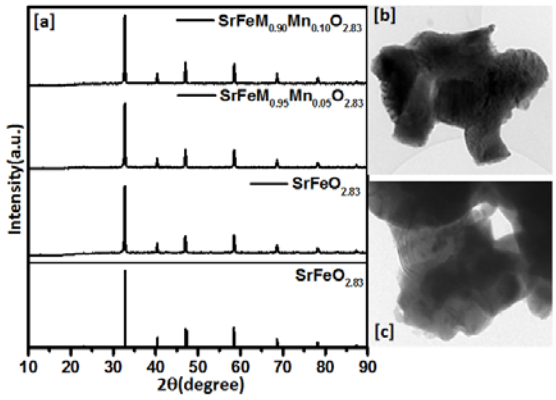

Fig. 1.a. pXRD patterns of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ **b.** HR-TEM image for $SrFeO_{2.83}$ and **c.** $SrFe_{0.95}Mn_{0.05}O_{2.83}$

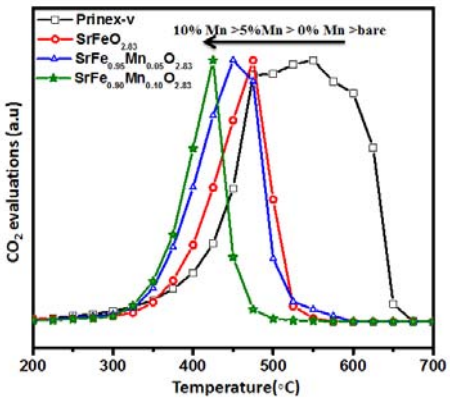

Fig. 2. Oxidation of soot on $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ using fixed-bed flow reactor

4 Conclusions

The pure perovskite phase of $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ (x = 5, 10) was synthesized through co-precipitation method followed by step-wise calcination at 900 ºC. Both $SrFeO_{2.83}$ and $SrFe_{1-x}Mn_xO_{2.83}$ showed the catalytic activity for the oxidation of soot and Mn-substitution enhances the catalytic activity significantly. The maximum catalytic oxidation temperature of soot decreased for 10 % of Mn-substitution in $SrFeO_{2.83}$ by 125 ºC. Present strontium ferrite type diesel soot oxidation catalysts are of significance considering commonly available abundant precursors of Fe and Mn and their relative environmental safety.

Selective Elecrochemical Reduction of NOx

Hansen K.K.*

Technical University of Denmark, Lyngby, Denmark

* kkha@dtu.dk

Keywords: NO, O_2, Ba, LSMC, CGO, deNOx

1 Introduction

Removal of NOx from diesel trucks and cars are of major importance. Traditionally the removal of Nox is done using the selective catalytic reduction (SCR) of Nox. Here a reducing agent is needed. An alternative solution is to use an all solid state electrochemical reactor based on an oxide ionic conducting electrolyte, as suggested by Pancharatnam et al. [1]. The major obstacle of this approach is high power consumption, due to the competing reduction of O_2 at the cathode [2]. One way to solve the selectivity problem is to add a Nox storage compound, in the form of potassium or barium nitrate. This can be done in two ways; either by adding the nitrates in a separate layer on the top of the electrode or by getting the nitrates into the structure, by wet infiltration. The latter approach will be described in this text. A concept useful for removal of Nox is a porous cell stack as shown in the figure below. The porous cell stack consists of alternating layers of electrode and electrolyte. By making the cell porous gas can be forced through the cell, thereby getting in close contact with the electrodes.

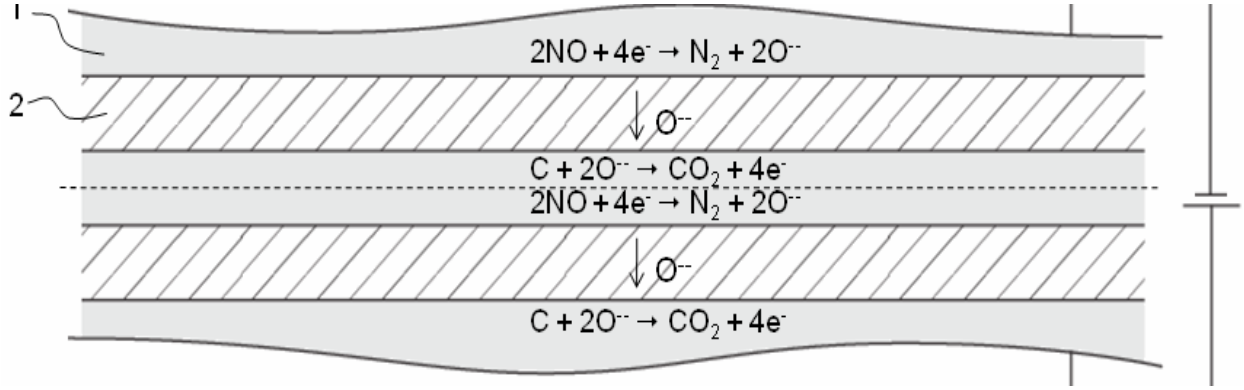

Fig. 1. A porous cell stack useful for removal of Nox from exhaust gasses. The porous cell stack is seen to be constructed from alternating layers of electrode and electrolyte. A potential is applied between top and bottom electrodes in order to reduce the Nox. 1 electrode, 2 electrolyte.

2 Experimental/methodology

Porous cell stacks of LSMC/CGO composite electrodes and CGO electrolytes were made by tape casting followed by lamination and sintering. Pore formers were added to the suspension used for the tape casting in order to produce the porous cell stacks. The cells were then coated with porous gold layers on the top and bottom electrodes. After this the cells were infiltrated with $Ba(NO_3)_2$. The cell was mounted in an one atmosphere setup with possibility of controlling the gas composition and flow rates. Electrical connection was done using two thermocouples mounted at the top and bottom electrodes respectively. A Gamry Ref 600 potentiostat was used for the electrochemical measurements. Gas conversion was measured using a Thermo scientific CLD and an Agilent μ-GC.

4 Results and discussion

Selected results are shown in Figure 2. As it can be seen the NOx can be reduced at temperatures down to 300 °C with a current efficiency of up to 32% (as the cell is a 11 layer stack, the current efficiency is actual 6.4%).

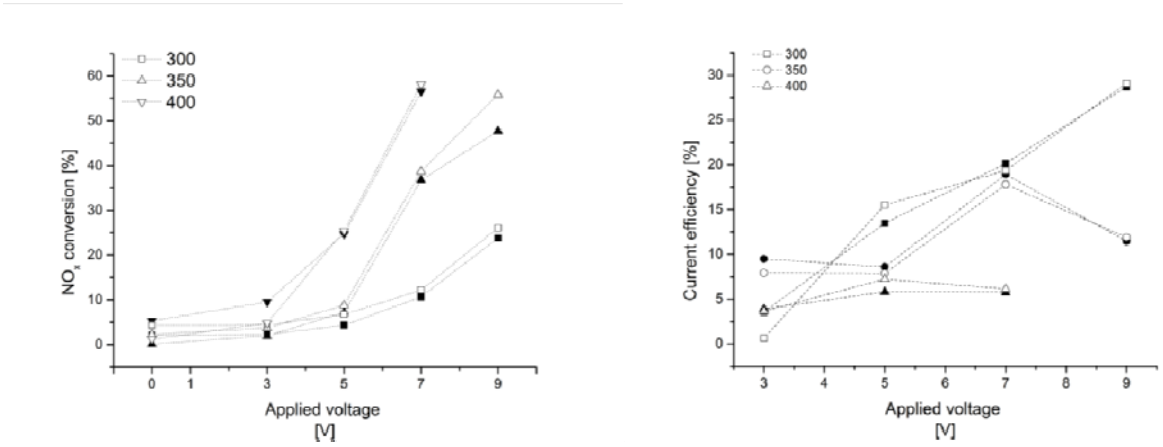

Fig. 2. Conversion of Nox to nitrogen shown to the left as a function of temperature and voltage. To the right current efficiencies as a function of applied voltage. Measured on an 11 layers porous cell stack with LSMC/CGO electrodes. 1000 NO ppm and 10% oxygen in Ar.

4 Conclusions

It has been shown that a full ceramic cell can be used to remove NOx from synthetic gasses containing large amounts of oxygen. Current efficiencies of up to 6.4% have been obtained. Removal of NOx at temperatures down to 300 °C has been shown possible.

Keywords: 2,4,6-trinitrobenzoic acid, 2,4,6-triaminobenzene, hydrogenation, carbon-supported, palladium catalyst

1 Introduction

The catalytic hydrogenation of trinitroaromatic compounds is of interest as a model reaction in the development of theoretical basis for the liquid-phase hydrogenation of organic compounds; in addition, it is of practical importance for utilization of explosives. The use of catalytic hydrogenation for safe deactivation of one of the most common explosives, trinitrotoluene (TNT), has substantial environmental advantages over its utilization by explosion, oxidation or chemical reduction. 2,4,6-Trinitrobenzoic acid (TNBA) is among the most accessible and promising products of trinitrotoluene transformation. The reduction of all nitro groups may lead to 2,4,6-triaminobenzene (TAB) – the essential component for the synthesis of various commercial products, in particular, phloroglucinol, which is used to produce azo dyes, as components of heat-resistant thermosetting resins and insulation for conductors, as well as in the synthesis of antibacterial and antiviral preparations [1].

Some features of trinitroaromatic compounds – high oxidation potential, strong adsorption on the surface of metal catalysts, high exothermic effect of the reduction to triamine, and side-reactions between the intermediates to polymers at hydrogenation – initiate studies that aim both to reveal the effect of reaction conditions on the rate and conversion and to obtain new stable catalytic systems. Our study examined the effect of TNBA hydrogenation parameters (temperature, pressure, concentration of reactant, and nature of solvent) as well as conditions of the catalyst synthesis and pretreatment on the process rate and selectivity. The mesoporous carbon material Sibunit, which has a high mechanical strength, chemical stability and a developed surface area [2], was chosen as a support for the palladium catalysts.

2 Experimental/methodology

The 5%Pd/C catalysts were synthesized by the hydrolytic precipitation of palladium polyhydroxo complexes (PHC) on the surface of the carbon material followed by palladium reduction with sodium formate. The texture properties of Sibunit were found by analyzing the nitrogen adsorption-desorption isotherms at 77 K (ASAP-2020, Micromeritics). Palladium content in the catalysts was determined by atomic absorption spectroscopy (AA-6300, Shimadzu). CO pulse chemisorption at room temperature (AutoChem II 2920, Micromeritics) and transmission electron microscopy (JEM-2100, JEOL) were used to estimate the particle size of palladium. The catalytic hydrogenation was performed in an autoclave with controlling the volume of absorbed hydrogen. The conversion products were examined by ^{1}H and ^{13}C NMR spectroscopy (Avance-400, Bruker), IR spectroscopy (IRPrestige-21, Shimadzu), and elemental analysis (Vario EL cube, Elementar Analysensysteme GmbH).

3 Results and discussion

Variation of the reaction conditions has demonstrated that hydrogenation of TNBA in the presence of Pd/C catalyst leads to the target TAB only at a high hydrogen pressure (0.5 MPa); however, a further increase in the pressure to 0.8 MPa (at a temperature of 50 °C) initiates undesirable reactions leading to the formation of by-products. Temperature elevation from 50 to 70 and 90 °C (at a pressure of 0.5 MPa) increases hydrogen conversion and results in a selective formation of TAB. The hydrogenation of TNBA was studied in different media: acetone, ethyl and isopropyl alcohols, water, and ethyl acetate. Water with the addition of $NaHCO_3$ was found to be the most efficient solvent. When the reaction is carried out at a temperature of 50 °C and pressure of 0.5 MPa, a complete hydrogenation of TNBA to TAB occurs at a 170 g TNBA / 1 g Pd ratio. An increase in the substrate concentration in a solution (420-1670 g TNBA / 1 g Pd) at the same catalyst weight and reaction conditions decreases the hydrogen conversion and reaction rate but increases the yield of by-products.

The role of H_2PdCl_4 hydrolysis conditions in the formation of palladium PHC to provide a necessary dispersion of the supported metal and activity in hydrogenation of TNBA was studied. The hydrolysis was performed with aqueous solutions of precipitants containing the K^+, Na^+ and Li^+ cations and the CO_3^{2-}, HCO_3^- and OH^- anions; the pH of precipitation was varied in the existence region of palladium PHC in the impregnating solution. Higher dispersions of the supported palladium were observed at pH below 5, with a potassium-containing precipitant, and in the presence of carbonate or hydrocarbonate anions.

4 Conclusions

The catalyst having the highest dispersion of palladium particles and synthesized with the use of $KHCO_3$ precipitant showed the maximum activity in the target reaction of TNBA hydrogenation to TAB (with a selectivity above 90%) under the specified conditions (a temperature of 50 °C and a pressure of 0.5 MPa). The NMR analysis of the products that formed upon variation of TNBA hydrogenation conditions was used to suggest a scheme of the transformations occurring in the presence of Pd/C catalysts:

Biocatalytic Generation of Oil-Displacing Systems in Low-Temperature Reservoirs of Viscosity Oil

Altunina L.K., Svarovskaya L.I.*, Guseva Yu.Z.

Institute of Petroleum Chemistry Siberian Branch of the Russian Academy of Sciences, Tomsk, Russia

* sli@ipc.tsc.ru

Keywords: carbamide, urease enzymatic, hydrolysis, viscosity oil, oil-displacement

1 Introduction

In some industrialized countries, viscosity oil is regarded as the main reserve of oil production in the coming years. In Russia there are two major fields of abnormally viscosity oil are under commercial development, the Yaregskoye oilfield and the Permocarbonic oil pool in Usinskoye oilfield (Komi Republic) with total geological reserves of 870 million tons [1].

To enhance oil recovery from low-temperature reservoirs, complex technologies have been developed. They are based on the injection of steam, which reduces oil viscosity, followed by the injection of surfactant-based oil-displacing systems [2, 3]. These oil-displacing systems, along with surfactants, contain nitrogen compounds, including ammonium nitrate and carbamide. The carbamide in the reservoir is hydrolyzed due to steam temperature to yield CO_2 and NH_3. Ammonia at dissolution in water forms an alkaline buffer solution, the maximum capacity of which ranges pH 9.0–10.0, which improves the washing properties of the system, stimulates oil desorption from the porous reservoir rock and thereby enhances oil recovery. Carbon dioxide, in contrast to ammonia, is much more soluble in oil than in water.

2 Experimental/methodology

To hydrolyze carbamide we used soybean meal containing the urease enzyme and crystalline urease at different concentrations. The hydrolysis rate was assessed by monitoring changes in pH with time, the carbamide concentration, and accumulation of CO_2 and ammonia in the solution. The 5–500 times diluted solutions of the oil-displacing system with carbamide concentrations ranging from 0.65 to 320 g/L were the objects under study. The initial 50% solution of the surfactant-based oil-displacing system consisted of (in g/L) Neonol AF9-12 (20), ammonium nitrate (160.0), carbamide (320.0), and water (500); pH 6.5.

The effect of the products of carbamide hydrolysis on the displacement of viscosity oil was examined using a linear oil-saturated reservoir model, which was represented by three thermostated columns packed with disintegrated carbonate rock (fraction 0.16–0.50 mm). The reservoir model was saturated with an iso-viscous degassed oil from Permocarbonic oil pool in Usinskoye oilfield. Oil displacement and after washing of the residual oil with water were simulated after the columns treating with a 10% solution of the system (control column) and solutions of the system added with 0.1% carbamide and 1% soybean meal (test columns). The after washing of the residual oil was performed with water until the complete water cut of the product at the outlet. The volume of the liquid phase, the pH, and the concentration of components of the buffer solution the system – ammonium nitrate and carbamide were determined at the outlet. Using the results of measurements we calculated oil displacement factor, the change in oil saturation, and the completeness of carbamide and ammonium nitrate yields.

3 Results and discussion

The maximum values of pH 9.3 were obtained in different modes of carbamide hydrolysis

by crystalline urease. The enzyme/substrate ratio of 0.1:32 was considered as optimal.

The catalytic activity of urease contained in soy-bean meal was investigated at concentrations of 0.1–10 g/dm^3. The optimal soybean meal : carbamide ratio was 5:32; at this ratio, the pH reached a value of 9.3 within 2 h.

The investigation of the influence of the surfactant-based oil-displacing system containing the products of enzymatic hydrolysis of carbamide on the viscosity of high-viscosity oil showed that after thermostatting, the viscosity of the oil from Usinskoye oilfield decreased at 20–40 °C minimally by 10–30 % and maximally by a factor of 2–4. However, the character of rheological behaviour of the oil (pseudoplastic) remained substantially unchanged.

The effect of the hydrolysis products on the viscosity oil displacement from the reservoir model was studied at a constant temperature of 30 °C, which was identical to the reservoir temperature in Usinskoye oilfield. The efficiency of oil displacement with water was 45.5–59.6 %. After the treatment of the model and thermostatting, to accumulate the hydrolysis products the ultimate displacement of the residual oil was carried out with water. The increment in the oil displacement efficiency for the control column treated with the enzyme-free solution of the system was 9.8, and that for the test columns it was 19.3 and 15.1 %. The absolute oil displacement efficiency, using crystalline urease hydrolyzing carbamide in the composition of the oil-displacing system, was 64.6 % and using soy-bean meal it was 74.7 %, against that of 55.3 % for the control column.

4 Conclusions

Therefore in the reservoir conditions to hydrolyze carbamide in oil-displacing system at pH increase to 9.0–9.3 one can use urease of vegetable origin, the activity of which depends on the substrate : enzyme ratio.

Carbon dioxide, formed during the carbamide hydrolysis at a low temperature, reduces the viscosity of the oil from Usinskoye oilfield minimally by 10–30% and maximally by a factor of 2–4.

When the enzymatic hydrolysis of carbamide by urease or soybean meal is employed in the process of oil displacement from the reservoir model, the absolute oil displacement efficiency increases from 55.3 (control) to 64.6 or 74.7 %, respectively.

Thus, simultaneous injection of an oil-displacing solution containing carbamide and a hydrolyzing enzyme into a reservoir generates *in situ* an effective oil-displacing system that is capable of increasing the displacement of viscosity oil from the low-temperature oil pool. The data obtained forms the scientific basis for biotechnology of enhanced oil recovery.

The Rehydration of Centrifugal Thermal Activation Products of Gibbsite – the Industrial Waste of Catalyst KDM

Matveyeva A.N.*, Pakhomov N.A.

St. Petersburg State Institute of Technology (Technical University), Department of General Chemical Technology and Catalysis, Saint-Petersburg, Russia

Keywords: catalyst KDM, gibbsite, CTA product rehydration, pseudoboehmite, bayerite

1 Introduction

A low-waste and reagent-free production arouses much interest. A carrier of manufacturing microspherical chromium oxide/alumina catalyst KDM for fluidized-bed isobutane dehydrogenation is the product of centrifugal thermal activation (CTA) of gibbsite (GB) [1]. The method of CTA based on a transformation of the nonporous crystalline gibbsite – $Al(OH)_3$, into an amorphous product (AM) by dint of fast heating up to the dehydration temperature and cooling. The CTA product is the pseudomorphosis over gibbsite, but unlike it has the developed volume of pore, specific surface area and high reactivity. A fractional structure of microparticles the catalyst KDM needs is from 50 to 140 microns for providing the stable mode in fluid bed in use. However all Russian works make the gibbsite with a large quantity of the small fraction. Therefore after the CTA process a classification is performed to separate the target fraction and the particles less then 50 microns are the industrial waste.

The purpose of present research is the development of ways for recycling the waste of carrier of KDM catalyst production. Among them was considered the most perspective way – the method of rehydration of CTA product into a pseudoboehmite (PB) or a bayerite (BA) of which is possible to get γ- and η-Al2O3 respectively.

2 Experimental/methodology

The conditions of synthesis of the PB and BA adjustment was performed on the samples of thermoactivated products, which were made on an experimental TSEFLAR™ installation in Boreskov Institute of Catalysis from Achinsk[1] (A-CTA) and Bogoslovsk[2] gibbsite (B-CTA).

In Table 1 the fractional structure of the original samples is shown, where d stands for the equivalent diameter of particles. For the rehydration the A-CTA product was used in the original form, and the B-CTA product was crushed in an agate mortar and only fraction ≤ 40 microns was selected.

Table 1. The fractional structure of the original samples

Sample	Mass content, %		
	d ≤ 40 μm	40 < d ≤ 100 μm	d > 100 μm
A-CTA	55	41	4
B-CTA	6	88	6

The rehydration of samples was carried out in the water environment (the ratio S/L=1:2-1:3) at various pH, achievable by adding in suspension of ammonia solution, azotic or acetic acid solution. After the rehydration the sediments were filtered, washed, dried at 110°C and investigated by the thermal (TA) and X-rays analyzes.

1 Product of Achinsk Alumina Refinery, Achinsk, Russia
2 Product of Bogoslovsk Aluminium Smelter, Krasnoturyinsk, Russia

3 Results and discussion

The formation of bayerite is shown in the alkaline environment and pseudoboehmite in the acidic one (Table 2). The degree of rehydration depends on the pH of suspension, the nature of the starting gibbsite, the morphology and the phase composition of CTA products.

Table 2. The characteristics of the CTA products rehydration in different conditions

Sample	Conditions of rehydration				TA, mass %					LOI[3] (800°C), mass %
	Electrolyte	pH	T_r, °C	t_r, h	$Al(OH)_3$		BE[1]	AM	PB[2]	
					GB	BA				
A-CTA	-	-	-	-	9	-	18	73	-	18,8
A-CTA-1a	$NH_3 \cdot H_2O$	10-11	30-35	24	9	44	4	43	-	30,9
A-CTA-2b	HNO_3	5-5,5	70-90	4	9	13	79			27,2
A-CTA-2d	CH_3COOH	5-5,5	70-90	4	9	4	16	71		28,0
B-CTA	-	-	-	-	-	-	-	+ χ-Al_2O_3	-	10,4
B-CTA-1a	$NH_3 \cdot H_2O$	10-11	30-35	24	-	21	+ χ-Al_2O_3		-	17,4
B-CTA-2a	HNO_3	5-5,5	70-90	4	-	-	+ χ-Al_2O_3			16,2

[1] Boehmite. [2] Borders of thermoeffect of PB are not distinctly detectable. [3] LOI – the loss on ignition.

The yield of BA from the B-CTA is almost twice as low as from the A-CTA, although the latter contains a large number of coarse particles. The starting B-CTA product, according to the data of scanning electron microscopy (SEM), consists of solid particles and contains besides the amorphous phase – the crystalline phase χ-Al2O3 with low reactivity. The A-CTA product, according to the data of TA and X-rays analyses, consists predominantly of the reactive amorphous phase and, according to SEM data, has more friable and easily peptizable structure.

4 Conclusions

The highest yields of product rehydration in the comparable conditions were achieved from the A-CTA gibbsite from nepheline raw material, lower – from the B-CTA gibbsite, which was obtained by the method of Bayer.

Keywords: Fe, catalyst, ozone, decomposition, water, treatment, green, chemistry

1 Introduction

In this research, we present the ecologically safe way of processing of ferriferous slimes, produced as by-products of underground water ozonation, as raw materials in the synthesis of the catalysts suitable for cleaning of dry air-gas streams from residual amounts of ozone. The technology of underground water purification by ozonation in combination with the sorption on the granulated activated absorbent carbon (GAC) and activated coal fiber sorbents (AF) provides full deodorization, disinfection, and decrease of concentration of ions of the total iron [1] from 0,57-0,94 mg/l to the maximum permissible concentration (MPC) for underground water of 0.03 mg/l or even lower amounts (Fig. 1).

About 4 tons of ferriferous slimes are annually formed at the water treatment station in Lianozovsky dairy plant (Moscow) as the result of the return washing of the pressure filters containing granular hydroanthracite. It is very desirable to find ways of utilization of this by-product, containing iron oxides. The synthesis of ozone and its application in water purification is a good example of implementation of green chemistry principles [2] in the industry. Ozone as a non-polluting oxidant is widely used in a number of modern technologies. However, due to its toxity, the problem of decreasing the concentration of residual ozone to maximum permissible concentration (MPC) is very important. The best way to destroy residual ozone is its catalytic decomposition.

2 Experimental

To prepare the catalysts, wet wastes were mixed in different proportions with cement- talume binder, granulated, subjected to hydrothermal synthesis at 90°C, and calcinated at 400°C. Catalysts were tested on porosity, specific surface, average mechanical durability of a granule and efficiency in ozone decomposition.

The activity of catalysts in ozone decomposition was estimated using γ value [3] that can be calculated according to the formula given below (i). The value of γ shows the number of ozone molecules that decomposed during collisions with the surface of the catalyst.

$$\gamma = 4\boldsymbol{\omega} \cdot ln[C_0/C]/\boldsymbol{u} \cdot \boldsymbol{S} \quad \text{(i)}$$

where C_0 and C (mg/l) are concentrations of ozone in the feed stream and in effluent from catalytic reactor respectively; $\boldsymbol{w}$ is space velocity of a gas stream, cm^3/s; $\boldsymbol{u}$ is thermal velocity of molecules, cm/s (u = 360 m/s for air at 20 °C); and $\boldsymbol{S}$ is external geometrical surface of all granules of the catalyst in the reactor, cm^2.

XRD analyses were conducted on powder diffractometer DRON-3M in filtered CoK_α-radiation. The porosity was measured using Quantachrome AUTOSORB-1 instrument. Mossbauer spectra of ^{57}Fe nuclei were measured on the spectrometer MS-1104Em using the "constant acceleration" mode.

3 Results and discussion

As was demonstrated by XRD analysis, the main components of the ferriferous wastes (slime after water treatment) are goethite α-FeO(OH), lepidocrocite γ-FeO(OH) and α-Fe_2O_3. During calcination at

400°C lepidocrocite converts to iron oxides: α-Fe_2O_3 (hematite) and γ-Fe_2O_3 (maghemite).

Using Mossbauer spectroscopy at 20°C, it was proved the presence of Fe^{3+} hydroxides and oxides (doublet designated as (1) in Fig. 2). The essential broadening of this doublet (1) confirms a nanodisperse state of the most part of the iron hydroxides and oxides in the calcinated ferriferous precipitate, with a size of particles of about 5 - 10 nm. The line (2) in Fig.2 confirms the data of XRD analysis about the presence of hematite in ferriferous raw materials. The line (3) corresponds to the presence of the phase comprising Fe^{2+} cations.

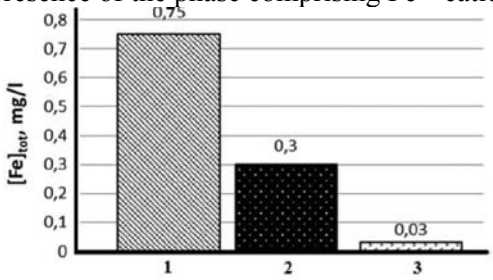

Figure 1 [1]. The total content of iron ions in initial water (1); in water purified by ozonation with GAC sorption (3); MPC of iron oxides in tap water (2).

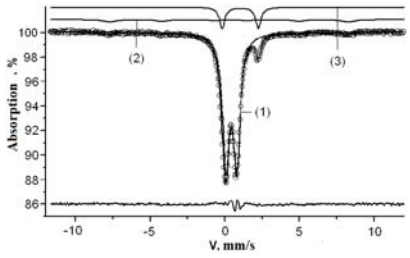

Figure 2. Mossbauer spectra of ferriferous raw materials obtained.

The optimal catalyst comprises 60 wt.% of the ferriferous raw material and 35 wt.% of cement binder (line 3 in Table 1). Such mixture provides mechanical strength and a high catalytic activity in dry ozone decomposition (Table 1), and can be used in industrial processes. After calcination the crushing strength is 1,8±0,1 kg/mm (based on diameter of granule) which is comparable with the characteristics of other industrial catalysts e.g. «Goptalum» GTT. Catalyst porosity is 53 ±5%. Specific surface area of this catalyst is 145 ±12 m^2/g. For comparison, «Goptalum» has specific surface area 125 m^2/g. Kinetic studies showed that the decomposition of ozone proceeds in internal diffusion region with activation energy about 15.5 ± 0.7 kJ/mol. This iron-containing catalyst contain no metal oxides from 1st substance hazard category.

Table 1. Activity of iron catalysts in the reaction of ozone decomposition in a dry gas flow

№	Ferriferous raw material, wt.%	Cement-talum, wt.%	Clay G-1, wt.%	S of all granules of the catalyst in reactor, см^2	Activity in the reaction of ozone decomposition $\gamma_{ср}\cdot10^4$
1	33	60	7	33	1,0±0,1
2	43	50	7	36	1,2±0,1
3	60	35	5	40	1,7±0,1
4	65	30	5	destruction of the catalyst granules	
5	80	15	5		
6	«Goptalum» GTT				2,4±0,2

4 Conclusions

Thus, the new iron-containing catalyst was synthesized using ferriferous wastes produced during ozonation of underground water coupled with sorption by carbonaseous absorbent. Production of the effective iron-containing catalysts from the wastes formed during purification of artesian water with subsequent use of the catalysts for residual ozone decomposition to ecologically safe concentrations agrees completely with the principles of green chemistry. Instead of landfilling iron-containing wastes are used in the downstream process of ozone decomposition to produce oxygen. Mechanical properties and catalytic efficiency in ozone decomposition of the optimized catalyst comprising : 60 wt.% of the ferriferous raw material and 35 wt.% of cement talume binder are comparable with those of industrial catalyst Goptalum GTT.

Sol-Gel Synthesis of Robust Silica Monoliths by Interfacial Solution/Precipitation Reactions: Application in the Preferential Oxidation of Carbon Monoxide

Garcia-Aguilar J.*, Miguel-García I., Berenguer-Murcia Á., Cazorla-Amorós D.

Inorganic Chemistry Department and Materials Science Institute, Alicante University, Alicante, Spain

* jaime.garcia@ua.es

Keywords: silica monolith, silica thin film, capillary, microreactor, PrOxCO

1 Introduction

The Preferential Oxidation of carbon monoxide (PrOxCO) in H_2-rich gas streams is one of the most important challenges for H_2 purification in fuel cell industry. The development of devices and micro-devices for small scale PEM fuel cells applications has considerably grown during the last decades and, in this context, the development of adapted PrOxCO catalytic systems for these low power devices would be mandatory for their implementation.

A very interesting alternative to already existing microreactor configuration for PrOxCO is the use of fused silica capillaries. In this sense, it is possible to synthetise the inorganic phase as a filling inside the capillary [1]. However, one problem of synthesizing a SiO_2 matrix in the capillary is the intrinsic shrinkage of the structure occurring during the synthetic protocol (hydrolysis, gelation and/or calcinations) [2]. This shrinkage may produce the detachment of the silica filling from the capillary walls and generate preferential gas paths, impoverishing the catalytic properties of the microreactor.

In this study, we report a new synthetic route to completely avoid the silica shrinkage during the formation of the structure, by incorporating a mesoporous silica thin film over the inner walls of the capillary prior to the SiO_2 filling synthesis. These novel materials have been loaded with Pt nanoparticles and tested as microreactors in PrOxCO reaction.

2 Experimental/methodology

Preparation of Silica Thin Film. A mesoporous silica thin film has been synthetized by a very well established sol-gel procedure, using CTAB as structure directing agent [3].

Preparation of Silica Filling. The silica filling has been synthetized inside de pre-coated capillary adapting an existing procedure (8738 H_2O; 410 TMOS, 237.6 Urea; 1.57 HAc; 1 F127, molar ratio) [2]. The silica gel inside the capillary is treated at 40ºC for (24 h) and 120ºC (6 h), the two steps are very important to produce the well-anchored silica network.

Preparation of Pt nanoparticles. Pt nanoparticles were synthesized by solvent reduction using ethylene glycol and PVP as reduction and capping agent, respectively. The necessary volume of the colloidal suspension (with a perfectly known concentration) was flowed with a syringe pump through the filled capillary. Three microreactors have been prepared to evaluate the catalytic behavior of the samples with different length (20 and 27 cm) and metal loading (1 and 2 wt % Pt, with respect to silica weight). Experimental conditions of the catalytic tests are; $CO/O_2/H_2$/He 2/2/30/66 % vol. GHSV= 120000 ml $h^{-1}g^{-1}$.

3 Results and discussion

In Figure 1, an enhanced adherence of the SiO_2 filling to the capillary walls can be observed for the sample where a thin film has been coated prior to the synthesis (Fig.1 right). On the contrary, in the absence of this coating (Fig.1 left), the SiO_2 structure suffers a non-negligible

shrinkage that reflects in an important detachment from the capillary support and poorer mechanical properties of the microreactor. FE-SEM analysis of a treated mesoporous silica thin-film confirmed that the aforementioned synthesis protocol results in the partial dissolution of the silica thin film, giving rise to an enhanced adherence of the catalyst to the support.

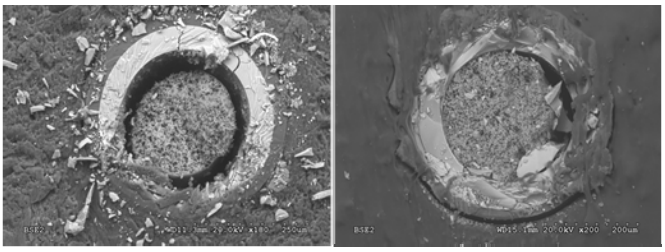

Fig. 1. Silica filled capillary, without and with mesoporous silica thin film (left and right, respectively).

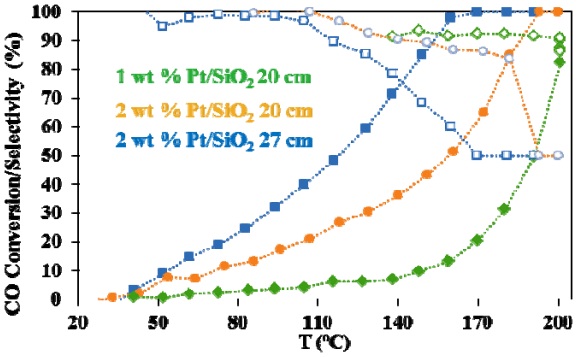

Fig. 2. Performance of the microreactors in the PrOxCO reaction. Solid symbols correspond to CO conversion and hollow symbols to the selectivity.

The catalytic results of the microreactors prepared in this work are shown in Figure 2. All the samples present a very good catalytic performance up to 200ºC. For the samples with the same length and different metal loading, a higher CO conversion is observed for the microreactor with 2 wt % of Pt, and a similar selectivity is obtained for the two samples. On the other hand, for the longest microreactor (blue) a higher CO conversion is observed, although at the expense of lower selectivity at high reaction temperature.

4 Conclusions

A novel methodology has been developed to anchor silica monoliths inside capillary tubes, depositing a mesoporous silica thin-film prior to the synthesis of the monolith. This technique has been successfully used to prepare Pt-loaded microreactors with a very good performance in the PrOxCO reaction.

Photocatalytic Removal of NO Under Visible Light Irradiation over Sol-Gel Synthesized $PbTiO_3$ Nanoparticles

Tabari T., Uner D.*

Chemical Engineering Department, Middle East Technical University, Ankara, Turkey

* uner@metu.edu.tr

Keywords: photocatalysis, $PbTiO_3$ perovskite tyor oxide, visible light, NO oxidation, sol-gel method

1 Introduction

TiO_2 has attracted intensive attention with the advantages of low-cost, high activity, photochemical stability and environmental friendliness [1]. However, TiO_2 only can absorb the ultraviolet (UV) light occupying a small fraction (<6%) of the solar energy due to its large band gap of 3.0 eV above, which limits its practical applications [2]. Many efforts have been made to extend the optical response of TiO_2 into the visible-light region (400-750 nm), including nonmetal (e.g. N, C, F, S) or transition metal doping (e.g. Cr, Cu, Fe), organic dye-sensitizing and compositing with a semiconductor of a narrow bandgap [3]. Nevertheless, the photocatalytic activity is still low, and there are problems in stability or applicability. Among the vast majority of metal oxide photocatalysts, perovskite-type oxides are prominent in their broad diversity of properties. As a typical $A^{2+}B^{4+}O_3^{2-}$ type perovskite structure photocatalyst, $SrTiO_3$ was found active in purification target decomposition without applying any external potential [4]. However, it requires ultraviolet (UV) radiation whose energy exceeds the bandgap of 3.2 eV of the perovskite crystalline phase, practically ruling out the use of sunlight as an energy source for photooxidation. $PbTiO_3$ perovskite type oxide material is important because of its piezoelectricity, ferroelectricity, and colossal magneto-resistivity which make it highly attractive for fundamental research and various technical applications [5]. Also, the catalytic and photocatalytic property of $PbTiO_3$ is studied against different type of pollutants [6-8]. In this work, for the first time photocatalytic oxidation of $PbTiO_3$ against NO is investigated under ambient light irradiation.

2 Experimental/methodology

The synthesis developed here to prepare $PbTiO_3$ is based on the sol-gel process involving polymeric glass network, which can be seen as deriving from ‘‘in situ polymerizable method’’. For the preparation of the photocatalyst, titaniumisopropoxide (TIP) and lead acetate was dissolved in ethyl alcohol at room temperature. Then, citric acid (Aldrich, purity> 99.5%) was added to the solution and the gel formed immediately. The obtained gel was placed in an oven and kept there for 24h at 120 °C, then calcined for 5h at 650 °C till obtaining a yellow powder. The photocatalytic oxidation of NO on $PbTiO_3$ surface was studied according to a modified methodology based on ISO-22197:2007(E) standard method. The optimal condition of reaction obtained at different concentrations of NO, different flow rates and different relative humidity. Further details of experimental methodology was reported in our previous work (I. Bayar, T. Tabari, D. Uner, Appl. Surf. Sci. under review).

3 Results and discussion

Physico-chemical properties of $PbTiO_3$ studied systematically by: XRD, DT-TGA, BET, UV-DRS, TPR, TEM and SEM. XRD showed pure crystalline structure of $PbTiO_3$, TG-DTA showed the crystallization temperature is around 650 ˚C, based on BET the surface area is

around 10.28 m^2/g. UV-DRS revealed $PbTiO_3$ bandgap (2.7 eV) is lower than that of TiO_2 (3.2 eV). TPR showed that $PbTiO_3$ release oxygen at lower temperatures and the activity of the catalyst is higher than TiO_2. SEM results revealed a porous structure of the perovskite and agglomeration of the particles that is also supported by XRD and BET results. The agglomeration of the nano-scale particles were revealed by TEM.

In order to investigate photocatalytic efficiency of the prepared material, the performance of $PbTiO_3$ (0.1 g) was compared to TiO_2 (Degussa P25, 0.19 g) as photocatalyst under ambient light irradiation. First the reactor was shielded with an aluminium foil. NO flow was started until the NO concentration was found to be stable for a 10 minutes. Then the reactor was exposed to the visible light by removing the aluminium foil and switching on the light source. An immediate decrease in the NO concentration was observed upon exposure to light. As shown in Figure. 1, a high conversion of NO is occurred over $PbTiO_3$ (46%), the NO conversion in the presence of TiO_2 under visible light is very low (10%). A sharp decrease of NO concentration over $PbTiO_3$ were recorded in the initial minutes of illumination. This enhanced activity at the beginning of illumination can be related to the light absorption by the catalyst because of additional short term activation. However, since the amount of $PbTiO_3$ is almost half of TiO_2, the photocatalytic activity of Perovskite is higher than TiO_2. In the presence of humidity and NO, structure of active surface of catalyst is changed to $PbTi_3O_7$ which leads to higher bandgap energy and lower tendency for oxygen releasing. So, the catalytic activity decreased in this case.

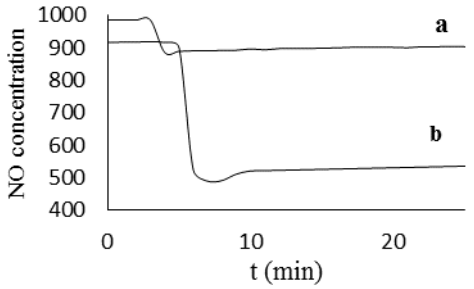

Fig. 1. Nitric oxide concentration against irradiation time: (a) TiO_2 (0.19 g) and (b) $PbTiO_3$ (0.1 g).

4 Conclusions

The results showed high photocatalytic activity of prepared $PbTiO_3$ against NO ambient visible irradiation. However, it should be emphasized that catalytic performance under solar light leads to better results than visible light irradiation.

Coherent Synchronized Monooxidation of Ethylene by Hydrogen Peroxide on a Biomimetic Catalyst

Nagieva I.T.[1,2], Gasanova L.M.[2], Nasirova U.V.[2*], Nagiev T.M.[1,2]

1 - Baku State University, Baku, Azerbaijan Republic
2 - Nagiev Institute of Catalysis and Inorganic Chemistry, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan Republic

* tnagiev@azeurotel.com

Keywords: biomimetic, kinetics, ethylene, hydrogen peroxide, monooxigenase, heterogenous

1 Introduction

Heterogeneous biomimetic catalysts synthesized on the basis of iron porphyrin complexes been the analogs of a ferment of cytochrome P-450, carry out efficiently the processes of gas-phase monooxidation, epoxidation and hydrooxilation of hydrocarbons [1]. Biomimetic catalyst- iron(III) perfluorotetraphenylporphyrin, drawn on aluminium oxide (per-FTPhPFe(III)/Al_2O_3) displayed high activity and selectivity in the processes of oxidizing a great series of hydrocarbons. Using of immobilized biomimetic catalyst, per-FTPhPFe(III)/Al_2O_3 and ecologically pure hydrogen peroxide as oxidizer ("green oxidizer") the high selective process of ethylene oxidation was realized [2].

2 Experimental/methodology

Experimental studies have demonstrated the possibility of flexible control over ethylene monooxidation by hydrogen peroxide for the production of both ethyl alcohol and acetaldehyde (temperature, 120°C; H_2O_2 concentration, 30%; molar ratio, C_2H_4:H_2O_2=1:1,7; rate of supply, C_2H_4 0,22 l/h, H_2O_2 1,72 ml/h) to obtain the best output of ethyl alcohol, 15.4 wt.% (acetaldehyde 12 wt. %) and, in contrast (temperature, 200°C; concentration of a solution of hydrogen peroxide in water, 30%; molar ratio C_2H_4:H_2O_2=1:1.7), an acetaldehyde yield of 34.6wt. % (ethanol 4.6 wt. %). The selectivity of the process under the conditions of maximum ethyl alcohol yield and minimum acetaldehydeyield was virtually 100 wt. %, recalculated for monooxigenase products. Selectivity in obtaining maximum acetaldehyde yield was somewhat lower (87 wt. %) due to the production of CO_2 as a by-product.

3 Results and discussion

The kinetic regularities obtained as a result of experimental studies provide an idea (albeit incomplete) of the mechanism of ethylene monooxidation by hydrogen peroxide.

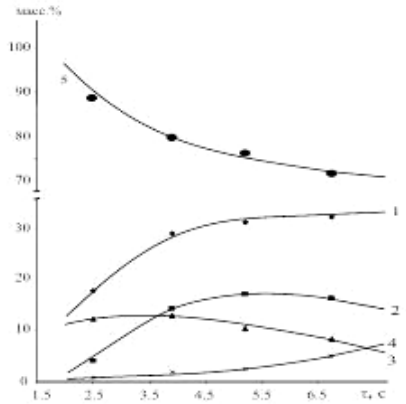

Fig.1. Product yields of ethylene monooxidation reaction as function of (a) the contact time τ under the following conditions: T =140 °C, (a) W_{C2H4}=0.22 l/h,(b) W $_{H2O2}$=1.72m l/h, C_{H2O2}=25% ;
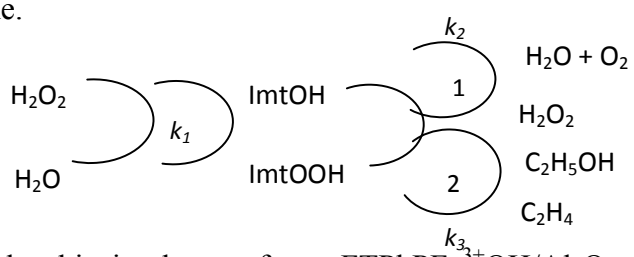
1-C_2H_4conversion, 2-CH_3CHO yield, 3-C_2H_5OHyield, 4 - CO_2yield,5 - O_2 yield.

It can be seen from the kinetic data shown in Fig.1 that kinetic curves 1 and 5 (which

correspond to the yields of monooxigenase products and molecular oxygen) are coherently synchronized; i.e., the highest O_2 yield corresponds to the lowest yield of monooxigenase products, while the lowest yield of molecular oxygen corresponds to the highest yield of monoxide compounds. Both curves (1 and 5) in Fig.1 approach one another asymptotically with a negligible phase shift.

The coherent synchronized character of the catalase and monooxigenase reactions is nicely illustrated by the scheme.



Where ImtOH is the biosimulator of per-FTPhPFe^{3+}OH/Al_2O_3, ImtOOH is the per-FTPhPFe^{3+}OOH/Al_2O_3intermediate, 1 is the catalase (primary) reaction, 2 is the monooxigenase (secondary) reaction, k_1 is the intermediate production rate, k_2 is the catalase reaction rate, and k_3 is the monooxigenase reaction rate.

Kinetic simulation of ethylene oxidation above a biomimetic catalyst by different methods:

1)UsingMichaelis-Menten equation in terms of the Lineweaver-Burk coordinates:

$1/V = 1/V_{\max} + k_m/V_{\max} \cdot 1/[C_2H_4]$ whichallowed to determine the effective reaction rate and effective activation energy for the ethylene oxidation reaction (E_{eff} =42.0 kJ/mol); this value agrees with the activation energy for enzymatic reactions.

2) Using the method of stationary concentration: $r_{C_2H_4} = k_{\text{eff}}[C_2H_4]$, $k_{эфф} = \frac{k_1 k_3}{k_2}[\text{Im } tOH]$

3)Applyingequation

Determinant $D = \nu\left(r_{2,H_2O_2}/r_{C_2H_4} + r_{1,H_2O_2} - r_{2,H_2O_2}/r_{C_2H_4}\right)^{-1}$ [3],whichdetermined quantitative characteristic of coherent-synchronized oxidation reactions - catalase and monooxigenase : $k_{эфф}^{мон} = \frac{r_{1,H_2O_2} D}{[C_2H_4]}$

4 Conclusions

By comparing the kinetic parameters obtained using the three different methods, we conclude that in kinetic descriptions of complex chemical reactions(includingcoherent-synchronized reactions) the determinant equation yields a more complete description than other methods.

Hydrogen Production from Olive Mill Wastewater through Steam Reforming. Catalyst Development

Casanovas G.A.*, Llorca P.J.

Institute of Energy Technologies. Technical University of Catalonia, Barcelona, Spain

* albert.casanovas.grau@upc.edu

Keywords: hydrogen, olive mill wastewater, cerium, lanthanum, oxide, steam reforming

1 Introduction

Olive mill wastewater (OMW) contains phenolic compounds, fatty acids, lipids and sugars among other organic molecules that transform this waste into a serious environmental problem affecting soils and aquatic ecosystems [1]. Currently this waste is mainly deposited into artificial ponds and its transformation and valorization is a key point in transforming the olive oil industry into an environmentally friendly one.

Hydrogen production from catalytic steam reforming of the liquid phase of OMW provides a reduction of organic content in this waste, and thus, a reduction of the environmental contamination, while producing a valuable product [2,3]. The catalyst must be capable to reform light and heavy molecules, cyclic and aromatic compounds, acidic and alcoholic compounds, among others. The different nature of organic compounds present in the liquid to be reformed forces a different approach of the catalyst development, looking for a stable multi-compound steam reforming catalyst.

In this work, catalytic honeycombs functionalized with several lanthanum-stabilized ceria as catalytic support and impregnated with platinum were tested for OMW steam reforming. Catalysts were also tested for steam reforming of model compounds such as acetic acid and 2-phenylethanol. Catalytic results were related to physical surface properties of support.

2 Experimental/methodology

A series of $Ce_{(1-x)}La_xO_{(2-\ x/2)}$ (x : 0-0.5) were prepared by precipitation of $CeCl_3 \cdot 7H_2O$ and $La(NO_3)_3 \cdot 6H_2O$ using NH_4OH as a precipitating agent and used as catalytic supports. Ceramic monoliths (Corning 400cpsi) were functionalized with approximately 500 mg (25% w/w) of catalytic support using a gel of polyvinylalcohol (PVA). The resulting monoliths were impregnated with a $PtCl_2$ aqueous-acetone solution to keep Pt load between 0,5-2% (w/w based on catalytic support weight).

Monolithic catalysts were tested under distillated OMW, acetic acid, and 2-phenylethanol steam reforming at atmospheric pressure, temperature between 873-1023K, and weight-to-flow (W/F) values ranging from 0.4 to 1.6 $g \cdot min \cdot mL_{OMW}^{-1}$. Results were evaluated by means of chromatographic analyses of effluent dry gas and post-reaction condensate liquid. Total Organic Carbon (TOC) and Chemical Oxygen Demand (COD) of reactants and post-reaction condensate were also used to evaluate the reaction extension. Characterization of supports was conducted by means of X-Ray photoelectron spectroscopy (XPS) analyses, X-Ray diffraction (XRD), Temperature Programmed Reduction (TPR), and Temperature Programmed Desorption of NH_3 (TPD-NH_3).

3 Results and discussion

Distillated OMW present values of 5.41 g $C \cdot L^{-1}$ and 4.05 g $O_2 \cdot L^{-1}$ in TOC and QOD analyses respectively. More than 90% of organic matter is removed after steam reforming conducted at 973K and W/F=0.83 $g \cdot min \cdot mL^{-1}$. The selectivity of the process, based on the effluent dry gas composition, mainly corresponds to H_2 (>72%) and CO_2 (>26%).

Samples were exposed to steam reforming of acetic acid and 2-phenyletanol at 1023K, atmospheric pressure, and W/F ranging from 0.4 to 1.6 $g \cdot min \cdot mL_{OMW}^{-1}$. Steam to carbon (S/C) was set at a value of 6 which represents a more severe condition than OMW steam reforming with TOC values 15 times higher. Under these conditions selectivity of H_2, CO, and CO_2, are close to 63, 9, and 26% respectively.

Figure 1 shows XPS results of $Ce_{(1-x)}La_xO_{(2--x/2)}$ powders. A slight enrichment of La on the surface at high Ce/La ratios is observed while $Ce_{0.5}La_{0.5}O_{1.75}$ presents a high enrichment of Ce on the surface, this result is in accordance with the literature [4]. A maximum in surface Ce^{4+}/Ce^{3+} concentration is found for $Ce_{0.75}La_{0.25}O_{1.875}$ support composition. This has been related to the catalytic behavior.

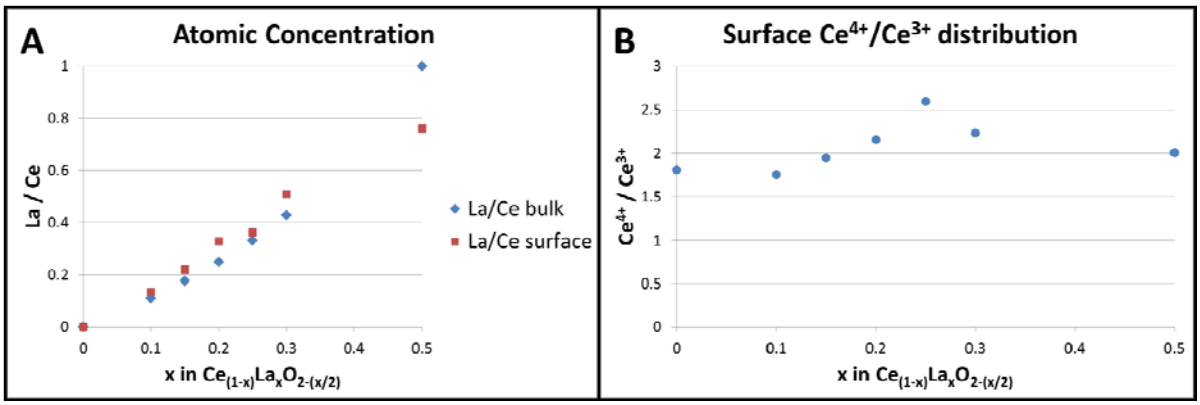

Fig. 1. XPS results of synthetized supports. A) Bulk and surface atomic concentration comparison. B) Ce^{4+} and Ce^{3+} surface distribution

4 Conclusions

Ceramic monoliths functionalized with Pt-based catalysts supported on various $Ce_{(1-x)}La_xO_{(2--x/2)}$ catalytic supports present good catalytic performance under steam reforming of distillated OMW, acetic acid, and 2-phenylethanol. Catalytic results have been related to surface properties of catalytic support.

Bulk Mixed Al-Transition Metal Oxide Catalysts for Enhanced Oxidation of 1,2-Dichloroethane

Khaleel A.*, Nawaz M.

UAEU, Al-Ain, UAE

* abbask@uaeu.ac.ae

Keywords: mixed, oxides, oxidation, chlorinated, organic, compounds, sol-gel

1 Introduction

Several catalytic systems based on metal particles or metal oxides can promote the oxidation of chlorinated organic compounds (COC) [1-2]. The decomposition of 1,2-dichloroethane (DCE) usually starts with dehydrochlorination resulting in vinyl chloride (C_2H_3Cl) and HCl. Further oxidation may take place yielding carbon oxides, CO and CO_2. However, deep catalytic oxidation of DCE and many other COC usually takes place at relatively high temperatures, ≥ 400 °C. In previous studies we found that catalysts based on bulk mixed oxides of transition metals and γ-alumina or titania exhibit significant catalytic activity in the oxidation of COC [3]. In the present study, mixed oxides of γ-alumina and different transition metals were prepared and studied for the oxidation of DCE. Catalytic activity and selectivity vs. composition and selected preparative conditions were investigated.

2 Experimental/methodology

Template-free sol-gel method was employed to prepare highly porous aerogel and xerogel metal-doped γ-Al_2O_3. Aluminum sec-butoxide and transition metal nitrates, or chlorides were used as precursors. Composites containing Cu (II), V(III), Cr(III), and other transition metal ions were prepared. The general formula Al-M-x will be used to represent the composites where "M" refers to the dopant metal ion and "x" refers to its molar fraction, 100 x M/M+Al.

The catalytic activity of composites containing different concentrations of Cu(II), V(III), and Cr(III) was studied in the oxidation of DCE. The reactions were investigated using a fixed-bed flow reactor under atmospheric pressure. The reactor was coupled with an FTIR spectrometer equipped with a continuous flow gas cell, from Pikes Technology, for continuous monitoring of the reaction products. DCE adsorption and subsequent decomposition on the surface of the catalysts was studied in-situ using DRIFTS.

3 Results and discussion

Mesoporous powders with relatively high surface areas, 300-500 m^2/g, and large total pore volumes, 1.4-2.0 cc/g, were prepared. Besides different other preparative conditions, the gel formation was dependent on the type of metal ion dopant and its concentration. As an example, the presence of Fe(III) or V(III) at a molar concentration of 10% significantly enhanced the gel formation process. The particle size, surface area, and porosity were also dependent on the preparative conditions and the composition. Surface areas of xerogel and aerogel powders were around 300 and 700 m^2/g, respectively. The type of precursor also played a role in the textural properties of the final product. Metal acetylacetonate (acac) as a precursor was compared with metal nitrates and chlorides. The presence of transition metal ions resulted also in noticeable enhancement of the surface acidic and redox properties as indicated by pyridine adsorption, NH_3-TPD, and H_2-TPR studies.

The catalytic activity study showed that Al-Cu and Al-Cr oxide composites possessed a promising catalytic activity for the oxidation of DCE as shown in Figure 1. Reactions over

undoped γ-alumina produced vinyl chloride (VC) and HCl as major products and relatively small amounts of CO_2. On the other hand, reactions over Cu- and Cr-doped catalysts showed enhanced capability for deep oxidation resulting in CO_2 as the major product. On the contrary, V(III)-containing catalysts showed a considerably lower catalytic activity. The nature of the products was also dependent on the transition metal present. While VC was the major Cl-containing hydrocarbon product from reactions over Al-V-3 and Al-Cr-3, it formed only in negligible amounts over Al-Cu-3 catalyst where the deep oxidation product, CO_2, was the major product. The catalytic activity of the Cu-containing catalysts decreased as the Cu ions concentration increased. The results of the catalytic activity and adsorption studies indicate that the tendency of γ-alumina towards adsorption and dehydrochlorination combined with redox properties of transition metal ions can be tailored to enhance the oxidation of DCE and possibly other COC.

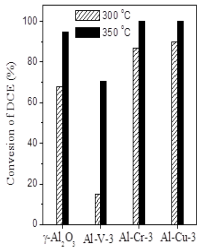

Fig. 1. Conversion of DCE over undoped and doped γ-alumina containing 3% metal ions at 300 and 350 °C

4 Conclusions

The employed sol-gel method resulted in mesoporous powders of undoped and metal-doped γ-alumina with high surface areas, large pore volumes, and significant acidity. The doped catalysts showed promising activity in the deep oxidation of 1,2-dichloroethane at relatively low temperatures compared with pure γ-alumina. The nature of the products was strongly dependent on the presence as well as on the type of dopant ion. Cu- and Cr-doped catalysts showed significantly higher catalytic activity in the deep oxidation of DCE. Retaining the γ-alumina acidity after doping combined with the redox properties of the transition metal ions promoted dehydrodechlorination and further oxidation of the reaction intermediates.

Green Alternative for Guideline Monoterpenoids to Value-Added Products – Tailored the Biocatalytic Transformation of α-Pinene

Tudorache M.*, Gheorghe A., Parvulescu V.I.

University of Bucharest, Bucharest, Romania

* madalina.sandulescu@g.unibuc.ro

Keywords: immobilised enzyme, alpha-pinene, alpha-pinene oxide, verbenol, biocatalytic oxidation, green process

1 Introduction

In the era of renewable carbon sources as a key element in biorefinery, we know of only biomass alternative for the replacement of fossil resources. Recently investigations demonstrated both terrestrial and marine environments contain important renewable carbon sources represented often by monoterpenoid compounds (monoterpenes).

Monoterpenes are important and abundant natural resources, well-known as the starting materials for industries of flavors, pharmaceuticals, perfumery and food as well as the precursors applied in the pesticides and polymeric industries. In this context, α-pinene is known as a platform molecule due to its high reactivity and potential to be transformed in various derivatives (e.g. α-terpinyl, bornyl acetates, ρ-cymene, α-pinene oxide, myrtenol, verbenol, verbenone, ρ-methyl-acetophenone, thymol, carvacrol, among others).

At present however, classical chemical procedures are still the primary approaches to obtain monoterpenes. Although some unique oxidants or catalysts are available, the conventional chemical procedures have generally been proved to be of low stereo-, regio-, and chemo-selectivity and as a consequence give rise to undesirable mixtures of products. Recently, there has been a significant progress in the field of monoterpene biotransformation which offers many advantages, such as: i) simple manipulation, ii) use of mild reaction conditions, iii) high efficiency, iv) appreciable reaction-, region- and stereo-selectivity, and v) it's more environmental friendly nature. Therefore, the biotransformation represents a powerful tool for the utilization of monoterpenes.

In this study, biocatalytic oxidation of α-pinene designed in varied configurations has been investigated for the production of value-added products (e.g. α-pinene oxide, verbenol, pinanediol, camphene, campholenal).

2 Experimental/methodology

Biocatalysts were constructed as lipase enzyme absorbed/entrapped/cross-linked leading to the specific configurations. The immobilization approaches are detailed in the previous papers [1,2]. Biocatalytic oxidation of α-pinene was performed in the mixture of substrate and oxidation agent (1:1= α-pinene:H_2O_2/UHP) catalysed by lipase enzyme (50 mg/mL). The reaction was developed in ethyl acetate for 24 h under room temperature. Then, the reaction phases were separated by centrifugation. The supernatant was further frozen and extracted with pentane. The evolution of the biocatalytic process was followed based on GC-MS/FID analysis of the reaction products.

3 Results and discussion

We developed a biocatalytic system for α-pinene oxidation based on lipase catalysis. Screening of the lipase enzyme from different sources (e.g. *Aspergillus niger*, *Candida antarctica*, *Candida cylindracea*, *Pseudomonas cepacia*, *Rhizopus niveus*, Porcine Pancrease) allowed to set up the most performing lipase on the proposed configuration. Therefore, *Aspergillus niger* lipase was chosen as biocatalyst for α-pinene derivatisation. Also, the biocatalytic system was tested for two different oxidation agents (e.g. H_2O_2 and UHP) demonstrating the influence of this reagents on the selectivity of the process.

Lipase enzyme was immobilized leading to varied configurations (e.g. absorption, entrapment, covalent and cross-linking). The biocatalysts were tested; the results are presented in table 1. Enzyme immobilization using the entrapment approach allowed to improve the α-pinene conversion and moreover to concentrate the selectivity onto verbenol production. The other biocatalyst configurations behaved similar between them in term of selectivity leading to α-pinene oxide as dominant product next to verbenol, camphene, campholenal.

Table 1. The effect of biocatalyst design on biochemical route of the α-pinene oxidation process.(CLEA-cross-linked enzyme aggregates and CLEMPA–cross-linked enzyme aggregates onto magnetic particles).

biocatalyst	**Conversion (%)**	**Selectivity (%)**			
		α-pinene oxide	camphene	verbenol	campholenic aldehyde
Free lipase	15.30	57.61	2.09	1.04	3.12
Adsorbed lipase	13.25	43.21	3.20	2.21	4.35
Covalent attachment of lipase	10.50	47.90	2.34	10.75	3.21
Entrapped lipase	22.58	26.34	1.36	21.00	1.67
CLEA	27.06	35.31	0.38	3.06	6.53
CLEMPA	9.61	42.37	0.89	3.06	8.20

4 Conclusions

Biocatalytic system for α-pinene valorization had been developed for production of value-added products, especially α-pinene oxide and verbenol.

Characterization and Application in Catalytic Reduction of MB of $Fe_3O_4SiO_2Ni$ Nanoparticles

Kurtoglu K., Gubbuk I.H., Akgemci E.G.*

Necmettin Erbakan University, Faculty of Ahmet Kelesoglu Education Chemistry, Department of Chemistry, Konya, Turkey

* eakgemci@konya.edu.tr

Keywords: dye degradation, magnetic, nanoparticle

1 Introduction

Design of nanocomposites consisting of functional metals and different matrices is a promising research area for the fabrication of a variety of catalysts, adsorbents, and optical and electrical devices. In this study, nickel ions intercalated into $Fe_3O_4SiO_2$ interlayer forming a nanocomposite of magnetic and nickel nanoparticles ($Fe_3O_4SiO_2Ni$). The magnetic nickel nanocomposites were characterized by scanning electron microscopy (SEM), X-ray powder diffraction (XRD) and measurements. $Fe_3O_4SiO_2Ni$ was used as a catalyst for reduction of organic dye with $NaBH_4$.

2 Experimental/methodology

All chemicals were analytical reagent grade: copper nitrate (Merck), sodiumborohydride and azo dyes (all from Sigma Aldrich). Water used for the preparation of all solutions was deionised by reverse osmosis. $FeCl_3$ and $FeCl_2$ were purchased from Sigma Aldrich.

The magnetic nanoparticle, Fe_3O_4, was prepared by a precipitation method. Briefly, 60mL of $FeCl_2$ and $FeCl_3$ aqueous ethanol solution with a concentration ratio of 5:1 was prepared, 1.0 mol/L ammonia solution was added drop by drop with vigorous stirring until pH 10, and a black product was obtained. Then, the black product was crystallized under 50 ◦C water bath for 3 h. Subsequently, separated with magnet, the obtained black magnetite particles were washed with ethanol for 3 times, dried at 50 ◦C for 12 h [1]. Fe_3O_4 spheres were coated by SiO_2 films, by using TEOS as a precursor. The resulting $Fe_3O_4SiO_2$ particles were loaded with *Ni* nanoparticles. The material showed better performance than a conventional Fe_3O_4 catalyst in catalytic reduction of methylene blue (MB) with $NaBH_4$. It can be separated from the reaction mixture by a magnet and be recycled without obvious loss of catalytic activity [2].

Catalytic activity of $Fe_3O_4SiO_2Ni$ was investigated by means of degradation of MB by sodium borohydride in aqueous solutions. Typically, 300 mL of the $1x10^{-4}$ mol L^{-1} MB solution was mixed with 0.010 g of $Fe_3O_4SiO_2Ni$. Thereafter, 5 mL of the sodium borohydride solution was added to the dispersion and the reaction was monitored by UV-VIS spectrometry. Study of the catalytic activity of $Fe_3O_4SiO_2Ni$ was conducted at the laboratory temperature.

3 Conclusions

In this study, $Fe_3O_4SiO_2Ni$ composites have been synthesized by a chemical method, with Fe3O4 as a substrat, nickel nitrate as a metal precursor and TEOS as a stabilizator. These composites accessible and highly dispersed Ni nanoparticles, thus resulting in high catalytic activities in the degradation of MB.

The chemical reaction between the MB and $Fe_3O_4SiO_2Ni$ in solution leads to the bleaching of MB diluted solution. The bleaching mechanism in acidic media is attributed to a pair of electrons belonging to nitrogen (N) atoms which would receive H^+ (proton). This leads to a

resonance with the benzene rings inside the MB molecule that is then itself reduced, forming a leucomethylene blue molecule (MB colorless solution) (Figure 1) [3].

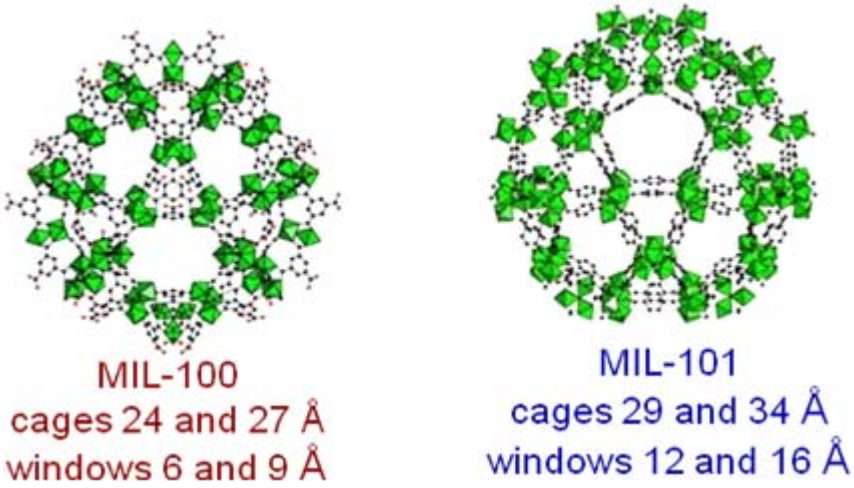
Keywords: selective oxidation heterogeneous catalysis, metal-organic frameworks, liquid phase

Porous coordination polymers or metal-organic frameworks (MOFs) have attracted much recent attention due to a unique ensemble of properties, such as crystalline open structures, extremely high surface areas, tunable pore size and functionality, as well as high contents of uniform and accessible metal sites [1]. In the past decade, a number of MOFs with good thermal and solvolytic stability have been designed and implemented [2, 3]. A considerable scientific effort was directed to evaluation of their potential as heterogeneous catalysts for organic synthesis, in particular, for the production of oxygenated compounds [3].

In this presentation, we give an overview of catalytic applications of MOFs of the MIL family (MIL stands for **M**aterials of **I**nstitute **L**avoisier) in liquid-phase selective oxidations [4-9]. Bearing in mind the growing environmental concern, we focus on the catalytic systems that employ environmentally benign oxidants, such as molecular oxygen, aqueous hydrogen peroxide and *tert*-butyl hydroperoxide (TBHP). Our aim is to demonstrate the possibilities of MOFs in the selective oxidation of a wide range of organic compounds, with special attention to



the critical issues of the catalysts stability and reusability and the nature of catalysis.

We will start with evaluation of the catalytic properties of the mesoporous chromium- and iron-based carboxylates MIL-100 and MIL-101 in the liquid-phase oxidation of hydrocarbons (alkanes, alkenes, aromatics) under mild conditions [4-6]. The impact of the transition metal nature on the reaction selectivity and the role of diffusion and adsorption will be discussed in the light of recent results acquired for solvent-free selective oxidation of cyclohexane and cyclohexene with molecular oxygen and/or TBHP and oxidation of anthracene with TBHP in chlorobenzene. Mechanistic features of the oxidation catalysis by MOFs will be addressed, and

a particular case of a biomimetic behavior of Fe-MIL-100(101) will be highlighted. Peculiarities of adsorption of various organic compounds on MIL-100 and MIL-101 and their consequences for catalysis are discussed.

In the second part of the lecture, we will provide examples of the application of MIL-101 as a mesoporous support for transition-metal complexes, such as polyoxometalates (POM) and phthalocyanines (Pc). The elaborated POM/MIL-101 hybrid materials demonstrate superior catalytic performance in epoxidation of a broad range of alkenes with H_2O_2 [7], while FePc/MIL-101 enables efficient oxidation of phenolic compounds using TBHP [8]. Effects of the MOF support on the catalyst activity and selectivity will be analyzed, and the reasons for the improved catalytic behavior will be suggested.

Stability of MOFs under turnover conditions and factors leading to catalyst deactivation were thoroughly investigated. Based on these studies, recommendations on the choice of proper reaction conditions for exploitation of MOFs in the liquid-phase oxidation processes can be given. Finally, we will show an example how a MOF, the structure of which is destroyed by the reaction medium, can act as a precursor for a highly active, selective, truly heterogeneous and recyclable catalyst. The case study is H_2O_2-based oxidation of alkylphenols over Ti-MIL-125 that affords corresponding *p*-bezoquinones with ca. 100% selectivity [9].

A comparison of the selected MOFs with conventional single-site catalysts (transition-metal-substituted zeolites, aluminophosphates and mesoporous silicates) will be provided in terms of catalyst activity (TOF), productivity (TON), selectivity, and stability toward metal leaching. The scope and limitations of the MOF-based catalyst systems will be discussed.

Microstructured Reactors as Efficient Toolfor the Operation of Selective Oxidation Reactions

Kolb G.*, Pennemann H.

Fraunhofer ICT-IMM, Mainz, Germany

* gunther.kolb@imm.fraunhofer.de

Keywords: selective oxidation, plate heat-exchangers, microreactors

1 Introduction

Selective oxidation reactions are re-considered currently to improve the efficiency and ultimately the sustainability of the processes under operation. The performance of the catalysts applied for these reactions highly depends on the operating conditions which are in turn determined by the reactor technology.

The exothermic character of selective oxidation reactions creates a challenging task for the heat management of the chemical reactor hosting them. Microchannel plate heat-exchanger technology offers unique opportunities of integrated heat removal by the introduction of energy consuming processes into the reactor, such as endothermic reactions or, closer to conventional solutions, evaporation of liquids. The plate heat-exchanger reactor, which is coated with thin layers of catalyst allows improved heat and mass transfer in the catalyst and therefore avoids hot-spot formation and related problems. Owing to the high rate of oxidation reactions, which creates most of the heat of reaction at the reactor inlet, it gets obvious that co-current cooling is the preferred solution for selective oxidation reactions. The current contribution provides an overview of the research activities in the field of selective, partial and preferential oxidation reactions.

2 Production of chemicals

The selective or better partial oxidation of ethylene to ethylene oxide is a prominent reaction which has attracted extensive efforts owing to its hazardous character and difficult heat management. While early work still focused on laboratory applications , microchannel reactors were designed and built in pilot scale to demonstrate the feasibility of the process. However, practical problems and system costs prevented the industrialization of the process to date.

Other reactions such as ammonia oxidation to nitrogen oxides , the oxidation of alcohols to aldehydes and of toluene to benzaldehyde and benzoic acid have been investigated, however, these early applications were still limited to laboratory scale. The production of hazardous chemicals such as hydrogen peroxide was investigated for the industrial scale through laboratory tests and scale-up calculations, however, the on-site production of hydrogen peroxide for sterilization purposes in de-centralised plants remains an interesting option. Further and mostly more recent publications deal with selective or preferential oxidation over zeolites also by photo-catalytic reactions .

3 Hydrogen supply for fuel cells

The partial oxidation of fuels is an alternative to steam reforming and autothermal reforming, which does not require complicated water management. However, the heat management of the reaction is a critical issue in adiabatic reactors which leads to degradation of the catalysts by severe hot spot formation. Operation without steam in the reactor feed leads easily to coke formation, which is dealt with by (a) specific catalyst design , (b) introduction of

coatings at the reactor walls resistant against carbon formation, (c) re-cycling of steam containing fuel cell off-gas into the reactor feed.

The selective or better preferential oxidation of carbon monoxide in a hydrogen rich product stream of a reformer is required, in case the reformate is fed to a PEM fuel cell ultimately, because the carbon monoxide poisons this fuel cell type. While larger amounts of carbon monoxide are removed by water-gas shift, the last portion (0.3-1%) is removed by selective oxidation over noble metal (platinum) containing catalysts. The practical application of the reaction suffers from two main issues, which are (a) the high degree of conversion required and (b) the high reaction enthalpy of carbon monoxide oxidation. Low temperature PEM fuel cells can tolerate only 10-100 ppm of carbon monoxide, depending on their specific design.

The application of ceramic or metallic monoliths as reactors for de-centralised applications, which is obvious at a first glance when considering aspects of system cost and future mass-production, creates problems of system control and complexity. The adiabatic monolithic reactor generates too much heat, which has led to the introduction of multiple (up to four) reactors switched in series . Fixed bed reactors with integrated cooling suffer from local over-heating of the catalyst, which impairs their performance dramatically. The group of the author has designed and operated single stage reactors of kW-scale for the selective oxidation of carbon monoxide with integrated cooling by water evaporation and two-staged oxygen addition, which allowed stable and dynamic operation of the system at the required low carbon monoxide concentration .

V-, Nb, and Ti-Promoted Hexagonal Tungsten Bronzes as Selective Catalysts in the Transformation of Glycerol and Methanol in Aerobic Conditions

Soriano M.D.[1], Chieregato A.[1], Zamora S.[1], Bandinelli C.[2], Cavani F.[2], Lopez Nieto J.M.[1*]

1 - Instituto Tecnologia Quimica, UPV-CSIC, Valencia, Spain
2 - Dipartimento Chimica Industriale e di Materiali, Universitá di Bologna, Bologna, Italy

* jmlopez@itq.upv.es

Keywords: metal oxides bronze, glycerol to acrylic acid, methanol oxidation, tungsten, vanadium, niobium

1 Introduction

Promoted mixed metal oxides bronzes have attracted considerable attention in the last years in the field of material science [1], although at the moment, they have been less studied in catalysis. Recently, they have been reported as selective catalysts in the one-pot oxidative transformation of glycerol to acrylic acid [2], when both redox and acid sites are present [2].
The catalytic transformation of methanol could be used for determining both redox and acid sites under reaction conditions [3]. In this paper we present the synthesis, characterization and catalytic performance for the aerobic conversion of glycerol and methanol of Nb-, Ti- and V-promoted tungsten oxide with hexagonal tungsten bronze (HTB) structures.

2 Experimental

The catalysts were prepared hydrothermally at 175°C for 48 h from gels with a X/(W+X) molar ratio in gel of 0.17 (X= Nb, Ti or V). Finally, they were heat-treated at 450-600ºC (in N_2 atmosphere) depending on precursor. The heat-treated materials were characterized with various techniques (XRD, N_2-adsorption, RAMAN, SEM/TEM, XPS, NH_3-TPD and TPR analysis).

Reactivity experiments for glycerol or methanol (in the 250-450ºC range) were carried out in continuous flow quartz reactor, operating at atmospheric pressure [2].

3 Results and discussion

Table 1 shows some characteristics of the catalysts. X-ray diffraction patterns of as-synthesized and samples heat-treated at 450 ºC can be assigned to hexagonal a tungsten bronze (HTB) structure (JCPDS: 85-2460).

Table 1. Characteristics of unpromoted and promoted hexagonal tungsten bronze (*h*-WOx) catalysts

Sample	Heat-treatment (ºC)	S_{BET} [a] $m^2\ g^{-1}$	M/(W+M) ratio [a]	TPD-NH_3 $\mu mol_{NH3}\ g^{-1}$
h-WO_X	450	31	0	135.0
Nb-WO_X	600	21	0.20	121.0
Ti-WO_x	500	17	0.12	72.3
V-WO_X	600	19	0.19	87.5
V,Nb-WO_X	600	57	0.28 (V/Nb=0 .75)	192

However, the thermal stability of this crystalline structure strongly depends on the promoter: up to 600ºC in Nb- or V-containing samples; up to 500ºC for Ti-containing sample

and 450ºC for unpromoted sample. The surface area of the solids synthesized decreased as follows: V,Nb-WOx > h-WOx > Nb-WOx > V-WOx > Ti-WOx (Table 1), although the higher surface area of h-WOx can be related to the lower heat-treatment temperature [4]). On the other hand, the chemical composition of these materials (determined by EDS microanalysis), revealed a homogeneous distribution of the elements.

Figure 1 shows the selectivity to the main reaction products during the aerobic transformation of methanol or glycerol. Dimethylether (DME), formaldehyde (FMA) and COx were mainly formed from methanol, whereas acrolein, acrylic acid and COx (in addition to heavy compounds) were formed from glycerol. In addition, V-free catalysts are active and selective to reaction products formed by acid catalysis (i.e. DME or acrolein) while the presence of V-sites favours, by redox mechanism, the direct formation of formaldehyde from methanol [2b, 3] or the consecutive reaction of acrolein to acrylic acid [5].

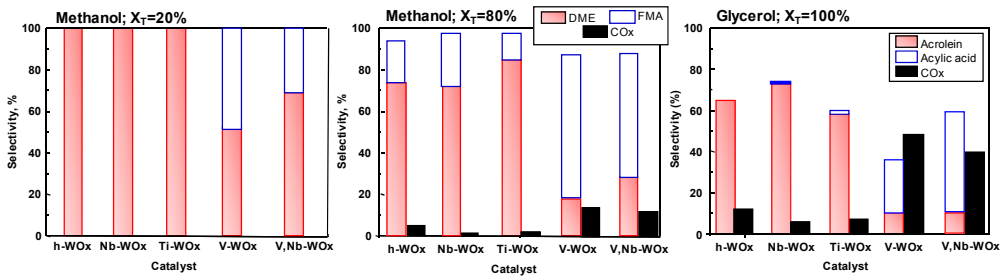

Fig.1. Selectivity to main reaction products during the aerobic transformation of methanol (at 20 and 80% conversion) and glycerol (at 100% conversion) over hexagonal tungsten bronzes.

However, the formation of carbon oxides is also favoured at high alcohol conversions, probably as a consequence of the minority presence of extra-framework V-species [2a]. In fact, it has been recently proposed how tailoring redox and acid sites makes possible to optimize formation of acrylic acid from glycerol [5].

4 Conclusions

Redox and/or acid sites can be incorporated in tungsten hexagonal bronzes by isomorphous substitution of W^{5+} and W^{6+} by M^{4+} and/or Me^{5+} such as Nb, Ti or V improving their catalytic performances in aerobic transformation of alcohols.

Metal-Free Heterogeneous Catalysts for the Epoxidation of Alkenes with H_2O_2

Lueangchaichaweng W.[1], Sheng X.[1], Vankelecom I.F.[1], Pescarmona P.P.[2,1*]

1 - COK, University of Leuven, Leuven, Belgium

2 - Chemical Engineering Department, University of Groningen, Groningen, The Netherlands

* p.p.pescarmona@rug.nl

Keywords: metal-free catalysts, functionalised carbon, epoxidation, hydrogen peroxide, heterogeneous catalysis

1 Introduction

The epoxidation of alkenes with H_2O_2 is an industrially relevant route to produce epoxides, which are valuable and versatile compounds. Many heterogeneous catalysts in which the active site is a metal centre have been developed for this reaction (*e.g.* TS-1, Ti-MCM-41, Ga_2O_3).[1] Here, we show for the first time that epoxidation reactions can be catalysed also by metal-free heterogeneous catalysts obtained by straightforward functionalisation of carbon materials.

2 Experimental

Activated carbon (AC, from Norit, surface area = 863 m^2/g) was refluxed in a concentrated HNO_3 aqueous solution (2, 6, 8 or 12 M) for a chosen time (t = 2, 6, 24 or 48 h). Next, the solid was washed with distilled and dried at 80°C. The obtained samples were characterised by TPD, XPS, ATR-FTIR, N_2-physisorption and SEM. The epoxidation tests were performed at 80°C using 2 mmol alkene, 4 mmol 50 wt.% H_2O_2, 40 mg of catalyst, 2.0 g of solvent.

3 Results and discussion

We present the design and synthesis of a novel class of metal-free epoxidation catalysts containing phenol and carboxylic acid groups as active sites (Fig. 1). The idea behind this original class of heterogeneous catalysts stems from the reported ability of phenol and carboxylic acids to activate hydrogen peroxide towards the epoxidation of alkenes.[2] The switch from a homogeneous to a heterogeneous system was achieved by functionalising the surface of activated carbon with the desired oxygenated groups by means of an acid treatment. Activated carbon is an attractive starting material, because it has high surface area, is inexpensive and sustainable, as it can be prepared from agricultural wastes.

A series of functionalised activated carbons was prepared by varying the concentration of HNO_3 and the time of the acid treatment. The obtained functional groups at the surface of the carbon material include carboxyl groups, lactones, anhydrides, phenol and carbonyl groups, as evidenced by TPD analysis.[3] The desired phenol and carboxyl groups are the major species (Fig. 2). All the functionalised carbon materials are active in the epoxidation of alkenes with hydrogen peroxide, with the activity being correlated to the amount of phenol and carboxylic acid groups present at the surface of the material. The most active catalyst could achieve high epoxide yields (Fig. 1). The selectivity varied according to the type of alkene employed: complete selectivity towards the epoxide was observed with cyclooctene, whereas both epoxide and diol products were obtained from limonene. The catalysts are truly heterogeneous (no leaching) and they retain their activity upon recycling.

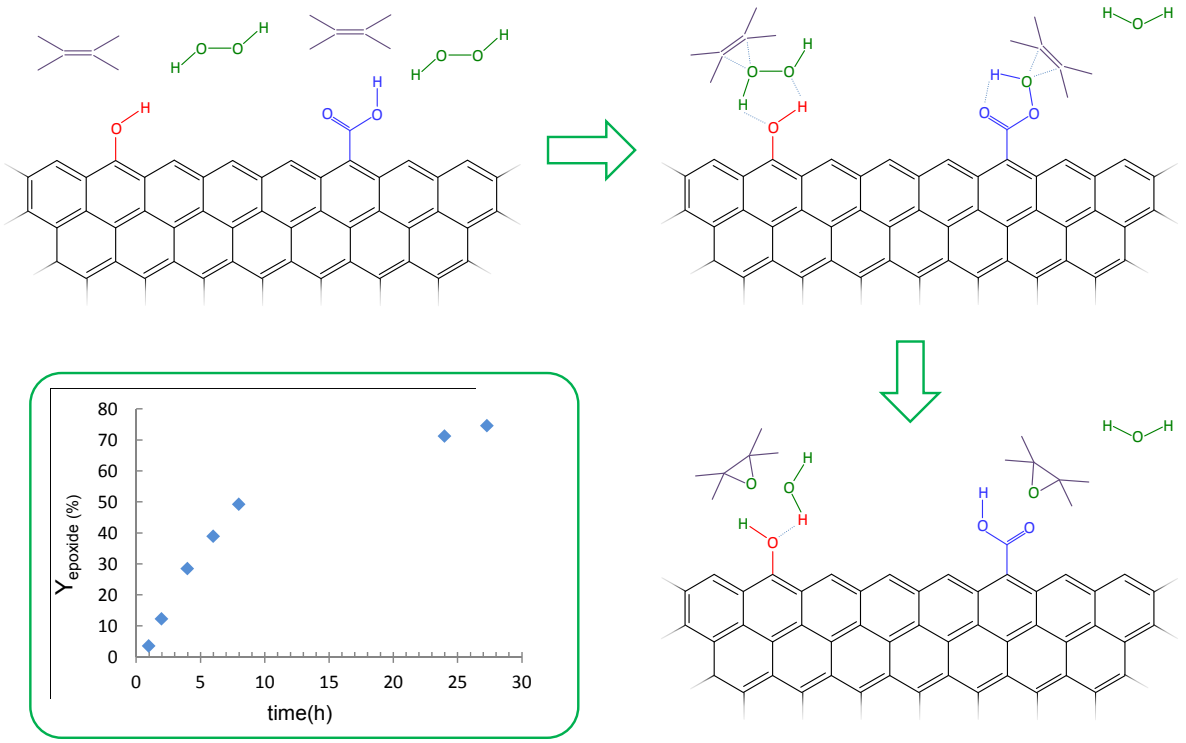

Fig. 1. Functionalised activated carbon as heterogeneous catalyst for the epoxidation of alkenes with H_2O_2.

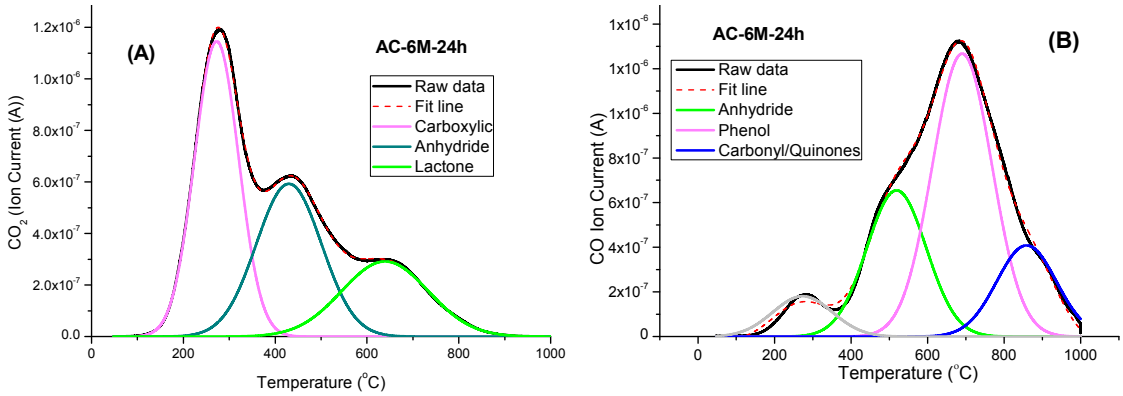

Fig. 2. Deconvolution of (A) CO_2 signal (m/z = 44) and (B) CO signal (m/z = 28) in the TPD profile of activated carbon treated with 6M HNO_3 for 24h (AC-6M-24h).

4 Conclusions

An innovative class of metal-free catalysts for the epoxidation of alkenes with the environmentally friendly oxidant hydrogen peroxide was introduced. These catalysts show promising epoxidation activity, thus opening new perspectives as a green alternative to conventional metal-based heterogeneous catalysts.

Tuning the Selectivity in Pd Catalyzed Liquid-Phase Oxidation of Benzyl Alcohol: an *in situ* ATR-IR Study

Campisi S.[1], Villa A.[1], Chan Thaw C.E.[1], Ferri D.[2], Prati L.[1*]

1 - Università degli Studi di MIlano, Dipartimento di Chimica, Milano, Italy
2 - Paul Scherrer Institute, Villigen, Switzerland

Keywords: selective oxidation, ATR-IR, support, bimetallic, alcohol oxidation, surface

1 Introduction

The liquid-phase oxidation of alcohols to the corresponding carbonyl and carboxylic compounds represents a relevant class of industrial catalytic process for fine chemicals production [1]. Employing heterogeneous catalysts in combination with molecular oxygen or hydrogen peroxide as oxidants can confer to these processes great benefits in terms of safety and sustainability. Supported noble metal nanoparticles (Pt, Pd and Au NPs) have been extensively investigated as catalysts in alcohol oxidation [1]. However tuning the selectivity in heterogeneously catalyzed reactions requires a fine design of catalysts with specific active sites. Indeed several parameters, such as the nature of the metal, particle sizes and morphology, support properties and metal-support interactions play a crucial role in determining the structure of active sites.

Selective oxidation of benzyl alcohol is a widely used model reaction but it is also an important industrial process for benzaldehyde production. In benzyl alcohol oxidation the main byproduct is toluene, which is reported to be formed by disproportionation of benzyl alcohol or by reaction of the intermediate metal-hydride with the alcohol instead of O_2 [2, 3, 4]. The addition of Au to Pd catalyst has been reported to limit the formation of toluene hindering the disproportionation pathway [5].

In order to clarify the role of the metal and the support in determining the selectivity of the benzyl alcohol oxidation, Au, Pd and AuPd catalysts were prepared by immobilizing polyvinyl alcohol (PVA) protected metal nanoparticles on different supports (TiO_2, NiO, Al_2O_3). Catalytic tests have been followed from both point of views, the substrate (by measuring product evolution), and the support (by using *operando* attenuated total reflection infrared (ATR-IR) spectroscopy) [6]. ATR-IR spectroscopy recently emerged as an ideal tool for this kind of study, allowing to probe the solid-liquid interface between the catalyst surface and the solution. Indeed by monitoring the evolution of surface species during the reaction it is possible to unravel mechanistic aspects and to obtain indirect information about the structure of active sites.

2 Experimental/methodology

Monometallic (Au, Pd) catalysts were prepared by sol immobilisation: a metal sol, formed by using PVA as protective and agent $NaBH_4$ as reducing agent, was immobilized on the support. Bimetallic catalysts were prepared following a procedure previously reported [7] which ensured the production of alloyed nanoparticles. The Au-Pd molar ratio was in all the cases 6-4 mol/mol. An exhaustive characterization of the as prepared catalysts was carried out with various complementary techniques (DRIFTS, TEM/SEM) which confirmed the alloy presence and the high metal dispersion on all the supports.

Catalytic tests were performed in a glass batch reactor at 60°C (0.3 $molL^{-1}$ benzyl alcohol solution in cyclohexane, alcohol/metal molar ratio 500, pO_2 2 bar).

A thin layer of catalysts deposited on an internal reflection element (ZnSe IRE) was used to

investigate the liquid-phase oxidation of benzyl alcohol by ATR-IR spectroscopy. For the measurement a home-built stainless steel flow-through cell serving as a continuous-flow reactor was mounted onto the ATR attachment (Optispec) within the FT-IR spectrometer. The cell was kept at 60°C throughout the measurements by a thermostat. Cyclohexane solvent and benzyl alcohol in cyclohexane (0.02 M) were flown over the catalyst layer at a rate of 10 mL min^{-1} by a peristaltic pump located after the cell.

3 Results and discussion

Pd and AuPd supported on Al_2O_3, TiO_2 and NiO were prepared by the sol immobilization technique. TEM experiments evidenced that Au and Pd show similar particle diameters and that the addition of Pd to Au clusters results in bimetallic particles even some differences in Au/Pd ratio were revealed considering different particles.
Catalysts were tested in liquid-phase benzyl alcohol oxidation. Au/TiO_2 (Table 1) was not very active, whereas Pd/TiO_2 showed higher activity than $AuPd/TiO_2$. Benzaldehyde was the main product in both cases (84-88%) but the nature of by-product differs in the two cases. Interestingly the Au addition prolonged significantly the catalyst life.

Table 1. Comparison of TiO_2-supported catalysts activities in benzyl alcohol oxidation

Catalyst [a]	Activity [b]	Selectivity (%) [c]			
		Toluene	Benzaldehyde	Benzoic acid	Benzyl Benzoate
Pd/TiO_2	532	10	84	1	3
$AuPd/TiO_2$	124	1	88	8	2

[a] Reaction conditions: alcohol/metal = 500/1 mol/mol, 60 °C, *p*O2 = 2 bar, 1250 rpm. [b] Mol of Benzyl alcohol converted per hour per mol of metal calculated after 15 min of reaction. [c] Selectivity at 90% conversion.

ATR experiments allowed us to highlight that the presence of Au facilitates the desorption of products thus possibly reducing deactivation due to irreversible adsorption. The correlation between higher catalyst-life and easier desorption of products was confirmed by testing the different catalysts prepared. Moreover this study took into account the influence of the preparation technique on the reaction pathway particularly studying the role of the protective agent used for generating the metal nanoparticles.

4 Conclusions

Monometallic Au and Pd and bimetallic AuPd nanoparticles were synthesized using sol immobilization technique and used in liquid phase oxidation of benzyl alcohol. The *operando* ATR-IR spectroscopy evidenced that the addition of Au to Pd drastically limited irreversible adsorption thus decreasing the deactivation and partially modifying the selectivity of the reaction. Not only the metal participates in determining this beneficial effect but also the support and the protective agent can be used to tune the reaction pathway .

Keywords: ethanol, partial oxidation, syngas, mechanism, SSITKA, microcalorimetry

1 Introduction

Biofuel derived from renewable feedstocks can be used as a source of hydrogen for fuel cells as well as syngas for chemical industry. Ethanol is the most widespread biofuel with the annual production rate of 84.5 billion L in 2011 [1]. Syngas production by ethanol steam reforming on traditional catalysts is hampered by their rapid deactivation due to coking. This problem can be solved by using catalysts based on oxides with a high lattice oxygen mobility and reactivity able to transform ethanol into syngas by selective oxidation (Pt/CeZrO etc) [2]. Their tailor-made design requires elucidation of the mechanism of ethanol selective oxidation on such catalysts, which is the aim of this work.

2 Experimental/methodology

$Pr_{0.15}Sm_{0.15}Ce_{0.35}Zr_{0.35}O_2$ fluorite-like oxide was prepared by polymerized complex precursor (Pechini) route and calcined in air at 900°C for 2 h [3]. Pt (1.4wt.%) was supported via incipient wetness impregnation with H_2PtCl_6 solution. Isotope transient experiments at steady state conditions in a flow reactor (SSITKA) were carried out as earlier described [4]. After achieving the steady state, a flow of 1% C_2H_5OH + 0.5% O_2 in He was switched to that of 1% C_2D_5OH + 0.5% O_2 in He (or 1% C_2H_5OH + 0.5% $^{18}O_2$), and concentrations of reagents and products were monitored by a mass-spectrometer UGA 200 (Stanford Research Systems, USA) and GC (Chromos GH-1000, Russia). Rates and heats of the catalysts reduction/reoxidation by pulses of ethanol/O_2 in He for catalyst in the steady state were estimated using a Setaram Sensys DSC TG calorimeter and a pulse kinetic installation equipped with GC, MS and gas sensors.

3 Results and discussion

At a low (350 °C) temperature, conversions of ethanol and O_2 were 45 and 90%, respectively, and CO to CO_2 ratio in products was ~ 1. ^{18}O in CO and CO_2 appears right after the switch to C_2H_5OH + $^{18}O_2$ feed, and its concentration slowly grows in time due to fast exchange with the surface and bulk of catalyst. At the steady state ^{18}O fraction in CO_2 and CO is equal to ~ 0.3 and 0.01, respectively. Hence, unlabeled CO is produced by ethanol/acetaldehyde decomposition on Pt, while CO_2 is formed with participation of the oxide support oxygen. A small fraction of $C^{18}O$ appears due to reverse water gas shift (RWGS) reaction. These conclusions agree with SSITKA results obtained at high temperatures. Two-fold increase in CO to CO_2 ratio was observed at 700°C while atomic isotope fractions of ^{18}O in CO_2 and CO became almost equal. This is explained by the increase of the reaction rate of RWGS leading to

CO formation and intense isotopic exchange between CO and CO_2.

In SSITKA experiments with switching the stream of $C_2H_5OH + O_2$ to that of $C_2D_5OH + O_2$ the value of the kinetic isotope effect is equal to 1. This proves that the rate of ethanol selective oxidation is determined by C-C bond rupture in ethanol or acetaldehyde molecules, while C-H bond rupture in the ethanol dehydrogenation step proceeds easily.

Typical results of pulse microcalorimetric studies are shown in Figure 1. In all pulses conversion of ethanol and O_2 was ~ 90-95%. The heat effects of the steady-state catalyst reduction by EtOH pulses correspond to ethanol oxidation by bridging surface oxygen species of support with the heat of adsorption ~ 550 kJ/mol O_2. The amount of oxygen removed by each pulse is in range of 5-7% of monolayer (up to 30% of monolayer after 4 pulses), thus exceeding greatly the amount which can be adsorbed on Pt particles. So, a high reaction rate and coking stability could only be provided by fast surface/lattice oxygen diffusion to Pt particles. Analysis of the data of oxygen isotope exchange between $C^{18}O_2$ and steady-state catalyst gives values for coefficient of fast oxygen diffusion along the surface/domains interfaces ~10^{-12} cm^2/s at 700 °C which is sufficient to provide required oxygen transfer [5]. Concentrations of products in the 1st pulse of ethanol are equal to those in the reaction mixture pulse (Fig. 1a). This result clearly demonstrates step-wise redox mechanism with independent activation of ethanol and O_2. Heats of the steady state surface reoxidation by O_2 pulses are in the range of 435-546 kJ/mol corresponding to replenishment of bridging M_2O species of the oxide support [5].

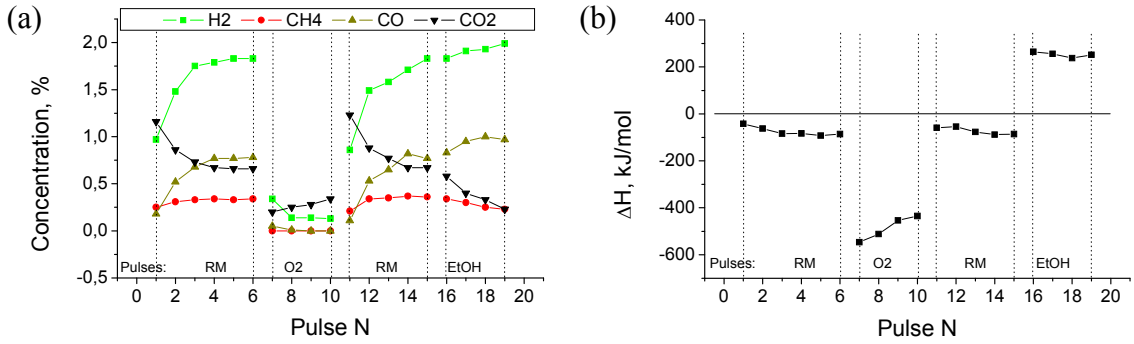

Fig. 1. Products concentrations (a) and heat effects (b) in consecutive pulses of reaction mixture (RM, 1% C_2H_5OH + 0.5% O_2), 0.5% O_2, 1% C_2H_5OH supplied at 450°C on the steady-state catalyst.

4 Conclusions

For Pt/ $Pr_{0.15}Sm_{0.15}Ce_{0.35}Zr_{0.35}O_2$ catalyst the mechanism of ethanol selective oxidation into syngas can be described by step-wise red–ox scheme including ethanol oxidative decomposition on Pt sites (the rate determining step is C-C bond breaking) and fast reoxidation of reduced support sites by O_2. Rapid oxygen migration from oxide support to Pt provides conjugation between these steps.

Selectivity Control in Oxidation of 1-Tetradecanol on Supported Nano Au Catalysts

Martínez-González S.[1], Ivanova S.[2], Domínguez M.I.[2], Cortés Corberán V.[1*]

Keywords: tetradecanol, alcohol selective oxidation, gold catalysts, fatty alcohols, myristaldehyde

1 Introduction

Selective oxidation of fatty alcohols, i.e., linear long-chain alkanols, has been scarcely investigated to date, probably due to their very low oxidation reactivity as non-activated, primary aliphatic alcohols, and to the challenges that their physical properties (hydrophobicity, high melting and boiling points) impose for its oxidation via green chemistry processes [1]. However, its use for high value chemicals production is of great interest, inasmuch their corresponding aldehydes and esters are commercially important for pharma, agrochemical and fragrance industries, among others. For instance, myristaldehyde (tetradecanal), used as flavor additive for human food, and myristyl myristate (tetradecyl tetradecanate), broadly used in cosmetics as skin conditioning agent and emulsifier, can be produced by selective oxidation of tetradecanol, a representative higher fatty alcohol.

Recently, we reported for the first time that the selective oxidation of tetradecanol is feasible in the liquid phase in accordance with green chemistry principles using nano sized gold catalyst, air as oxidant at near atmospheric pressure, and an alkane solvent without base addition [2]. The results showed that selectivity depended not only on the catalyst nature but also on the reaction conditions. Selectivity to the ester was better when decane was used as solvent instead of heptane. Under the conditions tested, i.e., using a constant alcohol/metal (A/M) ratio, a sharp selectivity trend change (increase of acid formation) was observed when conversion reached a critical value, regardless the temperature. It was hypothesized it was due to a change in the reaction mechanism caused by the water produced, once it saturated the hydrophilic support surface.

The aim of this work is to investigate the operation parameters that allow control the selectivity of the reaction to the desired product (aldehyde or ester), as well as to verify that hypothesis on the role of the support surface. To reach those goals we studied the effect of reaction temperature, A/M ratio and run time on the product distribution and its evolution with conversion.

2 Experimental

Catalyst was prepared by depositing Au by the direct anionic exchange method, assisted by NH_3, on a commercial CeO_2-Al_2O_3 support (Puralox® 20, Sasol), as detailed in [2]. Then it was dried at 100 ºC overnight and calcined at 300 ºC for 4h in air. Catalyst composition determined by X-ray microfluorescence spectrometry (XRMF) in wt.% was 2.0 Au, 77.7 Al_2O_3, 20.3 CeO_2. Samples were characterized by textural analysis, XRD and HRTEM. Gold particle size distribution was determined from HRTEM images.

Catalytic activity for *n*-tetradecanol oxidation was studied in a semicontinuous reactor. Tests were conducted at 80-120 ºC and atmospheric pressure for 6 h, using 0.1 M *n*-tetradecanol in *n*-decane with no base added, molar ratios A/M = 50-200, and 30 mL/min O_2 flow. Reactants and products were periodically analyzed by GC using a FID detector.

3 Results and discussion

In the conditions tested, the main product was tetradecanal (with selectivity up to 90%), with smaller amounts of the ester (octanyl octanoate) and, for some tests and at high conversions, tetradecanoic acid. As expected, final conversion increased by increasing the reaction temperature and decreasing the A/M ratio, reaching conversions as high as 60 % in 6 h (Fig.1). It is noteworthy that ester formation was detected in all analyses; even when acid was not detected. This implies that it is generated via formation of the hemiacetal, which consecutive oxidation produces directly the ester [3]. Its selectivity was higher (20-25%) at 80 ºC and slightly increased (10 to 15 %) with increasing conversion at higher temperatures, but was not affected but the sharp change in selectivity to acid (and aldehyde) observed 110-120 ºC (Fig. 1, down). As previously found [2], acid formation started when a certain value of conversion is reached. Interestingly, this critical value varied with A/M ratio, being roughly inversely proportional to it. Thus, it is proportional to catalyst load, and hence to the total bare support surface available. This agrees with our hypothesis: the higher the catalyst amount, the higher is the amount of water that can be absorbed by the catalyst bare support surface and, consequently, the higher is the conversion needed to produce the amount of water that may adsorb that surface before starting to react with the aldehyde to produce the acid.

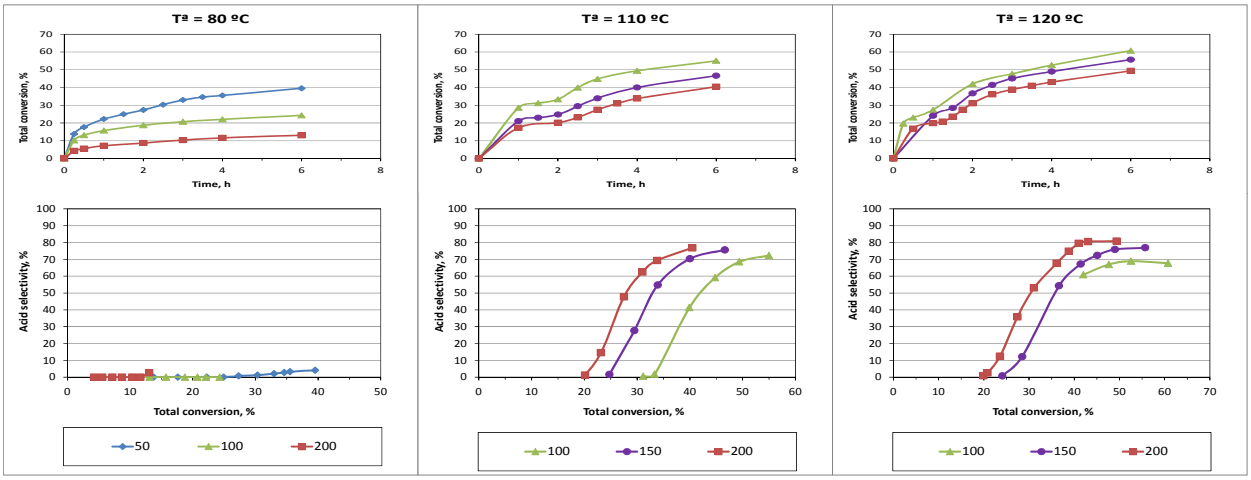

Fig. 1. Influence of A/M ratio on tetradecanol oxidation on Au/CeO_2-Al_2O_3: conversion *vs*. run time (upper row) and selectivity to acid as a function of conversion (lower row). T^a = Reaction temperature.

4 Conclusions

Product distribution in tetradecanol oxidation on Au/CeO_2-Al_2O_3 catalyst depends strongly on operation conditions. Formation of the acid requires the availability of free water reactant in the apolar solvent. This involves that water produced by the very reaction saturates previously the hydrophilic bare support surface. As a consequence, the alcohol/metal ratio is the critical factor to keep high selectivity to the aldehyde at high conversions. This could be a limitation for a continuous process. Nevertheless, by proper selection of conditions, aldehyde yields up to 30 % with 90% selectivity, and acid yields up to 40% with 90% selectivity can be reached.

Keywords: n-octanol oxidation, gold catalysts, silver catalysts, red-ox treatment, support modification

1 Introduction

The transformation of fatty alcohols (i.e., alkanols C_{8+}) as a source of fine chemicals is commercially attractive for pharmaceutical, agrochemical and fragrance industries, among others [1]. However, non-activated, primary aliphatic alcohols are the most difficult type of alcohols to oxidize selectively, as compared with the oxidation of more reactive benzyl or C_1-C_4 aliphatic alcohols. Thus, selective oxidation of *n*-octanol (one of the lower fatty alcohols) has attracted much less attention though 1-octanol is often used as the alkanols model molecule in comparative studies of alcohols reactivity on different catalysts, including very active Au nanoparticles (NPs). Some parameters that regulate the catalytic properties of Au NPs for the *n*-octanol selective oxidation (reaction conditions, support nature and its modification) have been systematically investigated [2, 3] as tools for improving their catalytic performance.

On the contrary few works report catalytic oxidation of *n*-octanol based on silver catalysts, but in vapor phase [4]. The main interest to replace Au for Ag in biomass transformation deals with the metals' price (Ag is 72 times cheaper than Au), although their catalytic properties differ. Therefore the investigation of the parameters that enhance the catalytic performance of Ag NPs without compromising the cost is of paramount importance.

In this work we compare the catalytic activity of Au and Ag supported on titania for liquid phase *n*-octanol selective oxidation to investigate the effect of: a) support modification with metal oxides (La, Ce, Fe or Mg); and b) catalyst pretreatment with H_2 and O_2 atmospheres.

2 Experimental

Titania Degussa P25 was used as base support. Oxide modifiers (of Ce, La, Fe or Mg) were deposited on support (molar ratio Ti/M = 40) by impregnation with aqueous solutions of nitrates, followed by drying at 110ºC for 4 h, and calcination at 550°C for 4 h. The nominal loadings were 4 wt. % Au and 2.3 wt. Ag, respectively. Au dispositive were made from $HAuCl_4 \times 3H_2O$ by deposition-precipitation (DP) with urea, Ag dispositive were prepared from $AgNO_3$ by DP with NaOH followed by vacuum drying with at 80°C for 2 h. Samples were characterized by FTIR of adsorbed CO, XPS, HRTEM, and textural analysis.

Catalytic properties for *n*-octanol oxidation were studied either without or with catalyst sample pretreatment at 300°C in H_2 or O_2 atmosphere. Tests were conducted at 80 ºC and atmospheric pressure for 6 h, using 0.1 M *n*-octanol in *n*-heptane with no base added, a molar ratio *n*-octanol/metal =100, and 30 mL/min O_2. Reactants and products were analyzed by GC.

3 Results and discussion

In the mild conditions tested, as prepared catalysts with Au showed higher activity, but those with Ag were also active for liquid phase oxidation. The main product was octanal, with smaller amounts of the ester (octanyl octanoate) and, for some catalysts, traces of the octanoic acid. Both, the titania modifiers (Ce, La, Fe or Mg) and the pretreatment in H_2 or O_2, showed a significant influence on the octanal selectivity and yield.

Support modification by the tested modifiers did not influence octanol conversion on Au catalysts, but the ester selectivity increased by La addition and decreased by Fe addition. On the contrary, support modification did not affect the higher octanal selectivity (90-100%) of Ag catalysts, but increased markedly (three to fivefold) their octanol conversion with Ce (Fig. 1a), Mg or Fe. Interestingly also red-ox pre-treatments had a different effect on the activity of Au and Ag catalysts: while activity of Au catalysts was increased by H_2 treatment from 4 to 40 mol. % (Fig. 1b), that of Ag catalysts was decreased by both treatments. They also increased the selectivity to ester for gold catalysts between two (with Ce, La, Mg) and fourfold (with Fe), but did not alter the product distribution for Ag catalysts. According to FTIR CO, HRTEM, XPS, H_2 TPR data, support modifiers influenced the structural and electronic properties of Au and Ag species through a metal-support and metal-modifier interaction.

Comparison of catalytic and spectroscopic data showed that partly charged metal clusters $Au_n^{\delta+}$ and $Ag_n^{\delta+}$ are probable active sites of their respective catalysts in the studied process. Therefore, additions of support modifying metal oxides influence structural and electronic properties of Ag species and stabilize the active species, while both redox pretreatments reduce their number.

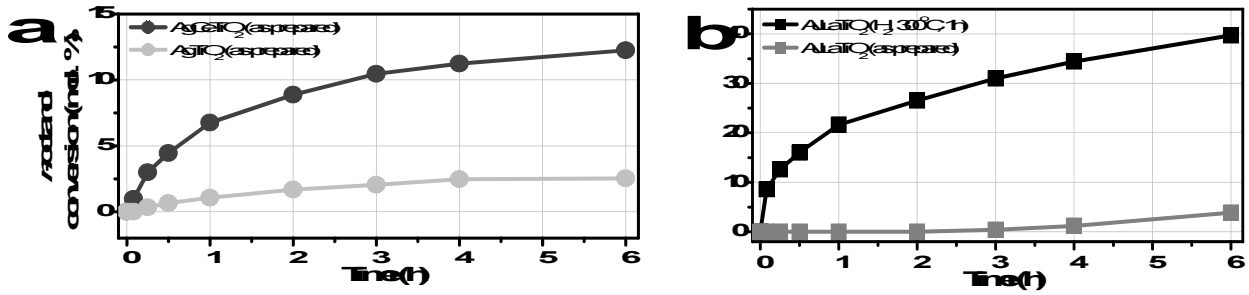

Fig. 1. Activity in *n*-octanol oxidation on the best catalysts: a) $AgCeTiO_2$ b) $AuLaTiO_2$

4 Conclusions

Both Au and Ag on titania are active for liquid phase *n*-octanol oxidation, and partly charged metal clusters $Au_n^{\delta+}$ and $Ag_n^{\delta+}$ are probable active sites of the catalysts for this. Ag catalysts are less active (but more selective to octanal). However, through the appropriate support modification Ag catalysts activity can be increased markedly. As a consequence, Ag catalysts supported on modified titania supports can be a promising alternative system for *n*-octanol oxidation. Reducing or oxidizing pretreatments are deleterious of these catalysts, but modify the product distribution on Au catalysts.

ISO-OP07

Selective Epoxidation of Propylene to Propylene Oxide on Gold-Based Catalysts: a Theoretical Study

Moskaleva L.V.*

Institute of Applied and Physical Chemistry and Center for Environmental Research and Sustainable Technology, Universität Bremen, Bremen, Germany

* lyudmila.moskaleva@gmail.com

Keywords: density functional theory, Au(321) surface, propylene oxidation, propylene oxide selectivity

1 Introduction

Epoxidation of propylene is crucial for the production of propylene oxide (PO), a valuable raw material for polyurethane foams and resins, and propylene glycol. [1]. At present, the two major methods used for the commercial PO production suffer from complexity and utilize hazardous or costly reagents [2]. Therefore, efforts have been made to develop a "green" process that could directly and selectively epoxidize propylene to PO.

The coinage metals (Au, Ag, and Cu) have been investigated as catalysts for propylene epoxidation [1]. The common challenge identified for all of them is the need to suppress undesirable reaction pathways leading to either total oxidation or the formation of other partially oxidized products, e.g., acrolein, acetone, propanal. The selectivity was shown to sensitively depend on temperature, particle size, and support as well as on the presence of co-reactants such as H_2 or H_2O in the reactants mixture [1]. Addition of hydrogen or water vapor facilitates the activation of O_2 and greatly increases the selectivity to PO. Thus far, the best performance was achieved on Au-based catalysts: C_3H_6 conversion of 5.0–9.8% [3], PO selectivity of 90–96% [3], and H_2 efficiency 30–47% [4].

In this work a detailed transformation network of competitive reaction pathways following the initial steps of propylene oxidation on the model Au(321) surface has been studied.

2 Computational methodology

The slab-model calculations were performed with a plane-wave DFT-based method using the gradient-corrected PBE exchange-correlation functional. The projector augmented wave (PAW) method was used to describe the interaction between atomic cores and electrons. The stepped and kinked Au(321) surface was selected to model defect-rich Au nanoparticles and Au surfaces with rough morphology in general. Transition states of the reactions were determined by applying the dimer method [5].

3 Results and discussion

The epoxidation of propylene on Au is believed to proceed in analogy to the accepted mechanism of ethylene epoxidation, via a primary or secondary oxametallacycle (OMMP1 or OMMP2) formed from addition of O to the C=C bond of propylene [6]. A competing H abstraction from the CH_3 group forming allyl is thought to be leading to total combustion [7]. In the present work several new interesting insights into the reaction mechanism have been identified:

(i) **A new direct pathway to epoxide**, not passing via an oxametallacylcle. This pathway of Eley-Rideal type, where propylene reacts directly from the gas phase with adsorbed O involves activation barriers (0.33-0.65 eV) of comparable height to those leading to the formation of a secondary metallacycle, OMMP2 (0.37-0.51 eV), a commonly assumed PO precursor. However, both metallacycle intermediates easily undergo an intramolecular H-transfer reaction to propanal

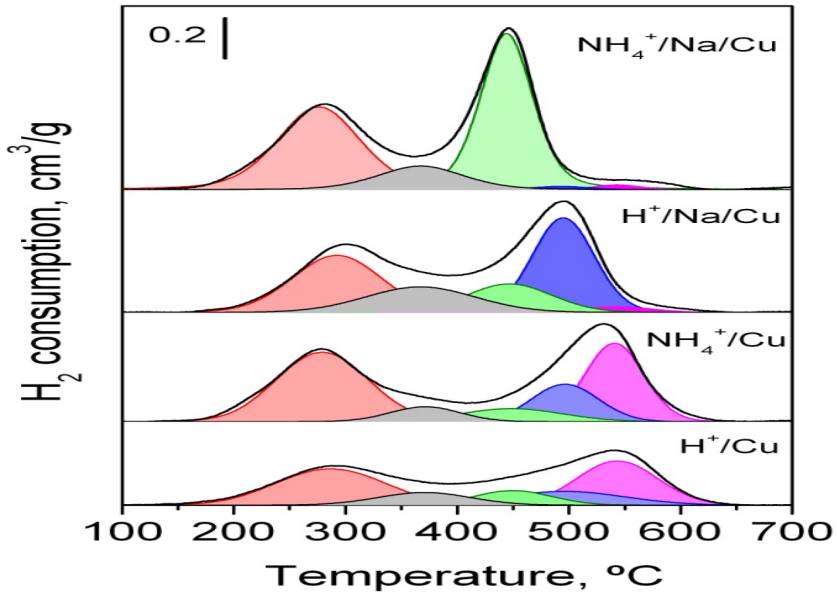

Fig. 1. Comparison of the energetics for the two epoxide formation routes: the O route (pink) and the OOH path (blue). Dotted lines indicate undesirable side reactions. Energies relative to gas-phase O_2, H_2, and clean Au(321). Stars indicate adsorbed species.

and acetone, respectively. The activation energy of the intramolecular H-transfer is always notably lower than that for the isomerization to PO. Therefore, a direct epoxide formation seems to be a more plausible route than the oxametallacycle path. Nevertheless, an abstraction of a hydrogen atom from the methyl group by adsorbed atomic O was found to have the lowest activation barrier of all primary pathways (0.11-0.47 eV).

(ii) It has been commonly assumed that the allyl species formed after the abstraction of a hydrogen atom from the CH_3 group of propylene is a precursor to total combustion. In contrast, this work shows that **allyl should easily react with O or OH forming acrolein or allyl alcohol, respectively**. More likely **precursors to total combustion are oxametallacycle intermediates**.

(iii) **Co-feeding of H_2 or water to the reactants mixture not only makes the activation of O_2 easier but also drastically improves the selectivity to PO due to the formation of HOO species** which further acts as an oxidizing agent as illustrated in Fig. 1. In the OOH pathway the formation of epoxide has a significantly lower activation barrier than the acetone formation. The peroxide pathway to PO lies overall lower in energy than the O-pathway.

4 Conclusions

The present work questions some of the earlier assumptions regarding the mechanism of PO formation. Peroxo species formed *in situ* are found to be responsible for the high selectivity of epoxidation on gold-based catalysts in the presence of H_2 or H_2O.

Keywords: oxidation, ruthenium, alcohols, carboxylic acid, deuteration, dehydrogenation

1 Introduction

Recently, a novel ruthenium catalyzed reaction discovered in 2005 in the Milstein group, has been used to transform alcohols into esters and amides without an oxidant, with the concurrent evolution of hydrogen gas [1]. This transformation and other like it that utilize the same basic mechanism, involving synthesis of amides, may have profound implications for chemical feedstocks as a number of new products becomes available at a cheaper price, since expensive oxidants do not need to be used, and the only byproduct is hydrogen. I will discuss previous work on the transformation of alcohols to carboxylic acid salts without the use of an oxidant with water as the only reagent [2] and selective deuteration of alcohols in the α carbon position [3]. In addition, current work focused on intercepting the putative intermediate aldehyde with a view to creating value added products, will also be discussed.

2 Experimental/methodology

The catalytic reaction for the modification of alcohols is typically carried out on a ~0.3 mmol scale (of the alcohol substrate) with 0.01 to 1 mol% of the organometallic Ru precatalyst that is activated by the presence of base. For the production of carboxylic acid salts (carboxylate), the solvent used was water and the reaction was carried out with a constant argon flow at rapid reflux to remove hydrogen gas produced. A slight excess of base is necessary in order to drive the reaction forward by deprotonating the catalyst-deactivating carboxylic acid, thus forming the carboxylate anion, and for activating the catalyst. For production of other organic substrates, dioxane solvent was used at reflux. The amount of base required depends on whether the base is necessary to just activate the catalyst, or whether it is needed to activate the alcohol coupling partner.

For the selective deuteration reaction, a similar procedure was used, but the reaction was carried out in a closed system in D_2O in order to prevent hydrogen gas escape and enable reversible hydrogenation of the carbonyl intermediate.

After a typical reaction time of 16-24 hours depending on the reaction, the product was isolated via extraction in an organic solvent and quantifying the amount produced by NMR and/or GC/FID against an internal standard. Isolation of the product via column chromatography, or acid/base extraction technique was performed in a few cases to confirm the yields obtained by other analytical methods.

3 Results and discussion

Benzylic and aliphatic substrates could be efficiently transformed to carboxylic acid salts utilizing water as solvent. The reaction proceeded more rapidly for benzylic substrates, but the yields of both types of products were high, generally more than 70/80% (Figure 1).

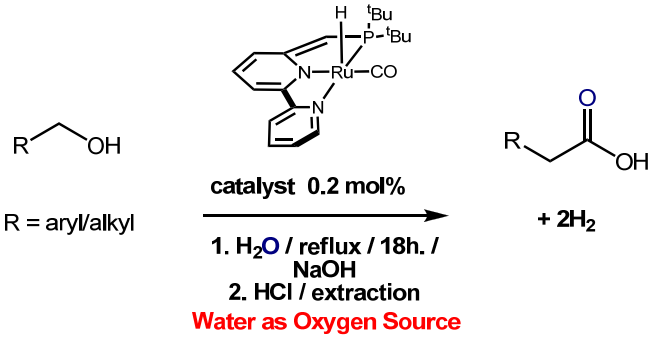

Fig. 1. General scheme for the production of carboxylic acids from alcohols without the use of an oxidant [2]

The same reaction, but carried out in a closed system in order to trap hydrogen gas, and utilizing D_2O as a solvent, was able to show selective deuteration of alcohols in the α carbon position when a catalytic amount of base was used. With the use of large amounts of base, deuteration in the β carbon position could also be observed. In this way, complete deuteration of ethanol, an important deuterated solvent, was achieved directly from deuterated water under relatively mild conditions. Secondary alcohols required milder conditions than primary ones and the transformation proved remarkably facile for benzylic substrates (Figure 2).

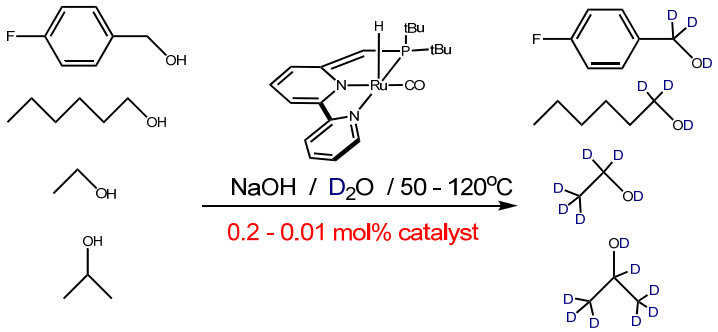

Fig. 2. General scheme for the selective deuteration of alcohols [3]

In addition to the above two examples, where an oxygen or H_2 unit was introduced into the substrate, it proved possible to introduce other additives that give higher value added products when organic solvents were utilized. These recent results will also be presented at EuropaCat.

4 Conclusions

Significant progress has been achieved in oxidation of alcohols by completely eliminating the oxidant. Transformation to the ester [1] can be avoided by introducing a suitable trapping agent for the aldehyde and/or ketone, enhancing the scope of the original ester forming reaction. These transformations are carried out in water or dioxane at refluxing temperature and may provide significant cost savings in the fine and bulk chemical industries.

Keywords: metal-support interaction, ultrasmall Ag particles, interface, low-temperature oxidation

1 Introduction

The metal-support interaction in supported catalysts is very important for understanding of both nature of catalytic action and mechanisms of oxidative reactions [1]. Catalytic properties of small (less than 5 nm) particles of active component depend significantly on chemical properties of support. Features of "metal/support" interface for Pd, Pt and Au catalysts are under close attention of investigators in recent years [2]. However, interest to supported Ag catalysts constantly increases due to unique catalytic activity of silver in oxidative reaction [3]. The aim of the present work is to reveal the role of silver-oxide support interaction in low-temperature oxidation. The Ag-"inert" support (Ag/SiO_2 catalysts) and Ag-"active" support (Ag/CeO_2 catalysts) interfaces were studied in details.

2 Experimental/methodology

The interfacial interaction between "inert" silica support and supported ultrasmall silver particles was studied by variation of ratio between Ag loading and concentration of SiOH groups on silica surface. First series of Ag/SiO_2 catalysts was prepared by wetness impregnation method using $AgNO_3$ as precursor of active component and silica with various surface concentrations of silanols.

To study the metal-support interaction in Ag/CeO_2 catalysts the co-deposition and wetness impregnation methods were used to prepare the catalysts. The samples prepared were studied using a complex of physicochemical techniques and tested in reactions of CO oxidation, deep oxidation of formaldehyde, aerobic and anaerobic dehydrogenation of ethanol to acetaldehyde. The features of metal-support interfaces were studied using a complex of TPx methods and HR TEM.

Series of $Ag/CeO_2/SiO_2$ catalysts were prepared by impregnation method with different order of ceria and silver precursors introduction to reveal the role of Ag-CeO_2 and Ag-SiO_2 interactions in different low-temperature oxidation reactions.

3 Results and discussion

According to IR spectroscopy data, stabilization of silver with formation of Si-O-Ag bonds took place on Ag-SiO_2 interface. High temperature pre-treatment of silica support (700-900 ^oC) led to decrease of silanols concentration from 5-7 to 0.5-1.0 OH group/nm^2 (measured by TPD H_2O). Weak interaction of silver with silica support and high re-dispersing ability of silver particles under red-ox treatments were observed for samples prepared on the basis of high-temperature pre-treated silica. High activity in low-temperature CO oxidation (from -40 ^oC) was observed for those catalysts.

High concentration of silanols on silica surface provided strong interaction between silver and silica with formation of small silver particles (Fig. 1a). Lower activity in CO oxidation was observed for Ag/SiO_2 catalysts prepared on the basis of hydrophilic silica.

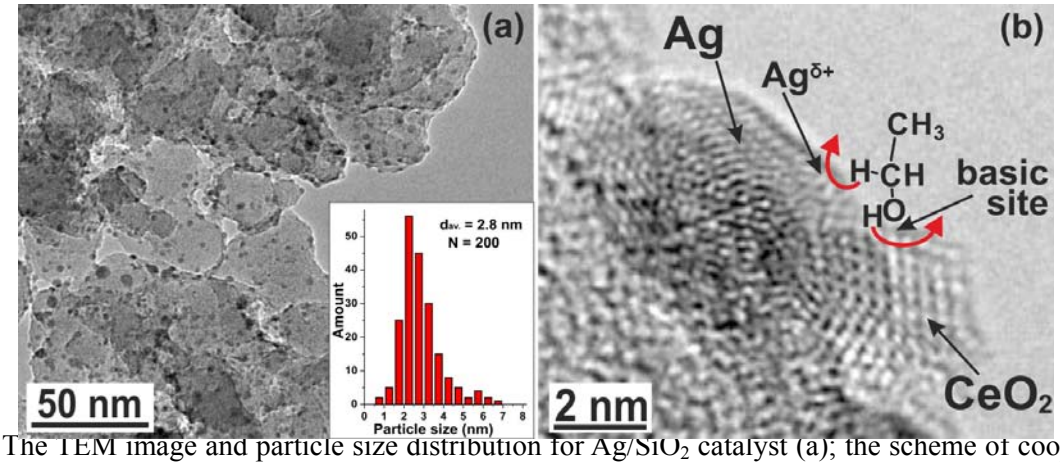

Fig. 1. The TEM image and particle size distribution for Ag/SiO_2 catalyst (a); the scheme of cooperation of active sites in ethanol dehydrogenation on Ag-CeO_2 interface in $Ag/CeO_2/SiO_2$ catalyst (b)

Strong interaction between Ag and CeO_2 was observed for Ag/CeO_2 catalyst prepared by co-deposition method. Formation of small clusters (less than 2 nm) weakly bonded with ceria surface were observed in case of Ag/CeO_2 catalyst prepared by impregnation method. The activity of Ag/CeO_2 catalysts prepared by impregnation method in CO oxidation was higher in comparison with one prepared by co-deposition method.

Impregnation of silica with ceria and Ag precursors was used to prepare $Ag/CeO_2/SiO_2$ catalysts. It was shown that silver particles were located on the surfaces of both ceria and silica particles. Introduction of ceria on silica surface did not significantly influence on its activity in low-temperature CO oxidation in comparison with Ag/SiO_2 catalyst. It is noteworthy that the influence of ceria addition on Ag/SiO_2 activity became significant at 80-150 ^oC in formaldehyde oxidation.

Significant activity increase in reaction of ethanol dehydrogenation to acetaldehyde over $Ag/CeO_2/SiO_2$ catalysts was observed compared to the one over Ag/SiO_2 catalyst. The mechanism of cooperation of CeO_2 and Ag active sites on the enhanced Ag-CeO_2 interface was proposed (Fig. 1b).

4 Conclusions

Thus, it was shown that silver-oxide support interaction plays the key role in oxidation of organic compounds. The weak interaction of ultrasmall silver particles with both "inert" (silica) and "active" (ceria) supports is a compulsory condition for high activity in low-temperature CO oxidation. The oxidation of CO even at temperatures below 0 ^oC takes place only in the presence of Ag-SiO_2 interaction, while the enhanced Ag-CeO_2 interface is a reason for elevated activity in deep oxidation of formaldehyde and dehydrogenation of ethanol to acetaldehyde. The cooperation of active site of silver and ceria takes place only at temperatures above 50 ^oC and depends on its interaction force.

Study of a New Process for the Synthesis of Adipic Acid: the Oxidative Cleavage of Trans-1,2-Cyclohexanediol

Solmi S.*, Rozhko E., Malmusi A., Lolli A., Albonetti S., Cavani F.

Alma Mater Studiorum – Università di Bologna, Dipartimento di Chimica Industriale "Toso Montanari", Bologna, Italy

Keywords: adipic acid, oxidative cleavage, supported, Ru, polyoxometalate, Au nanoparticles

1 Introduction

Adipic acid (AA) is an important chemical intermediate mainly used for the production of Nylon-6,6. All current industrial processes employ the final oxidation of either the KA Oil or of cyclohexanol with an excess of nitric acid and a homogeneous Cu/V based catalyst [1]. This procedure shows some drawbacks that imply relatively high costs in terms of energy consumption, materials and environmental protection.

This communication reports about the results of a study aimed at the development of a more sustainable catalytic process for AA synthesis, by means of a two-step transformation, in which cyclohexene is first transformed into *trans*-1,2-cyclohexanediol (CHD) with hydrogen peroxide [2], and the glycol is then oxidized with oxygen to AA [3]; more specifically, here we report about the second step, carried out using various heterogeneous and homogeneous catalysts.

2 Experimental

Catalytic tests were carried out in a semi-continuous glass autoclave reactor (100 ml) equipped with a vapor condenser. The substrate (0.5 g of CHD), the solvent (25 ml of H_2O), the catalyst and eventually a base or an acid, were loaded in the reactor. When the desired temperature was reached, the feed of oxygen was started (flow rate of 100 Nml/min, pressure 4 bar). At the end of the reaction, the catalyst was separated from reaction mixture and the pH was adjusted between 2 and 3. Quantitative analysis was done by means of HPLC.

3 Results and discussion

First we studied the reactivity of a $Ru(OH)_3/Al_2O_3$ (4.9 % wt) catalyst. Tests carried out at different pH showed that a strong basic pH is necessary in order to activate the hydroxyl groups of CHD; despite this, under these conditions support dissolution and metal leaching were negligible. After 5 hours, best results achieved were: CHD conversion 77 %, AA yield 3 %, Glutaric Acid (GA) yield 10 %, Succinic Acid (SA) yield 24 %, and 1-hydroxycyclopentanecarboxylic acid (HCPA) yield 19 %. The very low yield to AA was due to the concomitant occurrence of several side-reactions, as shown in Figure 1; the reaction scheme was determined by carrying out experiments at different reaction time and starting from the various possible intermediates, such as 1,2-cyclohexanedione (CHDO) and 2-hydroxycyclohexanone (HCHN). CHDO was found to be the key intermediate of the reaction, precursor for the formation of several by-products; this was due to the fact that CHD is oxidized directly to CHDO because the Ru^{n+} species coordinates both hydroxyl groups of CHD.

Tests with homogeneous $H_5PMo_{10}V_2O_{40}$ catalyst were conducted at pH 2; under these conditions, the reaction was very selective to AA, but the latter then reacted with the unconverted CHD generating the corresponding esters; therefore, we had to carry out an additional transesterification of the esters with methanol or hydrolysis to obtain the pure acid. Another drawback of the POM is that it is an homogeneous system difficult to recover from the

reaction mixture. In this case, the key intermediate compound was HCHN, and the reaction turned out to be very selective, because there was no formation of any of the by-products (HCPA, GA and SA) which formed under basic conditions with the Ru-based catalyst; however, after 6 hours, the yield of AA was 9.5 % only.

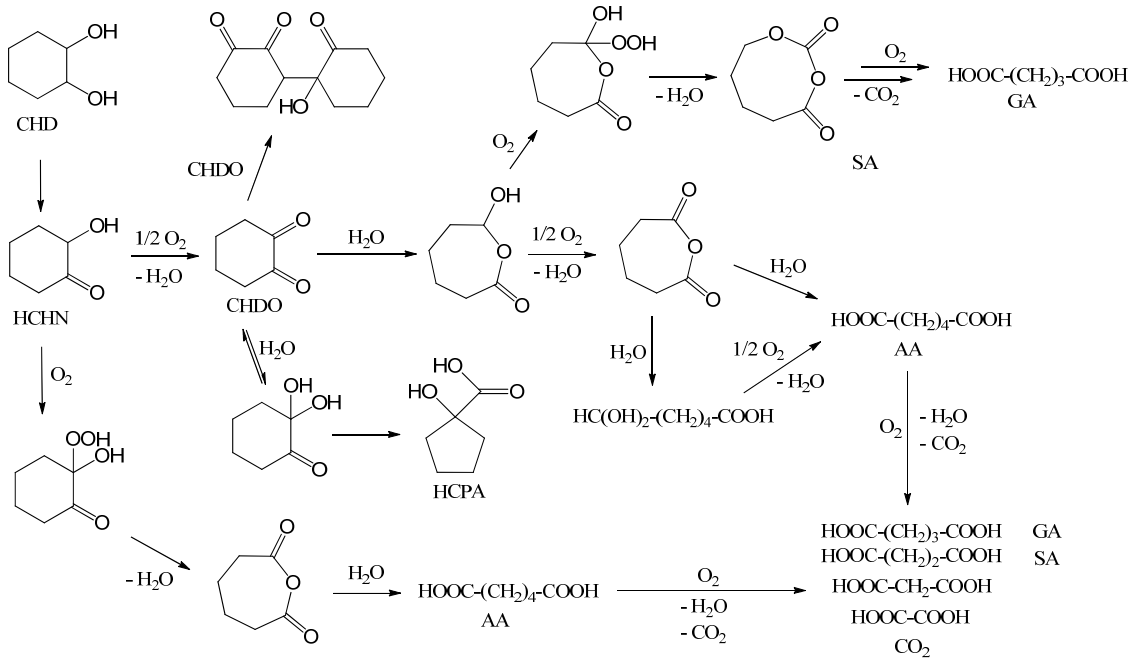

Fig. 1. Overall reaction scheme in CHD oxidation with Ru-based catalyst.

Finally, we studied the reactivity of Au nanoparticles supported on two different oxides: TiO_2 and MgO (in both cases containing 1.5 % wt Au). We tested the reactivity at different pH values, but with both catalysts a basic pH was anyway necessary in order to allow CHD oxidation; therefore, the basicity of MgO was not strong enough to activate the reactant. However, we obtained better AA yield (24 % with Au/TiO_2, 22 % with Au/MgO) and selectivity compared to Ru-based catalysts, while working with a less basic pH. In this case also, the key intermediate compound was HCHN and not CHDO, because of the ability of Au nanoparticles to coordinate only one hydroxyl group in CHD; this allowed to obtain better yield to AA than with the Ru-based catalyst.

4 Conclusions

With $Ru(OH)_3/Al_2O_3$ under the strongly basic conditions at which the catalyst was active, the reaction showed poor selectivity. Au-based catalysts were more selective to produce AA because the oxidation of CHD took place in less basic conditions than in the case of the supported Ru catalyst, and gave rise to the formation of HCHN as the key intermediate, which is oxidized into AA with good selectivity. P/Mo/V polyoxometalate catalyst was very selective in CHD oxidation, because there were no side reactions occurring under the acid pH at which the POM is active. However, an additional step of hydrolysis was necessary to obtain the pure product AA, and a precipitation was necessary to separate the catalyst.

Keywords: selective oxidation, glucose, molybdenum based catalysts, ionic liquids

1 Introduction

The biomass is an abundant carbon source and it is the only sustainable carbon source nowadays. Carbohydrates constitute 75% of the annual renewable biomass [1] with glucose as cellulose´s monomer the most abundant monosaccharide. Efficient conversion of cellulose and glucose to valuable compounds, as called platform chemicals, is of great importance and it is current topic of interest in Chemistry [2, 3].

Within the glucose platform chemicals, D-Gluconic acid is an important intermediate, which can be obtained by oxidation of glucose. It is widely used in food and pharmaceutical industries and it is usually produced by enzymatic oxidation of D-glucose with an annual market of about 100.000 tons per year [2]. However, the biochemical method has several drawbacks such as low space-time, slow reaction rate and difficulty in the separation of enzyme from product [4]. Replacing the enzymatic catalyst with efficient heterogeneous one seems the perfect solution and becomes a serious challenge in the recent years.

Generally, the selective oxidation of carbohydrates is difficult due to the multi-functionality of the molecules. In this way, glucose can be oxidized at anomeric position (C_1), at primary alcohol (C_6) or secondary alcohol (C_2-C_4) functions, resulting in distinct products. Therefore, the used catalysts have to be active and especially selective.

Recently, a group of compounds, the as called ionic liquids (ILs), shown a great potential in carbohydrate chemistry either as a catalyst or solvent. Many studies have reported the conversion of glucose into valuable compounds in ILs [4], however, the use of the ionic liquid as an integral part of the catalyst is scarcely studied.

In this context, the aim of this work is to study the influence of the IL on the catalytic performance of Mo based compounds, when used as solvent or as integral part of the catalyst in the selective liquid-phase oxidation of glucose by H_2O_2 under mild conditions.

2 Experimental

The catalysts used in this study are the oxodiperoxomolybdenum complex $[MoO(O_2)_2(H_2O)_n]$ dissolved in 1-butyl 3-methyl imidazolium hexafluorophosphate, [Bmim][PF_6], and 3 hybrids based on IL's cations (Emim, Bmim or Hexmim) and Keggin anion $PMo_{12}O_{40}^{3-}$.

Selective glucose oxidation was carried out in presence of catalyst in batch reactor in glucose:oxidant ratio 1:3 using as solvents distilled water and [Bmim][PF_6], respectively. When in aqueous solution appropriate amount of the heterogeneous hybrids (2.5 mol% of glucose) were added and, in the same way, the $[MoO(O_2)_2(H_2O)_n]$ complex was added to [Bmim][PF_6] solution. Both mixtures were heated under vigorous stirring till 60 °C during 18 hours. The samples were analysed by HPLC.

3 Results and discussion

The obtained results in terms of glucose conversion are presented in Fig. 1. The oxodiperoxomolybdenum complex exhibits higher conversion (53 %) in comparison to the heterogeneous [Bmim]-Mo catalyst (26 %) (Fig. 1. (a)), however, higher selectivity to gluconic acid is observed with the later catalyst (Table 1). When the IL part of the hybrid is modified the most active IL-Mo catalyst appears to be the [Emim]-Mo (Fig. 1. (b)) with 36 % of conversion followed by [Bmim]-Mo (26 %) and [Hexmim]-Mo (15 %). It seems that the activity of these catalysts strongly depends on IL component, with a smaller cation resulting in higher activity. The selectivity to gluconic acid follows the same trend, being [Emim]-Mo the most selective catalyst (79 %) followed by [Bmim]-Mo (28 %) and [Hexmim]-Mo (14 %).

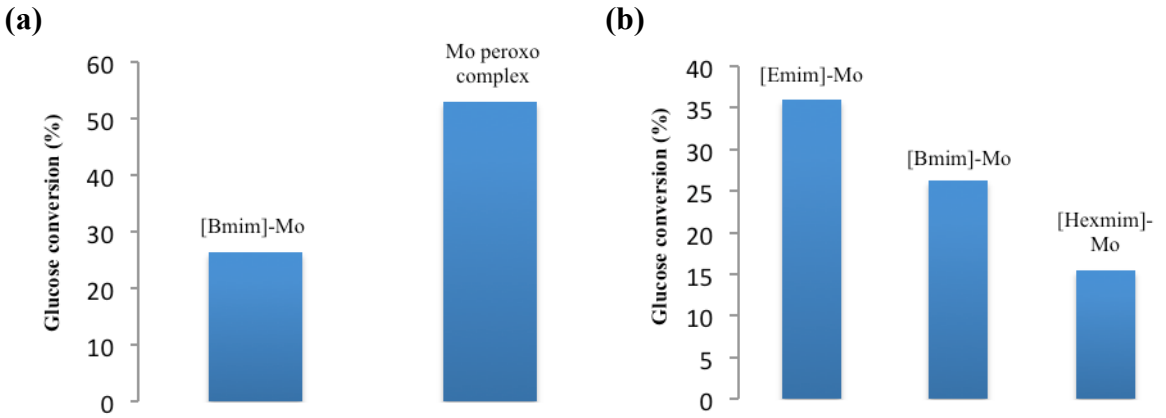

Fig. 1. Glucose conversion (%): (a) IL as part of the catalyst vs. IL as solvent, (b) Influence of different ILs as part of the same Mo based catalyst

Table 1. Product distribution (mol%) obtained for glucose conversion over molybdenum based catalysts.

Catalyst	Product distribution (mol%)				
	Glucaric acid	Glucuronic acid	Gluconic acid	Lactic acid	Formic acid
[Emim]-Mo	3	0	79	18	0
[Bmim]-Mo	6	46	28	20	0
[Hexmim]-Mo	0	17	14	22	47
Mo peroxo complex	1	37	9	15	38

4 Conclusions

The influence of ionic liquid presence on the selective oxidation of glucose over molybdenum based catalysts is studied. The ionic liquid is used either as solvent or as a part of hybrid material. Higher selectivity to gluconic acid is obtained when IL takes part of the molybdenum catalyst. The use of different ILs change the catalysts behaviour, smaller the IL component higher the activity and selectivity.

Morphology-Dependent Nanocatalysts: Rod-Shaped Metal Oxides

Li Y., Shen W.*

Dalian Institute of Physcial Chemistry, Chinese Academy of Sciences, Dalian, China

* shen98@dicp.ac.cn

Keywords: morphology-dependent nanocatalysis, metal oxides, nanorods, crystal facet, metal-oxide interface, metal-support interaction

1 Introduction

Nanostructured metal oxides are widely used in heterogeneous catalysis where their catalytic properties are closely associated with their size, morphology, and crystal phase at nanometer level [1]. The effect of particle size has been documented in the past two decades, but the morphology of the oxide nanoparticles has rarely been concerned. We illustrate that the redox and acidic-basic properties of metal oxides largely depend on their morphologies by taking Co_3O_4, Fe_2O_3, CeO_2, TiO_2 and La_2O_3 nanorods as typical examples. The catalytic activities of these rod-shaped oxides are mainly governed by the nature of the exposed crystal planes. Moreover, the exposed planes of these rod-shaped oxides mediated the manner and strength of metal-support interaction in the integrated metal-oxide catalysts.

2 Experimental

All the rod-shaped oxides were prepared by a hydrothermal method with the aid of proper surfactants. Loading of metal (copper and gold) particles on the oxides was done using a deposition-precipitation method. Structural analysis was conducted by Raman spectroscopy, XPS, NMR, XRD and TEM techniques. Catalytic reaction was conducted with a continuous-flow fixed-bed quartz reactor.

3 Results and discussion

Spherical Co_3O_4 nanoparticles have a size of ~10 nm and are mainly constructed by truncated octahedron, which are surrounded by the {111} and {001} planes. Co_3O_4 nanorods have a diameter of 5-10 nm and a length of 100-300 nm, and preferentially exposes the (110) planes [2]. When being used to catalyze CO oxidation, the Co_3O_4 nanoparticles showed marginal CO conversion and rapidly deactivated. But the Co_3O_4 nanorods showed 100% CO conversion during the initial 6 h, and the CO conversion only slowly decreased to 80% after reaction for 12 h at -77 °C. The reaction rate of CO oxidation over the Co_3O_4 nanorods was 3.91×10^{-6} mol CO/g.s, which was one order of magnitude larger than that over the nanoparticles. Kinetic studies confirmed that the preexponential factor of the nanorods is almost one order larger than that on the nanoparticles, suggesting the large presence of active sites. The {110} planes on the Co_3O_4 nanorods are rich in active Co^{3+} species that are responsible for the much higher activity in CO oxidation.

The crystal–phase effect of Fe_2O_3 nanorods in selective reduction of NO with CO or NH_3 was further examined [3]. For the reduction of NO by CO, the reaction readily started at 175 °C on the γ–Fe_2O_3 nanorods whereas it occurred at 325 °C over the α–Fe_2O_3 nanorods. At 500 °C, the conversion of NO approached 95% on the γ–Fe_2O_3 nanorods but it was only 40% on the α–Fe_2O_3 nanorods. In ammonia SCR, the γ–Fe_2O_3 nanorods showed 80% NO conversion in a temperature range of 200–400 °C with N_2 selectivity of about 98%. On the α–Fe_2O_3 nanorods, however, the temperature window for 80% NO conversion has shifted to 330–450 °C. These

outstanding properties of the γ–Fe_2O_3 nanorods are intimately associated with the exposed (110) and (001) planes. The simultaneous exposure of iron and oxygen ions on these facets have significantly enhanced the adsorption and activation of NO and NH_3 and thereby promoted the overall reaction efficiency.

The exposed surface planes of the rod-shaped oxides also mediated the manner and strength of metal-support interaction. Supported Au nanoparticles often show distinctively high activity at the initial stage of the reaction but suffer from a rapid deactivation caused by the easy sintering of gold nanoparticles. Rod-shaped ceria has the potential to stabilize gold nanoparticles of about 3nm at elevated temperatures and under reactive atmosphere [4]. The Au/ceria-rod catalyst was highly active and stable for CO oxidation at room temperature and the conversion of CO maintained at 75-90% for 100 hours. Kinetic studies revealed that the turnover frequency (2.7×10^{-2} s^{-1}) of surface gold atoms in the Au/ceria-rod catalyst was 1.5 times greater than the gold particles supported on conventional ceria (1.8×10^{-2} s^{-1}). That is, ceria nanorods not only enhanced the activity but also stabilized the Au particles during CO oxidation through the strong chemical bonding of gold onto the rod-shaped ceria. In addition, La_2O_3 nanorods greatly promoted the activity of copper nanoparticles in alcohol dehydrogenation [5]. The La_2O_3 nanorods exposed about 40% (110) plane that was terminated by La^{3+}-O^{2-} pairs acting as the basic sites. Cu particles of about 4.5 nm were preferentially anchored on the (110) surface, showing a crystal-facet selective deposition pattern. The basic sites on the (110) facet of the La_2O_3 nanorods activated alcohol while the neighboring Cu nanoparticles efficiently transferred hydrogen atoms.[4] Moreover, the shape effect of other metal oxides in the activation and conversion of small molecules like CO, CH_3OH, H_2, and O_2 are also discussed in the presentation.

4 Conclusions

The correlation between the catalytic properties and the exposed facets verified the chemical nature of the morphology effect. Moreover, the interaction between the rod-shaped oxides and the metal nanoparticles in metal-oxide catalyst systems showed a crystal facet-selective deposition pattern and the interaction on different crystal facets of the oxide supports varied significantly.

Keywords: C-H hydroxylation, asymmetric epoxidation, manganese, hydrogen peroxide, biomimetic

1 Introduction

The catalytic systems for selective and sustainable oxidative functionalization of hydrocarbons are of great demand, albeit natural oxygenases mediate such processes smoothly at mild conditions. In recent decades there have been huge efforts put on creating the synthetic biomimetic catalysts that could model the structures and functions of natural metalloenzymes, mainly focusing on iron-based systems. Manganese(II) complexes with chiral aminopyridine ligands turned out to be competitive counterparts of those iron catalysts in terms of activity and (stereo)-selectivity. However, the mechanisms of manganese-catalyzed selective oxidations, such as C-H hydroxylation and asymmetric epoxidation, still lack experimental evidence. Herein, we report the experimental insight into the mechanisms of regioselective and stereospecific C-H hydroxylations and enantioselective epoxidations with H_2O_2, catalyzed by aminopyridine manganese complexes.

2 Experimental/methodology

Chiral aminopyridine ligands and corresponding manganese complexes were synthesized as described [1]. ^{1}H NMR spectra were recorded on a Bruker AVANCE 400 or DPX-250 NMR spectrometer at 400.13 or 250.13 MHz. Enantiomeric excesses (*ee*) were measured on a Shimadzu LC-20 chromatograph equipped with a set of chiral columns. The incorporation of ^{18}O into the products of oxidation and the corresponding yields were determined using Agilent 7000B GC/MS with Triple Quad detector, chromatograph Agilent 7890 equipped with a capillary column "HP-5ms". $H_2{}^{18}O$ (97 atom % ^{18}O) was purchased form Sigma-Aldrich.

3 Results and discussion

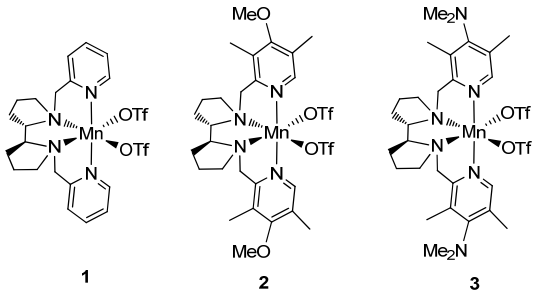

Fig. 1. Aminopyridine manganese complexes

Recently we proposed (on the basis of asymmetric epoxidations in the presence of different sterically hindered carboxylic acids) that the active oxidizing agent in the systems **1**/H_2O_2/RCOOH are complexes $[(\mathbf{L})Mn^{V}{=}O(OC(O)R)]^{2+}$ [2]. Additional evidence in favour of involvement of manganese-oxo species could be obtained in isotopic (^{18}O) labelling studies using $H_2{}^{18}O$. However, epoxidation of styrene by the system **Mn**/H_2O_2/AcOH in the presence of

large excess of $H_2{}^{18}O$ (1000 eq. *vs.* **Mn**) showed zero incorporation of labelled oxygen into the product. On the other hand, in the absence of carboxylic acid, the same system yielded a 35 % ^{18}O-enriched styrene epoxide, with mono-labelled styrene diol as by-product (87 % of ^{18}O), indicating a so-called "water-assisted" oxidation pathway (fig. 2). Active oxidizing species implied by this mechanism are *cis*-HO-Mn^V=O complexes. Adding large excess of carboxylic acid suppresses binding labeled water to Mn centre, thus accounting for the absence of ^{18}O-labeled epoxide. To disclose the nature of active Mn^V=O species, Hammett analysis was attempted (using *p*-substituted chalcones and **1** as catalyst). The active species was found to be electrophilic; good linear correlation between the log (k_X/k_H) and σ^+_p (ρ^+= -1.5, indicates an electron-demanding transition state) was obsereved. Furthermore, the log ((100+*ee*)/(100-*ee*)) was also highly linear versus σ^+_p of the substituents, the epoxides of more easily oxidizing substrates displaying lower *ee*s. Thus, the overall epoxidation rate is limited by an electron transfer to the oxometal species, to form an acyclic carbocationic intermediate [1].

Selective C-H hydroxylations of adamantane and *cis*-1,2-dimethylcyclohexane (DMCH) by the systems **2(3)**/H_2O_2/$H_2{}^{18}O$ also resulted in incorporation of ^{18}O into the corresponding tertiary alcohols (27 % and 18 % for adamantane and 18 % and 7 % for DMCH respectively), providing evidence in favour of "water-assisted" mechanism involving manganese(V)-oxo species (fig. 2). Competitive benzylic oxidations of *p*-substituted cumenes revealed a highly linear Hammett correlation vs. σ_p^+ (ρ^+= -1.0, indicates an electron-demanding transition state). The ρ^+ value is typical for a hydrogen-atom transfer mechanism, with formation of an electron-deficient radical intermediate. Primary *KIE* in the oxidation of cumene/α-D-cumene for complexes **1**-**3** was 3.8-3.9, the *KIE* values for the oxidation of cyclohexane/d_{12}-cyclohexane falling in the range 3.8-4.1 that, which is evidence for an H-atom abstraction mechanism. The H-abstraction results in formation of carbon-centered radicals (which was confirmed by partial erosion of *cis*-configuration in the oxidation of DMCH catalyzed by **3**: *RC* > 99 % at 0°C, = 97.1 % at +20°C and = 94.3 % at +30°C).

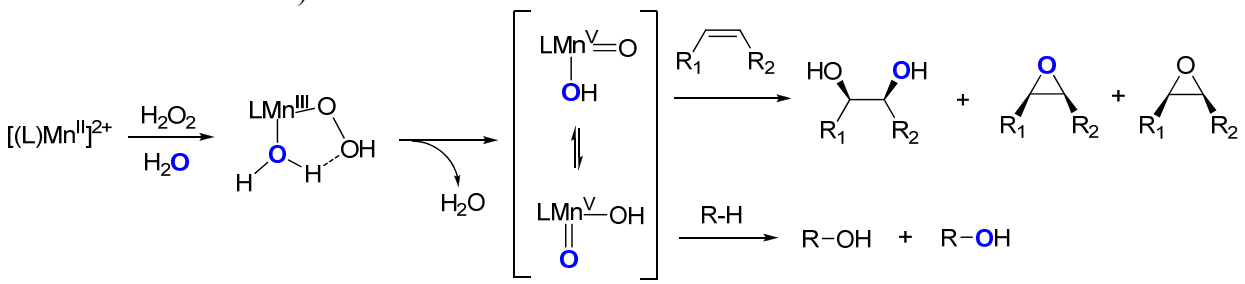

Fig. 2. Proposed 'water-assisted' oxidation mechanism for Mn catalyzed oxidations with H_2O_2. ^{18}O represented in blue.

4 Conclusions

In conclusion, insights into the mechanisms of (1) selective epoxidations and (2) C-H oxidations mediated by aminopyridine manganese complexes have been achieved on the basis of kinetic and isotopic labelling studies. The data obtained bear evidence in favour of the key role of Mn^V-oxo species, the most likely catalytically active sites of both processes.

Catalytic Upgrading of Furfural by Oxidative Methylation over Au NPs-Based Catalysts

Papanikolaou G.*, Ampelli C., Genovese C., Perathoner S., Centi G.

University of Messina, Dep. of Electronic Engineering, Industrial Chemistry and Engineering, Messina, Italy

Keywords: furfural, selective oxidation, Au nanoparticles (NPs)

1 Introduction

In the last years, the climate changes, the negative effects of the oil prices on the global economy and the depletion of the oil resources, have focused the attention to the development of new methodologies for biomass conversion into compounds with higher added value, to be used in the industry of fuels and fine chemicals. In this context, upgrading and valorization of C5 fraction coming from lignocellulosic wastes for the synthesis of important platform molecules, is of key relevance to diminish the dependence on fossil fuel sources [1]. By the oxidative esterification reaction of furfural, it is possible to produce methyl 2-furoate (2-MF), a compound that may widely be used in the field of flavourings and fragrances. The exceptional catalytic properties of Au nanoparticles (NPs) dispersed on metal-oxide based supports, has allowed to find a new and eco-friendly synthetic route for the oxidative esterification [2].

In this contribution, we report on a sustainable approach to produce 2-MF from furfural, by selective oxidative esterification with methanol using size-controlled Au NPs-based catalysts. Cerium dioxide (CeO_2) and zirconium dioxide (ZrO_2) were used as metal oxide supports and synthesized via chemical precipitation method. Gold nanoparticles were deposited onto the metal oxide support by two different techniques: i) deposition-precipitation and ii) photo-deposition. All the catalysts with Au deposited by precipitation were finally treated in air at different temperatures (200 and 400 °C). The main purpose was to optimize the methodology of synthesis of the Au NPs-based catalysts and identify a method to modulate size and dispersion of the Au NPs, in order to obtain high catalytic performances.

2 Experimental

CeO_2 and ZrO_2 were prepared by *chemical precipitation method*. Briefly, $Ce(NO_3)_3 \cdot 6H_2O$ (or $ZrOCl_2 \cdot 8H_2O$) was dissolved in distilled water and the pH was adjusted to about 8-9. Then, the precipitate was collected from the solution by centrifugation, dried and finally calcined at 300 °C (650 °C for ZrO_2). On each support, 1 wt. % Au was added by deposition-precipitation or photo-deposition techniques.

The as-prepared catalysts were fully characterized by AAS, UV-Visible Diffuse Reflectance Spectroscopy, XRD, and TEM analyses. Finally, they were tested in the process of oxidative methylation of furfural by using a modified lab-scale commercial autoclave reactor (Parr Instrument Company) at 120 °C and 6 bar O_2. The detection of the reaction products was performed by GC-FID and GC-MS analysis.

3 Results and discussion

The reaction mechanism for the furfural oxidative esterification with methanol can follow different schemes, passing through the formation of a hemiacetal intermediate. Subsequently, the hemiacetal can be oxidized directly into 2-MF, or can be converted into the corresponding 2-furaldehyde-dimethyl-acetal and then to 2-MF.

Analysis by TEM of the Au NPs-based catalysts was carried out in order to determine a correlation between structural properties and catalytic activity. Figure 1 shows some HRTEM images referred to Au/ZrO_2 with Au deposited by deposition-precipitation and treated at 400 °C. It can be observed that well dispersed and small Au NPs are present over the ZrO_2 surface (particle diameter below 5 nm).

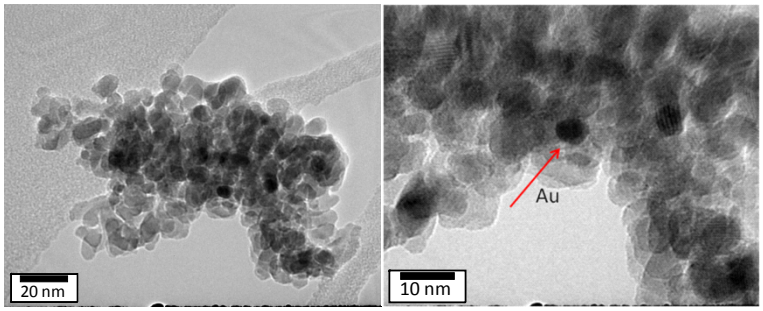

Fig. 1. HRTEM images of Au/ZrO_2 (Au reduced at 400 °C)

Table 1 reports the conversion and 2-MF selectivity values (after 6 h of reaction) for the most representative tested Au-NPs-based catalysts. Results obtained with Au/CeO_2 showed high conversion but low selectivity to 2-MF, except for the catalyst with Au deposited by photo-deposition which gave also high selectivity. On the contrary, Au/ZrO_2 catalyst with Au deposited by deposition-precipitation method and treated at 400 °C, allowed to obtain very high conversion (99%) and 2-MF selectivity (100%). Morphological characterization data of the most active catalysts suggest that having small and well dispersed Au NPs onto the metal oxide support is the key to enhance the catalytic performances, favouring the oxidation of the hemiacetal into ester, rather than the reoxidation of the acetal into the ester.

Table 1. Catalytic performances in the furfural oxidative esterification reaction.

Sample	T (°C)	Conversion (%)	2-MF selectivity (%)
Au/CeO_2[a]	200	88	8
Au/CeO_2[a]	400	81	10
Au/CeO_2[b]	-	84	82
Au/ZrO_2[a]	200	63	10
Au/ZrO_2[a]	400	99	100
Au/ZrO_2[b]	-	57	90

[a] Au loading by deposition-precipitation
[b] Au loading by photo-deposition

Conclusions

Gold NPs-CeO_2(ZrO_2)-based catalysts resulted very active in the catalytic oxidative esterification of furfural with methanol, opening new perspectives in the sustainable production of fine chemicals (perfumes and flavouring agents).

1 Introduction

5-Hydroxymethylfurfural (5-HMF) is one of the key bio-based platform chemicals identified by the U.S. Department of Energy. [1] Its structure contains a hydroxyl and an aldehyde moieties together with a furan ring, allowing many chemical reaction variations. However, this rich chemistry also makes 5-HMF suffer from poor stability. [2,3] In contrast, 2,5-diformylfuran (DFF) produced by oxidation of the hydroxymethyl group of 5-HMF (Fig. 1) proved to be stable under its crystalline form. [3] Interestingly, DFF can be used either as a monomer, or as a starting material for the synthesis of ligands, drugs, and antifungal agents. Vanadium-based catalysts have been proposed for the oxidation of 5-HMF into DFF. The use of V_2O_5 supported on TiO_2 increases the yield to DFF up to 97% at 110 °C in toluene after 1.5 h of reaction under air (P = 16 bar) [4]. Carlini et al. [5] found that $VOPO_4{\cdot}2H_2O$ could oxidize 5-HMF in MIBK, giving 50% selectivity at 98% of 5-HMF conversion under oxygen (P = 1 bar) at 80 °C after 6 h. Here, we report encouraging results on long alkyl chain trimethylammonium intercalated vanadium phosphorus oxides (I-VPO) for the efficient selective oxidation of 5-HMF to DFF under relatively mild conditions using conventional and green solvents. Mechanistic aspects of the reaction are also explored.

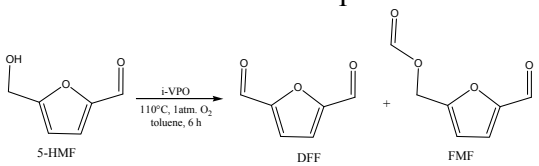

Fig. 1. Oxidation of 5-HMF to DFF

2 Experimental

$VOPO_4{\cdot}2H_2O$ was prepared by refluxing V_2O_5 (11.8 g) and H_3PO_4 (85%, 104.6 g) in water (275 mL) for 16 h. The resulting solid was isolated by filtration, washed with acetone, and dried under static air at room temperature (RT) for 2 days. $VOHPO_4{\cdot}0.5H_2O$ was prepared by refluxing V_2O_5 (11.8 g) and H_3PO_4 (85%, 16.5 g) in 2-butanol (250 mL) for 16 h. The resulting solid was recovered by filtration, washed with acetone, and dried under static air at RT for 2 days. The intercalated compounds (I-VPOs) were synthesized by adding $VOPO_4{\cdot}2H_2O$ or $VOHPO_4{\cdot}0.5H_2O$ (1 eq.) to an aqueous solution (30 mL) of CnTAB (1 eq.) at RT. The pH was adjusted to 7.5 using concentrated NH_4OH before the mixture was heated to 75 °C for 48 h. The resulting solids were recovered by filtration, washed with water, and dried under static air (50 °C, 2 days). The intercalated samples were labeled $C_nVO(H)PO_4$, where n indicates the length of the alkyl chain. The 5-HMF oxidation tests were performed in 30 mL glass tubes

equipped with a reflux condenser. The catalyst (30 mg) was introduced into the reaction tube and 3 consecutive vacuum/O_2 cycles were performed. A solution of 5-HMF (0.1 M, 3 mL) was added and the mixture was heated to the desired temperature under oxygen at 800 rpm stirring. After the test, the tube was cooled down to RT and the clear solution was recovered by syringe filtration. The analysis of the recovered solution was performed on a Varian CP 3800 – Saturn 2000 GC-MS equipped with a CP Wax 58 (FFAP) CB capillary column.

3 Results and discussion

Oxidation of 5-HMF over $VOPO_4 \cdot 2H_2O$ and $VOHPO_4 \cdot 0.5H_2O$ gave a high conversion of 5-HMF but yielded many by-products resulting in a poor selectivity to DFF (< 10%). Only aromatic solvents offered good DFF selectivity (> 63%) at full conversion. In contrast, the use of oxygenated solvents resulted in the formation of large amounts of degradation products originating either from 5-HMF or from the solvent itself. In contrast, the use of I-VPOs in toluene resulted in an increase of 5-HMF conversion as well as in the selectivity to DFF (82-83%) with a weak impact of the alkyl chain length (Table 1). The results were found independent of the initial vanadium oxidation state (V^{5+} for $VOPO_4 \cdot 2H_2O$ and $C_{14}VOPO_4$; V^{4+} for $VOHPO_4 \cdot 0.5H_2O$ and $C_{14}VOHPO_4$), which evidences that both oxidation states are involved during the catalysis supposedly via a Mars-Van Krevelen mechanism.

The only observed by-product in these cases was FMF (Fig. 1), which presumably forms via a homogeneous reaction pathway of 5-HMF involving radical intermediates (most likely on the hydroxymethyl group of 5-HMF) generated from the interaction of 5-HMF and C_nVOPO_4. In addition, this radical intermediate might also react with toluene to generate benzyl free radicals leading to benzyl alcohol and benzaldehyde upon reaction with oxygen. The fact that oxidation of 5-HMF performed in an oxygenated solvent such as MIBK gave poor selectivity to DFF can be then attributed to the weak stability of the solvent toward oxidative conditions and presence of free radicals.

Table 1. Performances of the intercalated VPOs in the catalytic oxidation of 5-HMF

Entry	Catalyst	5-HMF Conversion (%)	DFF Selectivity (%)
1	$C_{10}VOPO_4$	85	76
2	$C_{12}VOPO_4$	90	82
3	$C_{14}VOPO_4$	91	87
4	$C_{14}OHVOPO_4$	90	82
5	$C_{16}VOPO_4$	90	84
[HMF] = 0.1 M, toluene = 3mL, catalyst = 15 mg, time = 6 h, oxygen = 1 atm.			

4 Conclusions

Intercalation of alkyl trimethylammonium chains in $VOPO_4 \cdot 2H_2O$ generated heterogeneous catalysts that selectively oxidize 5-HMF to DFF with high yields using molecular oxygen at 110°C in toluene. In contrast, oxygenated or polar solvents favor 5-HMF degradation pathways. The formation of FMF was ascribed to a radical mechanism involving 5-HMF decomposition in solution, whereas the formation of DFF proceeded at the surface of the catalyst.

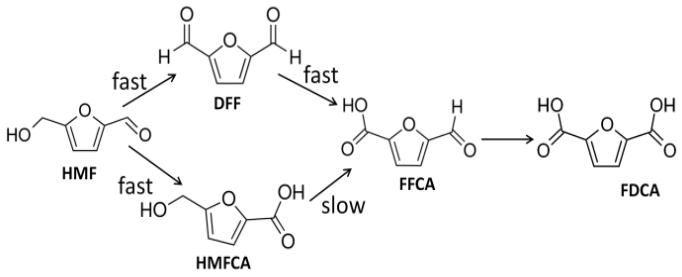
Keywords: HMF, DFF, heterogeneous catalysis, oxidation

1 Introduction

5-Hydroxymethyl-2-furfural (HMF) represents an important, versatile and available primary renewable platform molecule that is structurally found into numerous pharmaceuticals, antifungal agents, as well as polymers. 2,5-Diformylfuran (DFF) is one of the oxidation products of HMF which can be used as monomer for the production of fluorescent materials[1] or as a starting compound for the synthesis of drugs, antifungal agents or ligands[2]. Oxidation of HMF can lead to various other products (Scheme 1) and thus the selectivity to DFF remains an issue to be overcome under mild conditions. Recent reports revealed the use of stoichiometric oxidants generating toxic wastes[3], while the reported heterogeneous catalytic systems are active only in harsh reaction conditions[4]. Considerable efforts have been made to find versatile heterogeneous catalysts for the synthesis of DFF, but without a real progress. Herein, we report a manganese-copper catalyst able to perform the oxidation of HMF to DFF under mild aqueous conditions.



Scheme 1. Reaction pathways in oxidation of HMF (DFF : 2-diformyl furan; FFCA: 5-formyl-2-furancarboxylic acid; HMFCA: 5-hydroxymethyl-2-furancarboxylic acid).

2 Experimental/methodology

Catalysts synthesis

The Cu-/Mn-based catalysts were prepared by simultaneously adding dropwise two aqueous solutions into a flask under vigorous stirring at room temperature, while maintaining pH of 10: one containing copper nitrate (0.015 M), manganese nitrate (1.1 M) and aluminum nitrate (0.3 M) in deionized water (180 mL) and the second containing sodium hydroxide (2.5 M) and sodium carbonate (1 M) in deionized water (180 mL). The slurry was aged for 18 h at 75 °C. The final precipitate was filtered, thoroughly washed until pH 7 and dried overnight at 100 °C in an oven. The same procedure was used for the synthesis of catalysts containing only the

individual metals (Cu or Mn). For a better comparison, all the catalysts were used (i) as prepared, (ii) calcinated, and (iii) in the rehydrated form. In the last case, the samples were first calcined and then hydrated with bidistillated water at room temperature for 24h. The slurry was then dried overnight at 100 °C in air atmosphere.

Catalysts characterization

The prepared catalysts have been investigated using different characterization techniques like powder X-ray diffraction, DRIFT, and textural analysis. The XRD patterns were collected in the range 2θ from 5 to 80° in steps of 0.02° 2θ/s (Shimadzu 7000). DRIFT spectroscopy was used for the characterization of the heterogeneous catalysts and for the evaluation of their stability (Thermo Electron Corporation Nicolet 4700, with in-situ capabilities). The textural measurements using isothermal adsorbtion-desorbtion at N_2 liquid temperature and multi-point method were performed on a Micromeritic ASAP 2010 sorption analyzer.

Catalytic reactions

Catalytic experiments were performed under vigorous stirring in a stainless steel autoclave at temperature of 90 °C, 1 mmol of substrate (HMF), 10 mL of MiliQ water, 0.05 g of catalyst. The products were analyzed by high-performance liquid chromatography (HPLC).

3 Results and discussions

Synthesis of DFF from HMF was performed under various conditions. The effect of amount of catalyst, pressure of oxygen, reaction temperature and reaction time were studied. Also, materials containing only Mn or Cu have been tested for comparison. The best results are presented in Table 1. Higher amount of catalysts and oxygen pressures resulted in a higher conversion and selectivity to DFF, due to an increase in the availability and number of catalytic active sites and higher oxygen concentration in the reaction mixture, respectively. Contrarily, increasing the reaction temperature over 90 °C and the reaction time resulted in a decrease of selectivity in DFF. A higher temperature or reaction time favoured the formation of an advanced oxidation product like 5-formyl-2-furandicarboxilic acid (FFCA).

Table 1. Oxidation of HMF in different conditions.

No.	Catalyst	P_{O_2} (bar)	Temp (°C)	Conversion (%)	S_{DFF} (%)
1.	Mn-Cu dried	8	90	80	74
2.	Mn-Cu calcinated	8	90	90	87
3.	Mn-Cu calcinated	8	60	68	80
4.	Mn-Cu calcinated	4	90	54	60

Reaction conditions: 1 mmol 5-HMF, 10 mL water, 50 mg catalyst, Teflon-lined autoclave, 4- 8 bar, 60-90 °C, 24h.

4 Conclusions

In conclusion, this study proved that mixed manganese-copper oxide is a highly effective heterogeneous catalyst for the selective oxidation of HMF to DFF in the presence of molecular oxygen in water.

Key Parameters Controlling Selectivity and Conversion in OCM: from Experiments and Modelling, towards an Optimised Reactor Design

Serres T.[1], Alexiadis V.[2], Schuurman Y.[1], Thybaut J.W.[2], Mirodatos C.[1*]

1 - Institut de Recherches sur la Catalyse et l'Environnement de Lyon, Université Lyon 1, CNRS, Villeurbanne, France

2 - Ghent University, Laboratory for Chemical Technology, Ghent, Belgium

* Claude.Mirodatos@ircelyon.univ-lyon1.fr

Keywords: OCM, V/S, micro-kinetic, modeling, reactor design

1 Introduction

Despite decades of intense research on oxidative coupling of methane (OCM) catalysts, the yields in ethane and ethylene remain below ca 25%, which drives the research towards innovative engineering solutions. Thus, an integrated reactor-heat exchanger was proposed to combine the exothermic OCM with the endothermic reforming, where the unreacted methane and the non-selective coupling products (water and carbon dioxide) collected at the OCM compartment outlet are recycled and reformed into syngas through the reforming compartment [1]. These strategies imply a careful control of the catalytic/kinetic descriptors such as the ratio active catalyst surface to reactor volume. The latter was shown from micro kinetic modeling to monitor the distribution of radicals in the catalytic zone (inside and outside porous volume) as a strategic parameter for favoring the gas phase coupling rather than the surface full oxidation [2]. The present work focuses on the effect of this Volume-to-Surface (V/S) ratio on the catalytic performance (activity, C_2 selectivity and ethylene-to-ethane ratio) of two Sr-La/CaO (LSC) and Mn/Na/$WSiO_2$ (MNW) OCM catalysts.

2 Experimental/methodology

Figure 1 reports a scheme of the volume-to-surface ratio considered in this work.

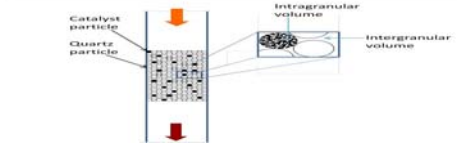

Fig. 1: Scheme of the volume-on-surface measurement for the fixed-bed reactor

All the experimental data obtained by varying the V/S ratio in a wide range are compared with model calculated ones. The latter are based on a comprehensive OCM microkinetic that specifically accounts for the V/S ratio via the corresponding catalyst and reactor descriptors.

3 Results and discussion

Figure 2 illustrates the similar trends observed for the changes in activity and C_2 selectivity vs V/S in the experimental as well as in the calculated data.

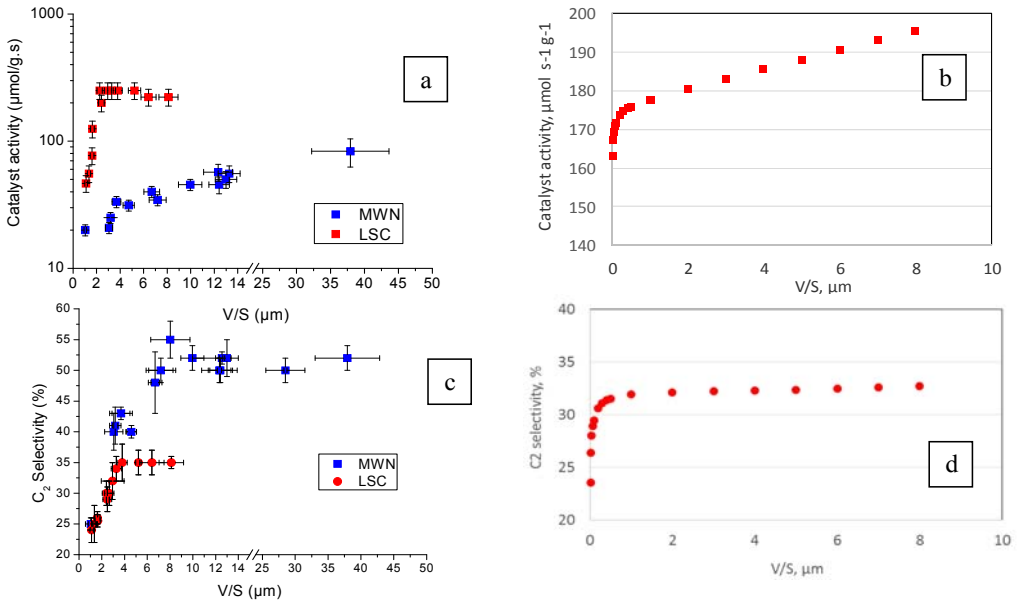

Fig. 2. *OCM activity (a,b) and selectivity (c, d) (in µmol of converted methane/s.g of catalyst) versus the V/S ratio. 10% methane conversion, 800°C, 16/4/1 vol/vol $CH_4/O_2/N_2$. (a, c) Experimental data and (b,d) Calculated results.*

The increasing C2 selectivity with increasing V/S is assigned to the increasing probability of coupling of methyl radicals in the gas phase to form ethane and the decreasing probability of their collision with the catalyst surface to form carbon oxides. According to the model simulations the CH_3 radical concentration is much higher in the catalyst pores as compared to the interstitial gas phase, since they are surface produced intermediates. A similar analysis was performed for the changes in the ethylene/ethane ratio vs V/S, indicating that ethane dehydrogenation is mainly a thermally induced, gas phase, phenomenon controlled by the gas phase reaction C_2H6 <-> C_2H_5·+H· with negligible contribution from the catalytic surface, since C_2H_5 radicals formed on the surface are quenched rapidly. It can be noted however that the nature of the catalyst plays also a major role, as expected from surface reactivity and selectivity depending strongly on surface composition.

4 Conclusions

A comprehensive OCM microkinetic model using catalyst descriptors was used to assess experimental data while fundamentally accounting for the observed dependence of the catalytic performance on the operating V/S ratio. The simulation results were found in line with the experimental observations. These results are deemed to provide strong guide-lines for further reactor design and optimisation.

Keywords: oxidative coupling of methane, catalyst, lattice, oxygen

1 Introduction

Supported mixed $NaWMn/SiO_2$ oxide is a promising catalyst for ethylene production from methane via its oxidative coupling [1,2]. Its structural features and catalytic performance have been extensively studied (see, e.g., [3]). In spite of that, some important issues are still not well understood, including the nature of its catalytic activity. Recently it was demonstrated that water has a strong positive effect on activity and selectivity of this catalytic system and the rates of methane and ethane oxidation tend to increase at increasing conversion [4,5]. On the other hand, it was shown that the rates of light alkane oxidation over this catalyst can be described in the framework of the classical Mars-van Krevelen (redox) kinetic scheme [6]. The latter agrees with the idea that the $NaWMn/SiO_2$ oxide lattice oxygen participates in the C-H bond activation [7]. In this work we attempted to shed more light onto the properties of reactive lattice oxygen, on the role of components in this mixed oxide system, and on the relationships between its composition, structure, oxygen availability and catalytic performance.

2 Experimental

Mixed $NaWMn/SiO_2$ oxide and samples containing its components (Na, W, Mn) and their combinations (Na-W, Na-Mn, W-Mn) supported on silica were obtained using two techniques: incipient wetness impregnation and sol-gel (S-G) synthesis. Correspondingly, Aldrich Davisil grade 646 and tetraethoxysilane were taken as silica sources. After gelation (in the case of S-G synthesis) and drying, all samples were finally calcined at 850-900°C. Their phase composition was studied using powder X-ray diffraction (DRON-2 diffractometer, Cu K_α radiation). Oxygen TPD and redox experiments were performed using differential scanning calorimeter (Setaram DSC-111) and thermobalance (Setaram Setsys TG) equipped with on-line GC and MS analytic systems, respectively. Catalytic performance in methane oxidation was studied using a conventional quartz microreactor with on-line GC analysis of the reaction mixture.

3 Results and discussion

The samples of the same composition obtained by impregnation and S-G synthesis have similar phase composition: all Na-free samples are amorphous, whereas in the presence of Na the formation of α-cristobalite as the main phase (in agreement with literature data) is observed.

Also in agreement with literature, the samples containing all three dopants (Na, W, Mn) demonstrate high selectivity (above 70%) to C_2-hydrocarbons at methane conversions exceeding 15%. Selectivity of one- and two-component systems is substantially lower. Such samples are also much less active compared to the three-component ones.

Catalytic performance correlates with the amount of oxygen that can be reversibly released from the samples during their heating in inert gas (He). Also, only three-component system

demonstrates a stable oxygen release-uptake behaviour in repeated cycles of heating in He and oxidizing O_2-He gas flows. One may conclude that the presence of all three doping components is critical for both catalytic performance and oxygen availability in such conditions. It is likely that Na is responsible for the formation of crystalline structure in which W and Mn interact in an optimal way to form the sites capable of providing such exchangable oxygen. If pulses of oxygen are supplied at 700-800°C onto the sample after heating in He at 800°C, a complex DSC signal that consists of fast exothermal and slow endothermal parts is observed indicating that the sample first consumes oxygen and then slowly releases it with a characteristic time about 150-200 s. The latter is much more than the characteristic time of OCM reaction at the same temperatures (< 1 s.). This allows one to consider this form of oxygen as a relatively weakly-bonded lattice oxygen that may participate in a catalytic reaction of redox type.

At heating between ~700 and 800°C the three-component sample can reversibly release ~16.5 μmole/g O_2, which is substantially less than the amount of transition metals present (170 and 72 μmole/g of W and Mn, respectively). On the other hand, the same sample can provide much more oxygen while reduced in methane and/or hydrogen (~300 μmole/g), which is nearly equivalent to the total content of transition metals (if the reduction of W^{6+} to W^0 and Mn^{3+} or Mn^{4+} to Mn^{2+} is considered). Although according to the data of MS analysis during the reduction with methane all gaseous products typical for OCM reaction (C_2-hydrocarbons, carbon oxides) form, it is very doubtful that such high degrees of reduction may take place during the steady-state catalytic reaction in the presence of even small concentrations of gaseous oxygen. After such deep reduction the sample starts to consume oxygen at temperatures as low as 350°C, and at typical OCM temperatures this process becomes almost instantaneous. But according to the data of kinetic measurements in steady-state regime [6], the rates of the catalyst reduction with methane and its re-oxidation with O_2 are comparable.

4 Conclusions

The alkali component (Na) in the mixed oxide system NaWMn/SiO_2 is required for the formation of appropriate crystalline phase (mainly α-cristobalite) in which W and Mn interact in an optimal way to form the structures containing exchangable oxygen that is responsible for light alkane activation in the conditions of steady-state OCM reaction. Almost total reversible reduction of transition metals (W and Mn) accompanied with the formation of gaseous products typical for OCM (C_2-hydrocarbons, carbon oxides) may occur if this system interacts with methane in the absence of gaseous oxygen.

Alkaline-Earth Promoted $SrTiO_3$ and Sr_2TiO_4 in Oxidative Methane Coupling: Role of Microstructure and Surface Composition on Activity, Kinetics and Oxygen Exchange

1 Introduction

Natural gas is an abundant resource for chemical industry. However, only 7% of the total amount produced natural gas is involved in chemical processing, mainly in production of methanol, ammonia and oxyaldehydes [1]. Therefore, direct conversion of methane, main component of natural gas, to the useful chemicals has been recognized as one of the most technologically important and challenging problems.

For about three decades the advantageous process of the direct methane conversation to C_2 hydrocarbons via oxidative methane coupling reaction (OCM) has been extensively studied, but never commercialized. The reasons are low selectivity and C_2 yield of the known catalysts, high exothermicity and technological restrictions. Perhaps the C_2 yield and selectivity limitations can be improved if we can understand what kind of surface oxygen species, being the active sites for methane activation, governs both the OCM reaction and the secondary total oxidation reaction, how its concentration depends on the catalyst composition.

In this work we attempted to take a close look in catalytic performance of alkaline-earth promoted strontium titanates $SrTi_{0.9}A_{0.1}O_3$ and $Sr_2Ti_{0.9}A_{0.1}O_4$ (A = Mg, Ca, Ba), being the active catalysts of OCM [2], and to find the correspondence between the microstructure, catalytic activity, kinetics of OCM and oxygen exchange properties.

2 Experimental/methodology

All the samples were prepared by mechanochemical method: activation in a planetary ball mill followed by calcination in air at 1100 °C. The samples were studied by XRD, XPS, HREM, IR, Differential Dissolution Method. Catalytic activity was measured in a fixed-bed quartz tube reactor (5 mm i.d.) at 850 – 900 °C and ambient pressure in the reaction mixtures varied from $40\%CH_4 + 5\%O_2$ in He to $10\%CH_4 + 5\%O_2$ with the flow rate varied from 2 to 8.3 cm^3/s, corresponding to the contact time $\tau = 0.05 – 0.012$ s. Oxygen exchange was studied by Steady State Transient Kinetic Analysis $^{16}O_2/^{18}O_2$ at 850 °C and contact time $6.5 \cdot 10^{-3}$ s.

3 Results and discussion

In this work we demonstrated high activity (Y C_2 > 20%) and selectivity (S C_2 > 60%) of Mg and Al-substituted Sr_2TiO_4 in OCM reaction. Detailed kinetic analysis, together with electron microscopy, XPS, XRD and IR methods, allowed us to establish the quantitative relationships between methane conversion, selectivity, temperature and reactant ratio and to reveal the influence of surface composition and microstructure on activity. As follows from microscopic data under reaction conditions the layered perovskite phase $Sr_{2-x}Mg_xTiO_4$ is

destroyed and nanoparticles of (Sr, Mg)O oxide are segregated on the surface (Fig. 1). It strongly increases the activity and selectivity of strontium titanates. The level of (Sr, Mg)O segregation correlates with the rate of methane conversion. It means that active oxygen ion-radicals under reaction conditions are formed in (Sr, Mg)O oxide.

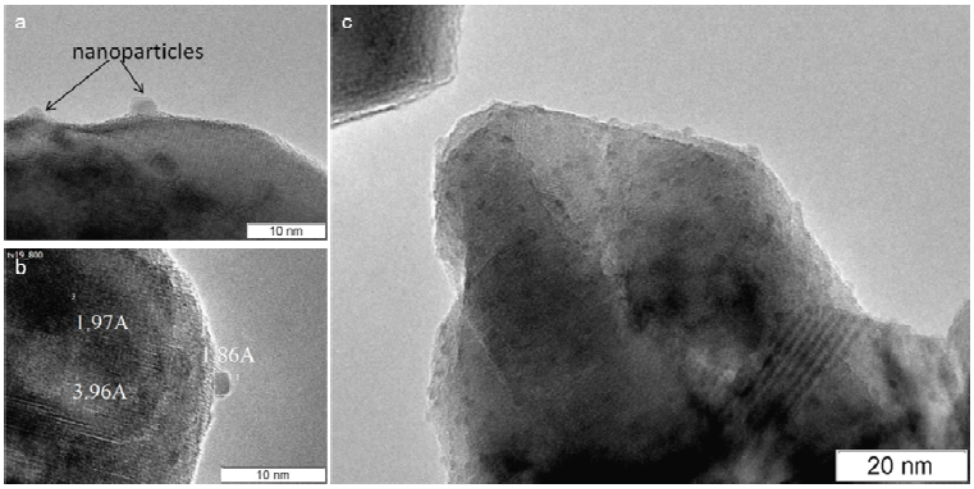

Fig. 1. HREM images of SrTiO3(a) and SrTi0.9Mg0.1O3(b and c) after catalytic tests [2].

To anticipate what kind of oxygen ion-radicals are formed (Sr, Mg)O oxide, we studied the CO_2 adsorption by IR spectroscopy and determine the type and concentration of the surface carbonate species, which decomposition under reaction conditions may result in active oxygen formation. It was found that most active catalysts contains mainly monodentate carbonate, characterized by IR bands at 1455–1460 cm^{-1}and1480–1500 cm^{-1}(asymmetric stretching vibrations of C-O).

Oxygen exchange experiments demonstrated that the most active catalysts are characterised by the highest rate of oxygen exchange at 850 °C. Moreover, the correlation was found between the yield of C_2 hydrocarbons and the ratio R_s/D_{bulk}, where R_s is the rate of the surface hetero-exchange and D_{bulk} is the coefficient of the bulk oxygen diffusion. It indicates that under the OCM conditions high oxygen exchange between surface and bulk takes place, which probably influence the surface concentration of the active oxygen species. The questions concerning the relationship between oxygen exchange properties and activity in OCM are discussed.

4. Conclusions

In this work we have demonstrated that under OCM conditions surface composition and microstructure of alkaline-earth promoted $(Sr,A)TiO_3$ and $(Sr,A)_2TiO_4$ may undergone a change revealing (Sr,A)O mixed oxide on the surface of the particles, which strongly increases both catalytic properties of titanates and the rate of the oxygen hetero exchange between surface and bulk. The correlation was found between the rate constant of methane conversion and the amount of (Sr, A)O oxide. It means that active oxygen ion-radicals under reaction conditions are formed in (Sr, Mg)O oxide and surface/bulk oxygen exchange may regulate its concentration.

Keywords: structural change, microporosity, selective oxidation of ethane

1 Introduction

Orthorhombic $Mo_{29}V_{11}O_{112}$ oxide (MoVO) has attracted much attention because of their outstanding catalytic performance for the selective oxidation of ethane [1]. MoVO is a layered structure comprised of pentagonal $[Mo_6O_{21}]^{6-}$ unit and $\{MO_6\}$ (M = Mo, V) octahedral. The arrangement of the pentagonal $[Mo_6O_{21}]^{6-}$ unit and the $\{MO_6\}$ octahedral forms framework unit. Voids in the framework are filled with pentamer units comprised of five octahedra, resulting in the formation of hexagonal and heptagonal channels. The heptagonal channel in MoVO structure acts as a micropore with 0.40 nm in diameter which can adsorb small molecules like as light alkanes. The size of the channel is tuneable by redox treatment [2]. Recently, we have reported that the heptagonal channel converts ethane to ethene inside the channel, resulting in significantly high catalytic activity [1]. This time, the relationship between the microporosity and the catalytic activity for the selective oxidation of ethane is discussed.

2 Experimental

An aqueous solution of $VOSO_4$ was added to the aqueous solution of $(NH_4)_6Mo_7O_{24}$ (Mo/V=4) and poured into an autoclave for hydrothermal reaction at 175 ºC for 48 h. Dried samples were treated with oxalic acid, then calcined at 400 ºC for 2 h under static air (MoVO (0)). MoVO (0) was heat-treated under 70 ml min^{-1} of 5% H_2/Ar at 400 ºC for a given length of time. Obtained samples are abbreviated as MoVO (δ) (δ: 0.8, 2.9, 4.2, 5.4, 6.1, 6.8) where δ corresponds to the number of oxygen evolved from the unit cell ($Mo_{29}V_{11}O_{112-\delta}$). MoVO (2.9) and MoVO (6.8) were again calcined under static air at 400 ºC for 2 h (MoVO (2.9)-AC and MoVO (6.8)-AC, respectively). The selective oxidation of ethane was carried out in gas phase at atmospheric pressure in a conventional flow system with a fixed bed reactor at 300 ºC under $C_2H_6/O_2/N_2$ = 5/5/40 ml min^{-1} gas flow.

3 Results and discussion

By the redox treatments, no impurities are observed by XRD, IR, Raman. In addition, the redox treatments caused no change in their bulk composition and external surface area. Figure 1 shows the micropore volume measured by propane adsorption (V_{C3H8}) and ethane conversions at 10 min from starting the reaction of MoVO catalysts. The ethane conversion were increased with increasing δ until MoVO (4.2) (from 13.7% to 33.0%) and then decreased drastically for the further δ increase (from 33.0% to 0.5%). For the catalysts after the air calcination, the ethane conversion of MoVO (2.9)-AC was 10.0%. Surprisingly, the ethane conversion of MoVO (6.8)-AC was 31.2%, three times higher than that of MoVO (2.9)-AC while both of them were calcined in the same condition. Adsorption behaviour of V_{C3H8} upon the reduction was well

matched with that of the ethane conversion. The molecular size of propane (0.43 nm) is a little larger than the size of the heptagonal channel (0.40 nm), indicating that the increase of V_{C3H8} between MoVO (0) ~ MoVO (4.2) corresponds to an expansion of the heptagonal channel. TPR shows that there are two kinds of lattice oxygen in the $Mo_{29}V_{11}O_{112}$ structure, one is evolved in the early stage of the reduction and hardly comes back by reoxidation. The other is continuously evolved during the reduction and reversibly comes back by reoxidation. We abbreviated the former oxygen as α-oxygen and the latter oxygen as β-oxygen. From TPR, it was found that the evolution of α-oxygen is finished by the reduction up to MoVO (4.2). XRD, IR, Raman showed that α-oxygen is placed in the pentamer unit and β-oxygen is placed in the framework unit. From the propane adsorption, an expansion of the heptagonal channel was implied by the reduction up to MoVO (4.2). Therefore, the α-oxygen should be the oxygen in the pentamer unit which faced to the heptagonal channel (O_{29} in Figure 2 (A)) and the evolution of the α-oxygen should be related to an expansion of the heptagonal channel. For the reoxidized catalysts, MoVO (2.9)-AC had the α-oxygen, while almost no α-oxygen in MoVO (6.8)-AC was observed. Actually, V_{C3H8} of MoVO (6.8)-AC was twice higher than that of MoVO (2.9)-AC. Since another catalytically affective factors of these catalysts were almost the same, we concluded that the evolution of α-oxygen increased the catalytic activity. The increase of the catalytic activity between MoVO (0) ~ MoVO (4.2) should be due to the evolution of the α-oxygen. The void generated by the evolution of the α-oxygen may moderately activate gaseous oxygen, resulting in the increase of the catalytic activity. The crystal structure of MoVO catalysts at each reduction state is simulated by Rietveld refinement. Figure 2 (B) illustrates the diameters of the heptagonal channel. The diameter in the short axis (D_2) increased with increasing δ in the range of MoVO (0) ~ MoVO (4.2), however, was drastically decreased for the further reduction by the expansion of pentagonal $[Mo_6O_{21}]^{6-}$ unit. The drastic decrease of V_{C3H8} (as well as V_{C2H6} (data not shown)) of the catalysts above MoVO (5.4) should be due to the decrease of D_2. Since ethane is converted inside the heptagonal channel, the loss of the catalytic activity by the reduction above MoVO (5.4) should be due to an inaccessibility of ethane to the heptagonal channel.

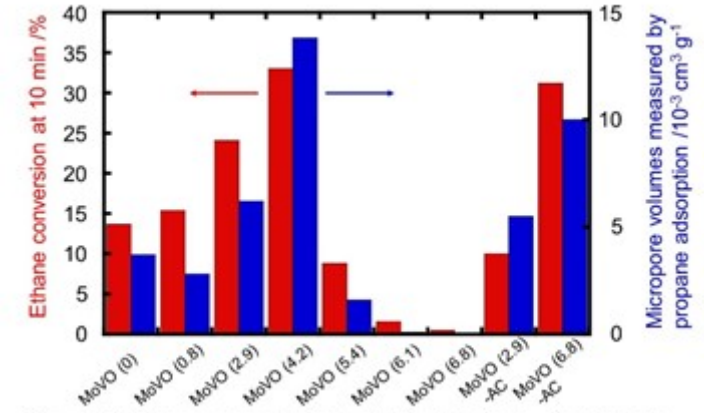

Figure 1 Ethane conversion at 10 min from starting the reaction (Red) and micropore volumes measured by propane (blue) adsorption of MoVO catalysts.

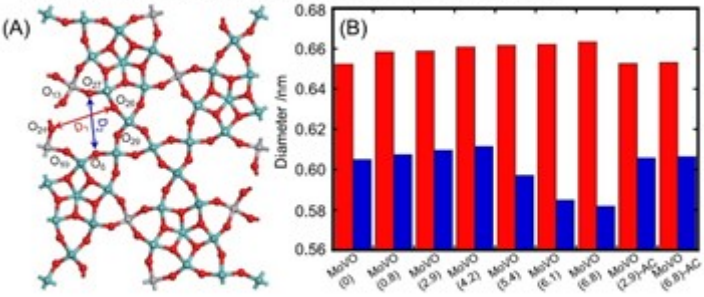

Figure 2 (A) Structural model of MoVO. (B) Diameters of heptagonal channel (Red bar, D_1, Blue bar, D_2).

4 Conclusion

Relationships between the crystal structure, microporosity, and catalytic activity was found.

Keywords: heteropoly acid, cellulose, hemicellulose, formic acid, formaldehyde mechanism

1 Introduction

Cellulose and hemicelluloses - the main components of plant biomass (40 – 60 % of biomass) are promising raw materials for production fuels and valuable chemicals. [1]. However polysaccharides derivatives reduction demands a lot of reducing agent. Molecular hydrogen produced from fossile hydrocarbons is usually proposed as a reducing agent. However formic acid produced from polysaccharides can be used as reducing agent or resource of hydrogen for fuels production [2].

P-Mo-V heteropoly acids having acidic and oxidative catalytic centers were suggested as bifunctional acidic-oxidative catalysts for formic acid production using one-pot processes of hydrolytic oxidation of natural polymers like cellulose and hemicelluloses under soft conditions [2 – 4]. Many researchers believe that one-pot process consists of two sequential catalytic steps (hydrolysis and oxidation). Acidic catalyst should be used for hydrolysis. Oxidation of monosaccharide to formic acid proceeds over oxidative catalyst via several steps. However high yields (more than 60%) of formic acid and absence of such intermediates as gluconic and glucuronic acids makes this hypothesis implausible.

The aim of this work was the study of kinetics and elucidation the mechanism of the process of one-pot oxidative hydrolysis of polysaccharides in the presence of HPAs providing the formation of formic acid with high selectivity.

2 Experimental

HPAs ($Co_{0.6}H_{3.8}PMo_{10}V_2O_{40}$, $H_5PMo_{10}V_2O_{40}$, $Co_{0.6}H_{3.8}PMo_{10}V_2O_{40}$, $Li_{2.4}H_{4.6}PMo_8V_4O_{40}$, $H_{11}P_3Mo_{16}V_6O_{76}$ and $H_{17}P_3Mo_{16}V_{10}O_{89}$) were synthesized, characterized by NMR and tested in ball-milled cellulose hydrolitic oxidation. All experiments were carried out in high-pressure autoclave (Autoclave Engineers, USA) under intensive stirring (1500 rpm). The concentration of cellulose or hemicelluloses was 10 g L^{-1} and heteropoly acid concentration calculated on amount of vanadium varied from 0.5 mM to 20 mM. The experiments were performed at various temperatures (130, 140, 150 and 180 °C) and different pressures (1, 2, 5 MPa) of gas mixture containing 20% of O_2 and 80% of N_2. Samples to analyze were periodically drawn from the autoclave. The aliquots of the reaction mixture were thoroughly filtered and the concentrations of products were measured by HPLC using a Shimadzu Prominence LC-20 system equipped with diode array and refractive index detectors and a Rezex Organic Acids H+ column (Phenomenex, 300 mm * 5.0 mm) thermostated at 40 °C. The eluent (1.25 mM H_2SO_4 aqueous solution) was supplied at the 0.6 mL min^{-1} flow rate. Formaldehyde concentration was measured after derivatization with chromotropic acid on λ 570 nm.

3 Results and discussion

The HPLC analysis of components dissolved in reaction solution showed that under all conditions the main product of the one-pot process is formic acid. Only low amounts of glucose and acetic acid were also detected at some cases. Besides the formation of the formaldehyde was registered after derivatization with the chromotropic acid.

The optimization of the process parameters was performed at the presence of $Co_{0.6}H_{3.8}PMo_{10}V_2O_{40}$ as the catalyst. The variation of temperature (130, 140, 150 and 180 °C) showed that the temperature 150 °C is the optimal for the cellulose and arabino-galactan hydrolytic oxidation, but 120 °C for xylan. Note, the optimal temperatures for hydrolysis of the tested polysaccharides with sulfuric acid are about 30 °C higher. The highest yield of formic acid were 66% for cellulose, 45% for arabino-galactan, 42% for xylan. The yields for formaldehyde were 2, 1,7, 2.2%, respectively. Activation energy for polysaccharide hydrolytic oxidation was measured using the dependence of reaction rates from the temperatures. The kinetics of the oxidation of the glucose, formic acid and formaldehyde were also studied.

The screening of the different catalysts was performed in cellulose hydrolysis under the optimal conditions (the temperature 150 ºC and pressure of gas mixture 5 MPa). $H_5PMo_{10}V_2O_{40}$, $Co_{0.6}H_{3.8}PMo_{10}V_2O_{40}$, $Li_{2.4}H_{4.6}PMo_8V_4O_{40}$, $H_{11}P_3Mo_{16}V_6O_{76}$ and $H_{17}P_3Mo_{16}V_{10}O_{89}$ were tested. The highest reaction rate is observed in presence of HPA which has higher oxidative potential and gives the lowest pH.

The influence of vanadium content on reaction rate was studied using $Co_{0.6}H_{3.8}PMo_{10}V_2O_{40}$. All experiments were made at pH of reaction solution equal to 1.50 for prevention the influence of acidic properties of HPA. The results obtained showed that the formic acid yield does not change when concentration of vanadium atoms decrease from 20 to 10 mM and sharply fall at content of vanadium less then 10 mM.

4 Conclusions

The observed results allowed us to suppose that one-pot oxidative-hydrolysis in the presence of P-Mo-V heteropoly acids proceeded by a mechanism similar to the periodate oxidation. Vanadium species can connect to hydroxide groups of sugars and broke C-C bond to give formic acid and shorted sugar. Finally such oxidation of C6-aldose leads to formation of 5 molecules of formic acid a 1 formaldehyde molecule (Figure 1). Moreover connection of vanadium to polysaccharides molecules facilitating hydrolysis is also possible.

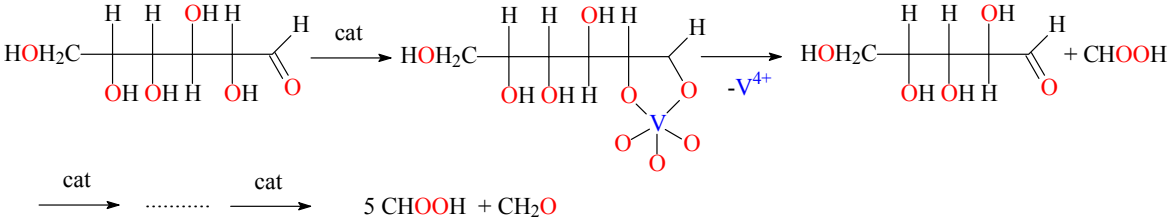

Fig. 1. Proposed mechanism of formic acid formation from C6 aldose in the presence V-containing heteropolyacyd catalysts.

Keywords: doped nickel oxide, electrical conductivity, ethane oxydehydrogenation, reaction mechanism

1 Introduction

Doped NiO has been reported [1] as efficient catalyst for the low temperature ethane oxy-dehydrogenation (ODH), which is an attractive alternative to the conventional steam cracking route for ethylene production. The electronic and redox properties of oxide catalysts strongly influence their catalytic performance in oxidation reactions [2]. *In situ* electrical conductivity measurements constitute a powerful technique for the investigation of electronic and redox properties of oxidation catalysts and can help understanding their catalytic behavior [3].

In this work, electrical conductivity of two series of doped NiO catalysts, i.e. M-NiO (M = Li, Mg, Al, Ga, Ti, Nb) and Nb(x)NiO (x = Nb at. %), was studied as a function of temperature and oxygen partial pressure and temporal responses during sequential exposures to air, ethane – air mixture (reaction mixture) and pure ethane in conditions similar to those of catalysis were analyzed. Comparisons between the different catalysts and correlations between their redox and semiconductive properties and their catalytic performance in ethane ODH have been established.

2 Experimental

Both M-NiO oxides with a M/(Ni+M) atomic ratio of 0.15 and Nb(x)NiO oxides with Nb/(Ni+Nb) atomic ratios of 0.01, 0.05, 0.10, 0.15 and 0.20 were prepared by the evaporation method, characterized with several techniques and tested in ethane ODH as described elsewhere [1, 4, 5]. The catalytic test was performed in a fixed bed quartz reactor operating at atmospheric pressure, in the temperature range from 300 to 425 °C. The electrical conductivity measurements were performed in the reaction temperature range under different flowing gases in a quartz tube cell containing the catalyst pellet between two platinum electrodes connected to a megaohmmeter.

3 Results and discussion

The intrinsic activity in ethane ODH roughly decreased while the ethylene selectivity at isoconversion continuously increased with increasing valence of the dopant cation and niobium content for both M-NiO and Nb(x)NiO series, respectively. Nb(15)NiO catalyst gave the lowest intrinsic activity but the highest ethylene selectivity suggesting that this material contains the lowest surface density of unselective (but also active) catalytic sites.

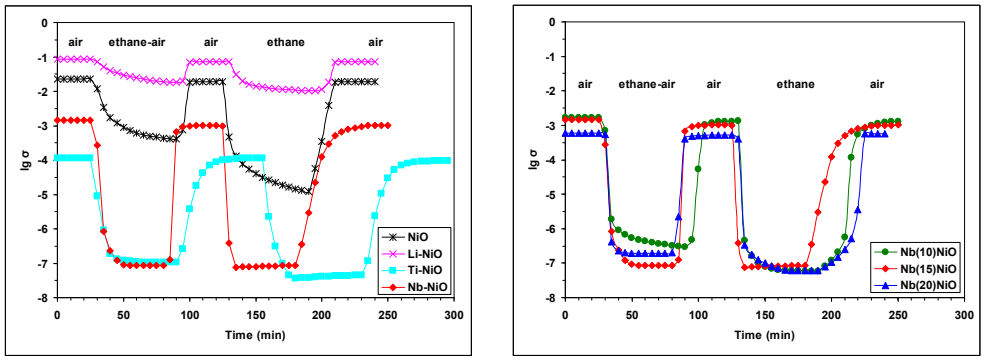

Fig. 1. Variation of σ during sequential exposures to different gas flows for selected catalysts at 400 °C.

The electrical conductivity measurements showed that pure NiO as well as all the doped NiO catalysts behaved as p-type semiconductors in the reaction temperature range both under air and under the ethane-air reaction mixture. The temporal responses of electrical conductivity of selected catalysts during sequential exposures to different gaseous atmospheres in conditions similar to those of catalysis are presented in Fig. 1.

Except for Nb-NiO, the electrical conductivity of the M-NiO catalysts in air decreased with increasing the valence of doping cation, indicating the consumption of charge carriers (positive holes) due to the doping effect. The different behavior of Nb-NiO can be explained by a reduction of the niobium doping cation valence. In the Nb(x)NiO series, the electrical conductivity in air decreased continuously with increasing the niobium content. The intrinsic activity in ethane ODH roughly followed the p-type semiconductivity under air for both M-NiO and Nb(x)NiO catalysts. All the catalysts were partially reduced under the reaction mixture at 400 °C (Fig. 1), an inverse correlation between their p-type conductivity in these conditions and the ODH selectivity being observed for both M-NiO and Nb(x)NiO series studied. The observed decrease of the electrical conductivity of the M-NiO catalysts in the presence of ethane suggests that ethane is transformed by consuming the positive holes existing in the p-type oxide catalyst. The observed correlations between the results of the *in situ* electrical conductivity measurements and the catalytic results indicate that O^- species, the chemical equivalent of the positive holes - charge carriers, are the active sites for ethane activation; however conversion to the targeted product, ethylene, occurs only when their concentration is low and the attack to the activated ethane is milder.

4 Conclusions

The *in situ* electrical conductivity studies performed in the present work and the important correlations of both activity and selectivity with electrical conductivity that were obtained highlight the role of non-stoichiometric oxygen species for ethane ODH over doped NiO based catalysts and provide a clear and direct evidence for a heterogeneous redox mechanism involving surface lattice O^- species.

In-situ XPS and XAS Studies of a New Phenomenon of Kinetic Hysteresis in Selective Methane Oxidation over Platinum

Pakharukov I.Yu[1,2*], Bukhtiyarov V.I.[1,2], Chetyrin I.A.[1,2], Prosvirin I.P.[1,2], Parmon V.N.[1,2], Murzin Y.V.[3], Zubavichus Y.V.[3]

Keywords: methane oxidation concentration, hysteresis, NAP-XPS, Pt catalyst

1 Introduction

Recently, we discovered a new phenomenon of kinetic hysteresis in selective oxidation of methane over platinum catalysts [1]. We found that the activity and selectivity of the platinum catalysts in a steady state depends greatly on a way of achieving the steady state. Using this hysteresis one can directly control the selectivity and activity of the platinum catalyst even with low initial activity (e.g., at low temperature), improve the conversion from 10 to 90%. For this purpose, oxygen concentration in the reaction mixture is decreased to a level less than O_2:CH_4=1.5 at the atmospheric pressure. It leads to certain increase in the methane conversion and selectivity. To achieve the maximum methane conversion (80-90%) the oxygen concentration in the initial reaction mixture is then increased up to a ratio of O_2:CH_4≤2.

Since this is undescribed phenomenon, we have no literature data to understand its nature. To establish the reasons of this phenomenon, we studied changes in oxidation state of the active component in real platinum catalysts by *in-situ* X-ray photoelectron spectroscopy (XPS) and X-ray absorption spectroscopy methods (XANES and EXAFS).

2 Experimental/methodology

In-situ XPS experiments were carried out on a photoelectron spectrometer VGESCALAB "High Pressure" [2] equipped with a special high-pressure cell and a quadrupole mass spectrometer with two-stage differential pumping and high-precision mass flow-controllers. Experiments were conducted at constant methane concentration (partial pressure of about 0.008 mbar) with varying the O_2:CH_4 ratio in the range from 0.2:1 to 2:1. *In-situ* XAS experiments were carried out at STM-station of Kurchatov Synchrotron Center (at the atmospheric pressure).

The catalyst (1 wt.%Pt/γ-Al_2O_3) under study was prepared via a wet impregnation of γ-Al_2O_3 with a platinum nitrate solution followed by air-drying and calcinations in air. The grain size of the catalyst is 0.25-0.5 mm. The average size of supported platinum particles was about 1.5 nm.

3 Results and discussion

Previous studies of the hysteresis were conducted in reactors at the atmospheric pressure. Therefore, there was no certainty that the experiment can be repeated at low pressures of about 0.01 mbar. However, our *in-situ* XPS experiments showed the presence of similar kinetic hysteresis (Fig. 1). Study included testing possible catalytic activity of the alumina support and *in-situ* cell. It was shown that the pure support and *in-situ* cell were not active in the reaction.

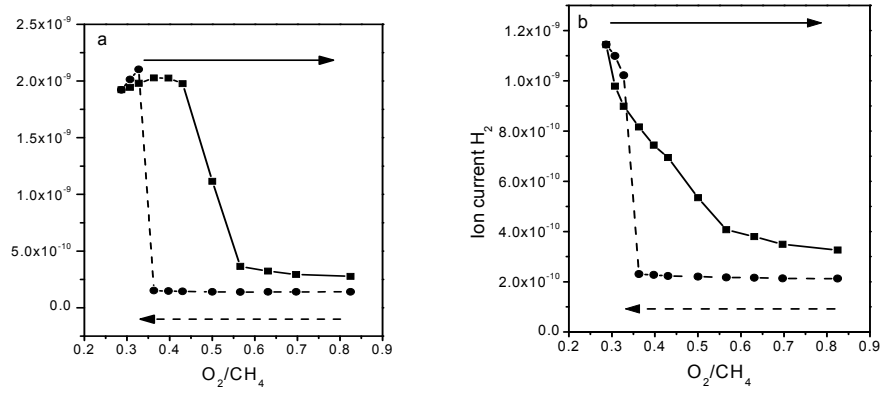

Fig.1. The kinetic hysteresis in the methane oxidation over 1 wt.%Pt/γ-Al_2O_3 catalyst detected by *in-situ* mass spectrometry at pressures of about 0.01 mbar, T=460°C

To identify the platinum oxidation state under the reaction conditions a number of reference compounds with different oxidation states of platinum (0, 2+, 4+) were investigated (Fig. 2a). The *in-situ* XPS spectra were recorded simultaneously with measurement of components concentrations. Analysis of XPS spectra showed that a transition of the catalyst to the active state was accompanied by shifting Pt4f line towards lower values of binding energy (Fig. 2b). Thus, activation of the platinum was associated with its partial reduction.

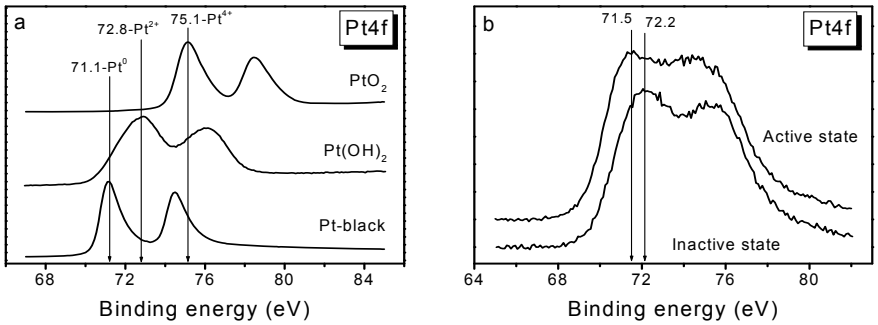

Fig.2. Changes in the platinum oxidation state: a - reference samples; b – Pt in the reaction

The XAS data obtained at the atmospheric pressure also implied that the activation was associated with predominant formation of the metallic platinum, whereas oxidation of platinum surface was responsible for less active state. The reaction mechanisms for explanation of these data are discussed.

4 Conclusions

The *in-situ* experiments allowed us to find out the cause of the kinetic hysteresis phenomenon in the selective methane oxidation over platinum catalysts.

Keywords: methane to methanol, nitrous oxide, FeZSM-5, zeolite, Alpha-oxygen, quasicatalytic reaction

1 Introduction

Huge natural resources of methane and the ability of Fe-containing enzymes methane monooxygenases (MMO) to perform its oxidation to methanol inspire new and repeated attempts of chemists to run this reaction in a catalytic way. However, for many decades this problem remains unsolved. In this connection, of great interest are FeZSM-5 zeolites containing special Fe^{II} complexes (α-sites) that are capable of stoichiometric decomposition of nitrous oxide with deposition of the oxygen anion-radical (the α-oxygen, O_α) [1]:

$$(Fe^{II})_\alpha + N_2O \rightarrow (Fe^{III}\text{-}O^{\bullet-})_\alpha + N_2 \quad (1)$$

Similar to the active oxygen of MMO, O_α exhibits a very high reactivity at 25°C. The present work is devoted to the α-oxygen oxidation of CH_4, including both the surface formation of methanol and a catalytic cycle of the reaction with the products desorption into the gas phase.

2 Experimental/methodology

The study was carried out with a sample of FeZSM-5 zeolite containing 2.0 wt% Fe, similar to the one that has been used in our previous studies [2, 3]. The sample had $C_\alpha = 5.7\times10^{19}$ site/g (95 μmol/g). Experiments on methane oxidation were performed with a conventional flow setup with chromatographic analysis of the gas phase. In quasicatalytic experiments, surface products were extracted with an aqueous solution of acetonitrile and analyzed using GC, ^{1}H NMR, and gas chromatography-mass spectrometry [3, 4].

3 Results and discussion

This work is a continuation of our studies [2-4] on the mechanism of methane oxidation by α-oxygen over FeZSM-5. Previously, using a vacuum setup, it was shown that at 160°C methane is oxidized to methanol. Spillover of methanol from α-sites liberates them for further oxidation cycles. Such a surface reaction with TON greater than 1, but without product desorption into the gas phase, we have named quasicatalytic. Based on this result one can assume that this quasicatalytic mode of reaction can be conducted also in a conventional flow-type setup, which is well supported by the data presented in Table 1.

Table 1. Quasicatalytic oxidation of methane in a flow-type setup. Reaction conditions: 0.36 g catalyst; feed mixture: 20% CH_4 + 2% N_2O with He balance; flow rate 30 cm^3/min.

Exp. no.	T, °C	Time, h	TON per α-site			Composition of products extracted, mol. %				
			Total products	Products extracted	Coke	CH_3OH	DME	C_2H_4	AA	Others (heavy)
1.	160	4	4.4	2.6	1.8	87	13	0.0	0.0	0.0
2.	175	4	5.2	3.3	1.9	77	23	0.0	0.0	0.0
3.	200	4	6.9	4.1	2.8	68	32	0.0	0.0	0.0

The main products produced by the quasicatalytic reaction and extracted from the surface

are methanol and DME. In addition, coke is formed, the amount of which was determined in situ by burning it in an air flow. The total amount of methane oxidation products increases with the temperature rise. The fraction of methanol in the products decreases due to its conversion into coke and DME.

In the temperature range 275-300°C the reaction proceeds in a catalytic way with desorption of methanol, CO, CO_2 acetaldehyde (AA) and ethylene into the gas phase (Table 2). The addition of water vapor in the feed mixture substantially reduces the formation of coke and strongly increases the selectivity for methanol. At 275°C and a 30% H_2O, the major product of the reaction is methanol, which selectivity is 62%. The yield of methanol is rather small. But variety of approaches available for modifying the catalytic properties of zeolites can certainly improve the result.

It is interesting to note that the selectivity for CO strongly increases with increasing the selectivity for methanol. Experiments have shown that this is due to the Cannizzaro reaction: $HCHO \rightarrow CH_3OH + CO$. The occurrence of this reaction explains the absence of formaldehyde in the products of methane oxidation. It is noteworthy that DME was not detected among the products although, as shown above, it was one of the main products in the quasicatalytic oxidation of methane. This is because at catalytic conditions DME acts as an intermediate and is fully consumed by the process of coke formation on the FeZSM-5 surface.

The reaction of methane with O_2 (instead of N_2O) is very slow and totally unselective, producing only small amounts of CO and CO_2 (no. 9).

Table 2. Reaction parameters of 2-h catalytic experiments. Reaction conditions: 0.36 g FeZSM-5; feed mixture: 20% CH_4 + 2% N_2O + (0÷30%) H_2O with He balance; flow rate 30 cm^3/min.

Exp. no.	T, °C	H_2O in the feed, %	Average conversion, %		Average selectivity, %						Coke amount, μmol C/g

8	300	30	21	0.75	42	45	4.5	1.0	0.0	7.5	58
9[a)]	300	20	0.4[a)]	0.02	0.0	70	30	0.0	0.0	n/d	n/d

[a)] The feed mixture contains 2% O_2 instead of 2% N_2O.

4 Conclusions

The present study was conducted over a wide temperature range covering both the quasicatalytic and catalytic modes. An important result of the work is that a comparison of quasicatalytic and catalytic data can provide new information on the reaction mechanism, including a possibility of identifying potential intermediates that are invisible under conventional catalytic conditions. A mechanistic scheme presenting main steps of both reaction modes was suggested.

Keywords: methane, methanol, trinuclear, Cu/ZSM-5

1 Introduction

The unique ability of over-exchanged Cu/ZSM-5 zeolite to oxidize CH_4 to CH_3OH at low temperature of 100 °C has been related to extra-framework binuclear $[Cu(\mu\text{-}O)Cu]^{2+}$ complexes [1]. However, an inherent limitation of this catalyst system is the difficulty of extracting the methanol product mainly caused by the strong binding of the extra-framework oxygen (O_{EF}) bridging between the two Cu^{2+} ions and the high Lewis acid strength of the cuprous sites formed upon methanol formation. In this work, we report the results of a computational study on the nature of active Cu complexes in Cu/ZSM-5 zeolite and their reactivity towards methane oxidation. We address the feasibility of the formation of larger trinuclear Cu complexes in the zeolite micropores. This is followed by a computational analysis of the reactivity of the most stable bi- and trinuclear Cu complexes towards methane oxidation.

2 Methodology

DFT calculations were performed using the VASP software. The exchange-correlation energy was described by generalized gradient approximation PBE functional. Plane-wave basis set with a cutoff of 400 eV in combination with the projected augmented wave (PAW) method was used. Brillouin zone-sampling was restricted to the Γ point. The nudged-elastic band method was used to determine the minimum energy path and to locate the transition state structure for methane oxidation to methanol reaction.

To account for the effect of temperature as well as presence of H_2O and O_2 upon the catalysts activation on the stability of different extra-framework Cu complexes in Cu/ZSM-5 *ab initio* thermodynamic analysis was employed. The following reversible reactions were considered to compare equilibria among species with different chemical compositions:

$$\frac{2m-n-2x+2}{4}O_2 + \frac{n-2}{2}H_2O + x(CuO) + 2H\text{-}ZSM\text{-}5 \leftrightharpoons Cu_xO_mH_n/ZSM\text{-}5$$

The reaction free energy $\Delta\Gamma$ was calculated per zeolite unit cell according to:

$$\Delta\Gamma(T,P) = \Delta E - \frac{2m-n-2x+2}{2}\Delta\mu_O - \frac{n-2}{2}\Delta\mu_{H_2O}$$

ΔE is the total electronic energy and $\Delta\mu_i$ are the chemical potential differences of water and oxygen.

3 Results and discussion

The stabilities of different potential cationic Cu complexes in ZSM-5 zeolite were investigated by periodic DFT calculations. We assume that multinuclear Cu cations are formed in ZSM-5 zeolite via self-organization of cationic Cu species [2] such as Cu^+, CuO^+ and $[CuOH]^+$, previously considered as extra-framework species in Cu/ZSM-5, and their protolysis with zeolitic Brønsted acid sites. The DFT-computed energies predict binuclear Cu complexes to be the preferred species in Cu/ZSM-5 at 0 K. However, a finite temperature analysis of the Cu speciation including the effect of the gas atmosphere by the *ab initio* thermodynamic approach demonstrates that oxygenated $[Cu_3(\mu\text{-}O)_3]^{2+}$ and hydroxylated $[Cu_3(\mu\text{-}OH)_2(\mu\text{-}O)]^{2+}$ trinuclear

complexes (Figure 1a) are preferred over mono- and binuclear species at conditions typically employed for the activation of Cu/ZSM-5 catalysts, i.e. high-temperature treatment (800 K) in an O_2-rich atmosphere or in the presence of water vapor, respectively.

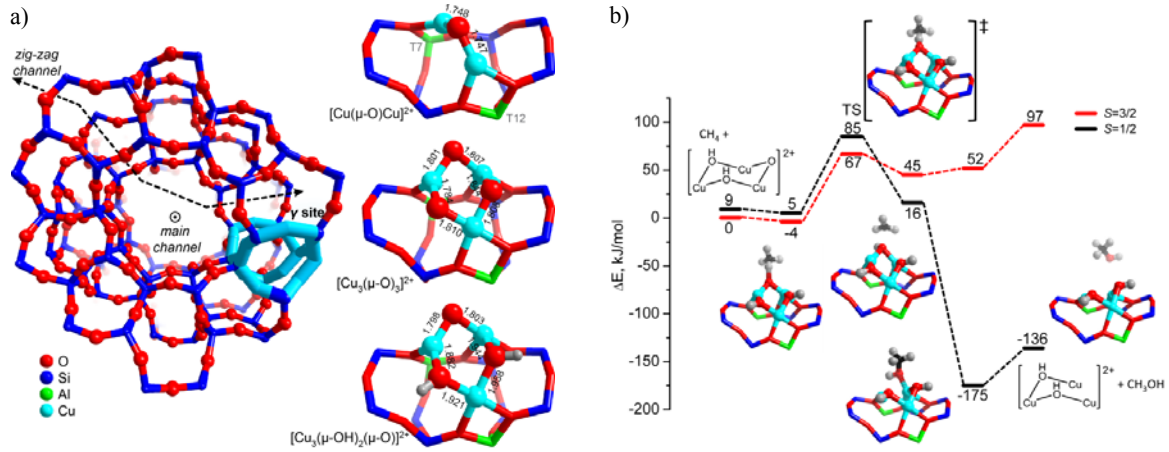

Figure 1. a) Schematic representation of ZSM-5 framework and selected location for accommodation extra-framework Cu-containing species. b) Reaction paths for methane oxidation to methanol over trinuclear hydroxylated $[Cu_3(\mu\text{-}OH)_2(\mu\text{-}O)]^{2+}$ complex in the high (S = 3/2) and low-spin (S = 1/2) electronic configurations.

The reaction energy diagrams for methane oxidation over trinuclear $[Cu_3(\mu\text{-}OH)_2(\mu\text{-}O)]^{2+}$ complex are shown in Figures 1b. Methane is activated in a similar manner as on binuclear Cu site via homolytic C–H bond cleavage The reaction product is a $CH_3^{\bullet}$ radical and a biradical $[Cu_3(\mu\text{-}OH)_3]^{2+}$ extra-framework ion. Accordingly, direct formation of CH_3OH via a rebound mechanism is thermodynamically unfavorable over the high-spin PES. Thus, C–H activation over $[Cu_3(\mu\text{-}OH)_2(\mu\text{-}O)]^{2+}$ will most likely involve a spin-crossing transition (S = 3/2 → S = 1/2). The resulting radical pair in the S = 1/2 electronic configuration recombines readily, resulting in CH_3OH coordinated to a single Cu ion in the partially reduced $[Cu_3(\mu\text{-}OH)_2]^{2+}$ complex. Methanol desorption from this cluster is much more favorable than from the Cu^+ dimer. The regeneration of the initial active complex can be accomplished by oxidation in O_2.

4 Conclusions

Using the combined approach of periodic DFT calculations and *ab inito* thermodynamic analysis, the reaction mechanism of methane oxo-functionalization over extra-framework Cu complexes in Cu/ZSM-5 zeolite has been explored. It is demonstrated that trinuclear Cu-oxo cationic complexes correspond to the most thermodynamically stable species in Cu exchanged zeolite activated in O_2-rich atmosphere. The reactivity comparison predicted that the trinuclear complexes provide a more energetically facile reaction pathway towards methanol than the binuclear sites. Besides the facilitated initial C–H bond activation, the specific electronic configurations of such sites favor the direct radical rebound resulting in methanol formation.

Keywords: heterogeneous catalysis, YSZ, perovskite, isotopic exchange, partial oxidation of methane

1 Introduction

To find an alternative to polluting energies, the demand for natural gas to produce synthetic fuels has drastically increased in recent decades. Methane conversion to synthesis gas (CO/H_2) is a promising way to yield more easily transportable liquid fuels such as Fischer–Tropsch products or chemicals like methanol [1]. Catalytic partial oxidation of methane (CPOM) was suggested first by Liander for producing syngas [2]. In recent works, yttria-stabilized zirconia (YSZ) has appeared as a promising catalyst for this reaction in which lattice oxygen ions are incorporated into the products via a *Mars-van Krevelen (MvK)* mechanism at 1173 K [3]. Some perovskite solids also demonstrate catalytic efficiency in CPOM [4]. In this work, we used oxygen isotopic exchange technique to demonstrate a remarkable oxygen activation and mobility on YSZ surface at moderate temperature (698 K) when perovskite materials is placed upstream in a dual catalyst bed. Then this system is investigated in CPOM to check whether its behaviour resulted in an improvement in catalytic activity.

2 Experimental/methodology

$LaMnO_3$ perovskite (35 $m^2.g^{-1}$) was prepared by the citrate route and the 8mol% YSZ material (13 $m^2.g^{-1}$) was supplied by TOSOH. For the Pd/YSZ material, 0.2 wt% of Pd was added by wet impregnation. We have undertaken heterolytic temperature programmed oxygen isotopic exchange (TPOIE) and CPOM experiments in a set-up already described elsewhere [5]. A U-form reactor was placed in a closed recycle system connected to a mass spectrometer for the monitoring of the gas phase composition. Experiments were undertaken on 13.3mg of $LaMnO_3$ and 20mg of YSZ or Pd/YSZ. The samples were subjected to an activation step (flow $^{16}O_2$ at 973 K), a purge (using vacuum), then reactants were charged: 55mbar of $^{18}O_2$ at 473 K for TPOIE and 60 mbar of $2CH_4$:$^{18}O_2$ at 698K for CPOM experiments. The m/z values of $^{16}O_2$, $^{16}O^{18}O$ and $^{18}O_2$ were monitored to follow the exchange and H_2, CH_4, $H_2{}^{16}O$, $H_2{}^{18}O$, $C^{16}O$, $C^{18}O$, $C^{16}O_2$, $C^{16}O^{18}O$, $C^{18}O_2$ were also recorded during CPOM experiments.

3 Results and discussion

The fraction of 18O16O and 16O2 formed during the TPOIE experiments is shown in Figure 1. The exchange started respectively at 533 K and 773 K on LaMnO3 and YSZ isolated samples via a simple mechanism (18O2(g)+16O2(s) ⇔ 18O16O(g)+18O(s)) involving a single lattice oxygen atom to form in gas phase $^{16}O^{18}O$ isotope. For the dual-bed $LaMnO_3$-YSZ, the exchange activity started at 533 K with a considerable enhancement of the exchanged atom fraction contrasting with the expected cumulative number of atoms exchanged. This surprising activity is characterized by the modification of the isotopic distribution since isotope $^{16}O_2$ is first observed in the gas phase (Fig. 1 red curves). Additional experiments revealed that

$LaMnO_3$/YSZ contact is not necessary to observe the phenomenon in contrast to the presence of oxygen vacancies in the YSZ solid since it is not observed with pure ZrO_2 or Y_2O_3 materials. Furthermore, the improvement of the exchange was also detected with other perovskite materials such as $LaCoO_3$. This considerable activity is suspected to be due to the formation of an active singlet oxygen species (E=+94.7kJ/mol) on perovskite bed able to activate the exchange at moderate temperature on YSZ placed downstream [6].

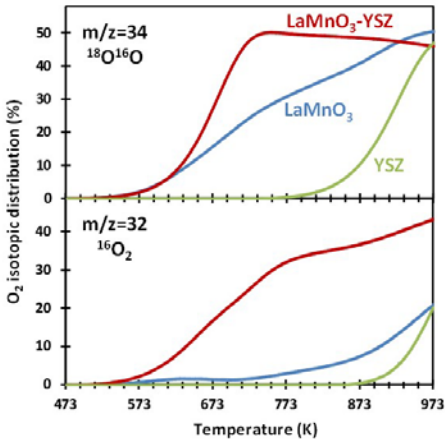

Fig. 1. Evolution of $^{16}O^{18}O$ and $^{16}O_2$ distributions during the TPOIE experiments.

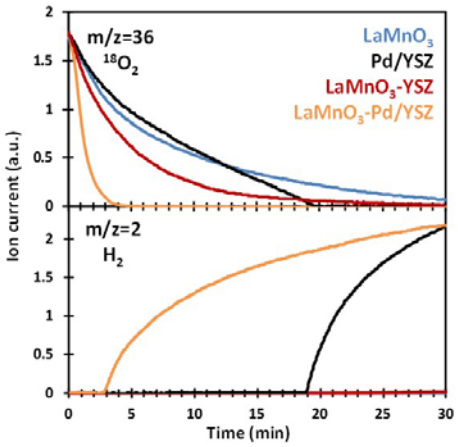

Fig. 2. Evolution of $^{18}O_2$ and H_2 intensities as a function of time during the CPOM reaction at 698 K.

In a second part, the behaviour of the dual-bed system was investigated in CPOM and to prevent the limiting step of methane activation, 0.2 wt% of Pd was added on YSZ what does not affect the oxygen exchange properties. Two steps are identifiable during the reaction: 1/ a consumption of the CH_4 and $^{18}O_2$ was observed while there was an increase in CO_2 signals. This is clearly due to the complete oxidation of CH_4, which is confirmed to occur through a *MvK* mechanism for dual catalyst bed. 2/ the appearance of H_2 slightly before the total consumption of O_2 occurred with the simultaneous production of CO. Direct CPOM is proposed to explain the formation of H_2. Different formulations are compared in Figure 2 for $^{18}O_2$ conversion and H_2 production. Complete oxidation is enhanced in the dual-bed systems (only 3 min against 19 min for Pd/YSZ alone), thus indicating that the beneficial effect observed in terms of oxygen exchange positively influences the oxidation activity. Finally, *MvK* mechanism is not observed for $LaMnO_3$ alone and Pd particles are crucial at this temperature to activate CH_4.

4 Conclusions

The perovskite bed, placed upstream YSZ, enables the formation of an active singlet oxygen species able to activate the exchange process from 533 K with O atoms of the YSZ structure. This behaviour positively influences the catalytic oxidation activity at 698 K. This discovery opens avenues to explore new combinations to produce efficient and industry-compatible catalytic systems for syngas production.

A Qualitative Kinetic Analysis of Steady-State Selective Oxidation Process: Role of Water and Oxygen

Sprung C.[1*], Yablonsky G. S.[2], Schlögl R.[1], Trunschke A.[1]

Keywords: selective oxidation, kinetics, role of water and oxygen, two-route mechanism on two different sites, apparent kinetic orders

1 Introduction

Acrylic acid is a valuable large-scale product in the chemical industry. The currently applied two-step process starts with propene as reactant, forming acrolein as major intermediate, which is then further oxidised. A one-step process, starting from propane, has been the subject of intensive research for more than two decades, however not yet transferred into production.[1] The underlying sequence of consecutive and perhaps parallel reaction steps reveals great diversity from a chemical point of view; the rather inert C-H bonds have to be activated under the same conditions as a more reactive intermediate shall be oxidised selectively. The first hydrogen abstraction may be considered rate determining, however, more valuable is the mechanistic understanding beyond this step, which is the key for the formation of selective oxidation products. In this contribution, the focus was put on the role of water and oxygen on possible active sites and the oxidation and reduction, respectively, of those sites.

2 Approach

There were analysed trends in steady-state kinetic dependences obtained in experimental studies of selective oxidation of propane over a MoVTeNb M1 oxide catalyst.[2] Based on these experimental results, various reaction networks and corresponding steady-state kinetic models have been studied systematically using graph theory methods.[3] The conceptual investigation was based on a reaction network containing two independent cycles: (i) propane dehydrogenation and (ii) selective oxidation of propene (considered as the only product of cycle 1). Propane, oxygen, water, propene, and acrylic acid were considered as components in this reaction network. Non-selective oxidation products were left out preliminary for reasons of simplification. The dynamically changing active sites at the surface of the catalyst were included in the catalytic cycles.

In analysis of kinetic trends, a special attention was paid to detailed analysis of apparent kinetic orders, $n_{app} = \partial \ln R / \partial \ln C_i$, where R is a steady-state rate of substance change, and C_i is a concentration of gaseous substance. In a number of typical situations, apparent kinetic orders (n_{app}) provide information on the mechanistic framework and moreover present an estimate of some surface intermediates.[3]

3 Results and discussion

The kinetic trends observed in experiments did show a positive apparent kinetic order for both propane and water. The conversion rates of propane and oxygen were, however, independent and inverse proportional on the oxygen partial pressure, respectively. Different functions of water were analysed systematically: (1) activation and (2) deactivation in the corresponding "buffer" steps, (3) participation in the catalytic cycle, and (4) a function as spectator. An impact of water on the kinetic apparent orders of all reactants was characterized.

The mechanism presented in Figure 1 is in agreement with the experimental trends. Propane

reduces an oxidised centre ZO to Z while oxidized to propene (first cycle). Z is subsequently re-oxidised to ZO by gas-phase oxygen. Water activates this cycle through a buffer step, without participating in the reaction. The selective oxidation of propene takes place on a second, independent, centre X. Propene reduces the hydrated centre XH2O to X, which is subsequently oxidised and re-hydrated. An oxygen buffer step causes the negative apparent kinetic order of $R(O_2)$ regarding the oxygen concentration. Table 1 summarises the apparent kinetic orders of all reactants with respect to the rate of propane consumption, $R(C_3H_8)$(1. cycle), rate of propene consumption, $R(C_3H_6)$(2. cycle), and rate of oxygen consumption, $R(O_2)$ (both cycles). In our analysis, two balances on two independent centres, Z and X, were considered. It was found that apparent kinetic orders can be presented as a concentration of one centre or a sum of several centres (see Table 1). The re-oxidation steps to XO and ZO could be assumed fast compared to the other reaction steps, hence, the concentrations of centres X or at least Z can be considered low. Under these assumptions, the propane conversion rate is independent on $p(O_2)$. The oxygen conversion rate is of negative kinetic order with respect to $p(O_2)$. It can be explained by the role of oxygen in propene consumption (Table 1): oxygen participates in the buffer step reducing the abundance of XH2O centres. This phenomenon was more pronounced for high partial pressures of water supporting the presence of such a buffer step.

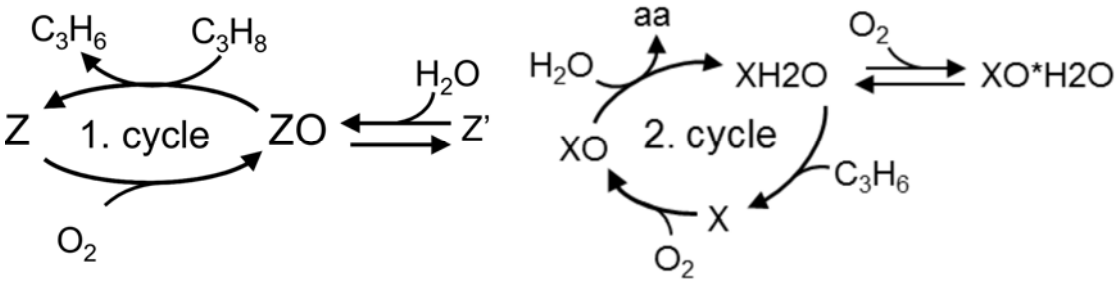

Fig. 1. Two-route mechanism: propane dehydrogenation (1. cycle) and selective oxidation (2. cycle).

Table 1. Representation of apparent kinetic orders of C_3H_8, H_2O, O_2, and C_3H_6 with respect to the rates of C_3H_8, O_2, and C_3H_6 by surface coverages θ. $R(C_3H_6)$ represents the rate of the second cycle.

n_{app}	$R(C_3H_8)$	$R(O_2)$	$R(C_3H_6)$
C_3H_8	$\theta_{ZO} + \theta_{Z'}$	$\theta_{ZO} + \theta_{Z'}$	no influence
H_2O	$\theta_{Z'}$	$\theta_{Z'} + \theta_{XO}$	θ_{XO}
O_2	θ_Z	$\theta_Z + \theta_X - \theta_{XOH2O}$	$\theta_X - \theta_{XOH2O}$
C_3H_6	no influence	$\theta_{XH2O} + \theta_{OXH2O}$	$\theta_{XH2O} + \theta_{OXH2O}$

4 Conclusions

The mechanism in Fig. 1 represents a two-route mechanism on two sites of different nature for understanding kinetic features of selective oxidation of propane to acrylic acid over a MoVTeNb M1 oxide catalyst, potentially carrying multiple active centres.[2] Water activates as a buffer the catalytic centre for propane consumption. In the propene consumption route, oxygen is both a participant and a 'poison', which reduces the number of active centres probably in combination with water.

Keywords: carbon monoxide, low-temperature oxidation, SiC, nanodiamond, TiC, TiN

1 Introduction

Catalytic systems working efficiently at low concentration of CO at room temperature are to be used in devices for air purification from carbon monoxide (CO) in homes and offices. It was found [1-4] that , the use of nanodiamond (ND) and nanosized silicon carbide (SiC) supports for platinum metals allows the development of catalysts for oxidation of CO, which can operate efficiently at low concentration of carbon monoxide at room temperature.

2 Experimental/methodology

We synthesized CO catalysts based on nanosized supports (titanium nitride, titanium carbide, titanium carbonitride and titanium dioxide) including platinum and/or palladium clusters. Catalytic oxidation of CO was studied at room temperature at low concentration (less than 200 ppm) characteristic of homes and offices. TiN, TiC and TiC_xN_y particles of 10 ÷ 60 nm size prepared by us by plasma chemical method and industrial titanium dioxide crystallites of 5-9 nm size were used as supports. The CO catalyst was synthesized using the procedure described in [1-3].

3 Results and discussion

The clusters (Pt, Pd) are specified by high quantity of surface atoms and, hence, high catalytic activity in the reaction of CO oxidation at low concentration. The catalysts showed high catalytic activity in the reaction of oxidation of CO at room temperature.

4 Conclusions

New nanomaterial based CO catalysts can possibly be used in catalytic and photocatalytic systems for air purification from toxic gases in homes and offices.

Gold Supported on Fe-Doped Ceria Supports Prepared through the Microemulsion Method for the PROX Reaction

Laguna O.H.[1*], Centeno M.A.[1], Boutonnet M.[2], Odriozola J.A.[1]

1 - Instituto de Ciencia de Materiales de Sevilla, Seville, Spain
2 - Royal Institute of Technology (KTH), Department of Chemical Technology, Div. of Chemical Technology, Stockholm, Sweden

* ohlaguna@icmse.csic.es

Keywords: water-in-oil microemulsion, Fe-doped ceria, oxygen vacancies, gold catalyst, PROX, CO oxidation

1 Introduction

The purification of H_2 produced by reforming of organic molecules is required for the feed of PEMFC that present a low tolerance to CO (< 50 ppm). Such purification is carried out in different steps but the final levels are achieved in units of CO selective oxidation under the presence of H_2. In this sense, active and selective catalysts able to oxidize CO without H_2 consumption are required. Gold-based catalysts have been widely employed in oxidation reactions [1]. Similarly, reducible oxides such as CeO_2 have demonstrated an acceptable performance in the CO oxidation reaction due to their oxygen mobility and oxygen storage capacity. The modification of the CeO_2 framework with heteroatoms like Fe significantly improves the oxygen mobility of the ceria through the creation of oxygen vacancies [1].

Considering the described scenario, the present work proposes the synthesis of gold catalysts combining the ability of adsorbing and dissociating CO of this noble metal, and the oxygen mobility of the Fe-doped ceria systems for supplying structural oxygen. The gold nanoparticles may cooperate with the modified supports for the enhancement of the activation of the O_2 and CO molecules during the oxidation reaction.

2 Experimental/methodology.

Fe-doped ceria systems (10, 25 and 50 Fe At.%) previously studied by us [2], were employed as supports. These solids were synthesized through the microemulsion method (N-octane 53 wt.%; cetyl trimethyl ammonium bromide 13 wt.%; 1-butanol 13 wt.%; aqueous phase 21 wt.%). For every system, two microemulsions were prepared. The first one containing the required amounts of cerium and iron nitrates dissolved in the aqueous phase, and the other microemulsion containing an excess of NH_3. After the mixture of both microemulsions, a precipitate was obtained and kept under stirring during 24 h. The precipitate was washed with a 50/50 vol.% methanol/chloroform mixture, then dried at 60 ºC for 24 h and finally calcined at 500 ºC for 2h. The gold catalysts were prepared by the deposition-precipitation method employing $HAuCl_4 \cdot 3H_2O$ as precursor for obtaining a 1 wt.% loading of gold . After gold deposition, the catalysts were calcined at 300 ºC for 2h. The obtained solids were characterized by means of XRF, N_2 adsorption/desorption isotherms, XRD, H_2-TPR, UV-Vis, Raman spectroscopy and XPS. The catalytic activity measurements were carried out in a fixed-bed reactor. Prior to the catalytic tests the solids (100 mg, particle size ϕ =100–200 μm) were activated with 30 ml/min of air for 1 h at 300 ºC. Then, the materials were submitted to a 100 ml/min of the mixture of reaction (CO = 2 vol.%; O_2 = 1 vol.%; H_2 = 50 vol.% and N_2 for balance). The products of reaction were followed by on-line gas chromatography in a Varian® CP-4900 instrument equipped with two modules (a Porapak® Q column in the first one and a Molecular Sieve 5A in the second one, and TCD detectors in both cases).

3 Results and discussion

The XRF results demonstrated that the obtained loadings of gold were similar to the intended values for the systems doped with 10 and 25 Fe At.%. Nevertheless, the AuCeFe50 solid exhibited a lower amount of loaded gold. No modification of the XRD diffraction lines of the supports was detected in the patterns of the gold samples.. In the case of the catalysts with 10 and 25 Fe At.%, no signals associated to the presence of gold phases were observed either. However the AuCeFe50 not only presented the segregation of crystalline α-Fe_2O_3, but also the (111) crystallographic plane of metallic gold was detected. The Raman signal associated to oxygen vacancies of the supports was vanished after the deposition of gold in all cases, demonstrating the capital role of these defects on the nucleation of gold deposits.

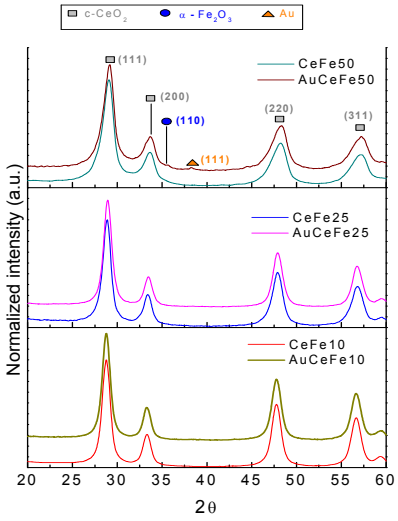

Figure 1. XRD patterns of the supports and the gold catalysts

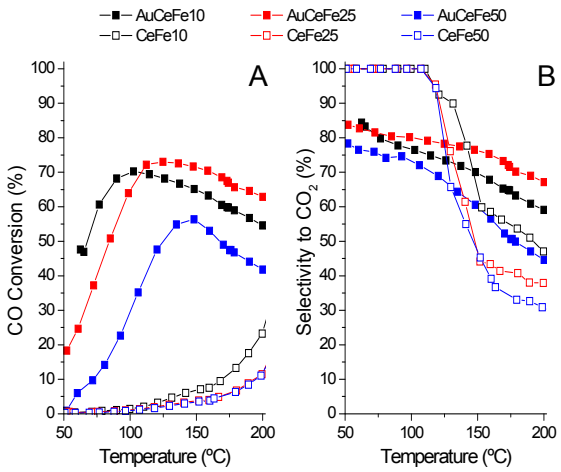

Figure 2. Catalytic activity of the supports and the gold catalysts: A) CO conversion; B) Selectivity to CO_2

The catalytic activity measurements showed a huge increment of the CO conversion at lower temperatures after the deposition of gold. This suggests the enhancement of the oxidation abilities of the catalysts. Considering that as higher the population of oxygen vacancies in the support is, higher the catalytic activity (at lower temperatures) of the corresponding catalyst, these punctual defects must be responsible of the easier activation of the O_2 and CO molecules for the oxidation reaction.

4 Conclusions

The oxygen vacancies population of the Fe-doped support strongly influences their interaction with gold. Higher the amount of oxygen vacancies higher the amount of gold deposited. Concerning the catalytic activity, the presence of noble metal greatly increases the CO conversion at lower temperatures of the Fe-doped supports in all cases. However, a superior catalytic activity is showed by the gold catalyst whose support presented the highest oxygen vacancies population.

Keywords: selective oxidation, ethanol, manganese, octahedral, molecular, sieve, silver, silica

1 Introduction

High activity of supported silver catalysts in selective oxidation of alcohols was shown in many studies [1, 2]. Catalytic activity of Ag-containing catalysts, in particular, Ag/SiO_2, may be increased by addition of transition metal oxides [3]. Manganese oxides are expected to be suitable modifiers for Ag/SiO_2 catalyst due to reversible Mn^{4+}/Mn^{3+} redox cycle. It is known that silver-containing cryptomelane-type manganese dioxide catalysts (Ag/OMS-2) have high activity and selectivity in oxidation of alcohols, in particular, octanol-1 and ethanol [4, 5]. However, oxidation of ethanol over OMS-2 catalysts is carried out using gas mixture containing low concentration of oxygen, generally 1-10 vol. % [5, 6] because of high activity of these catalysts in deep oxidation. One of the ways to control the redox, catalytic and acid-base properties of metal oxides is the use of different supports. The purpose of present research work is to design the method to prepare highly effective $Ag/OMS\text{-}2/SiO_2$ catalysts and investigate their catalytic properties in oxidative dehydrogenation of ethanol.

2 Experimental

To prepare Ag/OMS-2 catalysts two different methods were used. At first, OMS-2 sample was prepared by procedure described in [7], and then it was impregnated with water solution of $AgNO_3$ followed by calcination in air flow at 500 ^oC (Ag/OMS-2-I). In the co-precipitation method (CP) $AgNO_3$ was added in course of preparation of OMS-2. Nominal amount of Ag was 5 % wt. The $Ag/OMS\text{-}2/SiO_2$ catalysts were prepared by the sequential impregnation (SI) and co-precipitation (CP) methods. In the first method silica was impregnated with appropriate quantity of $KMnO_4$ solution and then dried at 60 ^oC. The obtained $KMnO_4/SiO_2$ sample was added into the acidified water solution of $Mn(NO_3)_2$ under stirring. After that the obtained mixture was heated in autoclave for 24 h, then the precipitate was filtered, washed and dried. The obtained $OMS\text{-}2/SiO_2$ sample was impregnated with water solution of $AgNO_3$ followed by calcination in air flow at 500 ^oC. According to the second method, $KMnO_4/SiO_2$ was added into the mixed solution of $Mn(NO_3)_2$ and $AgNO_3$. The catalysts were characterized by TPR-H_2, TPO, TPSR-C_2H_5OH, XRD, TEM, AES and N_2 adsorption at -196 ^oC. Catalytic activity of the samples in ethanol oxidation was tested in a flow fixed-bed reactor at atmospheric pressure using 0.5 g of catalyst. Gas mixture containing 2 %vol. C_2H_5OH and 18 vol. % O_2 in He was passed through reactor at total flow rate of 60 cm^3/min. The effluents from the reactor were analyzed by on-line gas chromatography. Prior to catalytic experiment the catalysts were treated in 8 % O_2/He at 500 ^oC for 1 h.

3 Results and discussion

Investigation of chemical composition of the prepared catalysts revealed that using of co-precipitation method (CP) resulted in partial loss of Ag due to leaching of silver in course of hydrothermal treatment.

The OMS-2, Ag/OMS-2-I and Ag/OMS-2-CP catalysts were used as model systems for detailed characterization of supported catalysts. To investigate the effect of silver addition on the active sites of OMS-2 TPSR of adsorbed ethyl alcohol were carried out. Formation of water was observed for all catalysts at 80 °C in course of ethanol adsorption in pulse mode, therefore adsorption and dehydration of ethanol occurred on the acid sites. The quantity of adsorbed alcohol was 221, 172 and 142 μmol/g for OMS-2, Ag/OMS-2-CP and Ag/OMS-2-I catalysts, respectively. Carbon dioxide was the main product of TPSR and released at 170 and 230 °C.
Investigation of catalytic activity of prepared OMS-2/SiO_2, Ag/OMS-2/SiO_2-SI and Ag/OMS-2/SiO_2-CP catalysts in oxidative dehydrogenation revealed that addition of silver results in increasing of the ethanol conversion. This may be explained by increasing of reaction ability of surface oxygen in the presence of silver, which was confirmed by TPR-H_2. The effect of silver content and Mn/Ag molar ratio on the catalytic properties was investigated. It was stated that silver content insignificantly effect on the ethanol conversion. However, selectivity towards acetaldehyde depends on silver content. For Ag/OMS-2/SiO_2-CP catalyst the selectivity towards acetaldehyde at temperatures above 200 °C is lower in comparison with the one for Ag/OMS-2/SiO_2-SI due to low silver content (higher molar ratio Mn/Ag) or formation of mixed Ag-Mn phase in course of synthesis via co-precipitation.

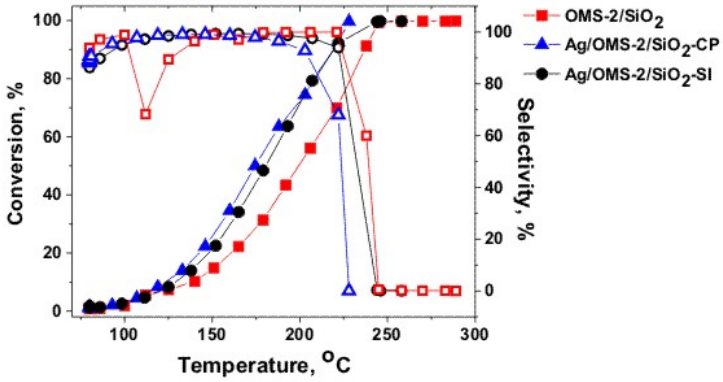

Fig. 1. Catalytic properties of OMS-2/SiO_2, Ag/OMS-2/SiO_2-SI and Ag/OMS-2/SiO_2-CP

Generally, deep oxidation activity of Ag-containing supported catalysts is higher than the one for OMS-2/SiO_2, which may be associated with increasing of reoxidation ability in presence of silver (according to TPO data).

4 Conclusions

The Ag/OMS-2/SiO_2 and OMS-2/SiO_2 catalysts were synthesized and tested in ethanol oxidation. It was stated that silver addition increases the reducibility and reoxidation ability of OMS-2, as a consequence catalytic activity increases. Catalytic properties of Ag/OMS-2/SiO_2 catalysts may be controlled by variation of Mn/Ag molar ratio and preparation method.

A Heterogeneous Single-Site Organocatalyst for Alkene Epoxidation

Tyablikov I.A., Romanovsky B.V.*

Department of Chemistry, Lomonosov Moscow State University, Moscow, Russia

* igortabl3@gmail.com

Keywords: heterogeneous organocatalyst, SBA-15, mesoporous, silica, alkene epoxidation

1 Introduction

Organocatalysis is one of the most challenging goals in modern catalytic chemistry. Many key organic reactions such as aldol condensation, Mannich reaction, numerous cycloadditions, and other were shown to be carried out in homogeneous metal-free conditions using organocatalysts [1]. On the other hand, in the literature there are some excellent examples of solid catalysts with immobilized organocatalytic centers [2], which show the activity quite analog to homogeneous ones, so as to realize the well-known concept of single-site catalytic materials. These catalysts are evident to be of both academic and industrial interest. 2.2.2-trifluoroacetophenone (TFAP) [3] is proven to be an effective organocatalyst for selective epoxidation of alkenes with hydrogen peroxide under room temperature conditions.

Given that, in this work we aimed to develop catalyst with immobilized TFAP organocatalyst for the epoxidation of alkenes.

2 Experimental/methodology

Heterogeneous epoxidation catalyst based on TFAP was synthesized by three-step assembling procedure. First step was a synthesis of the SBA-15 support according to the method reported in [4]. Second step was the modification of SBA-15 via interaction of silanol groups with trimethoxyphenylsilane in toluene under refluxe using hydrochloric acid as a catalyst. Finally, the acylation of surface anchored phenyl groups with trifluoroacetic anhydride in the presence of aluminum chloride was performed.

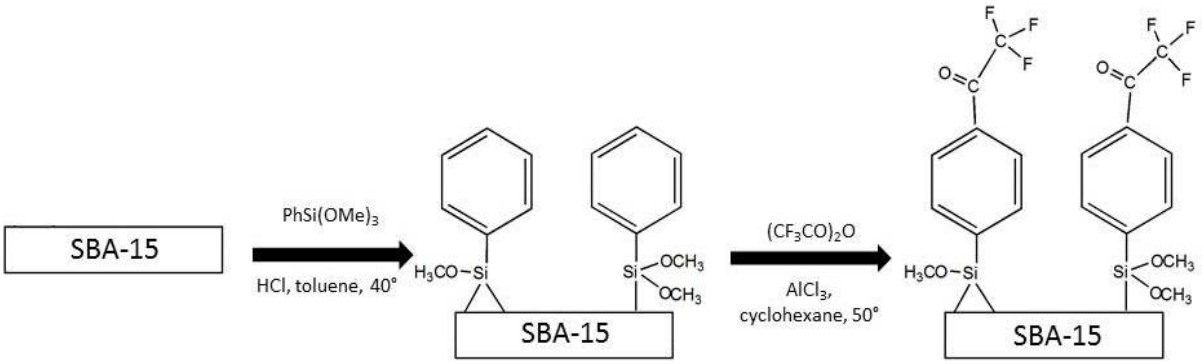

Fig. 1. Synthetic route to produce heterogeneous TFAP catalyst

Obtained samples were characterized by nitrogen adsorption-desorption measurements, UV-Vis and NMR spectroscopy. Liquid-phase epoxidation of propene substrate was performed in a batch reactor at 25 °C and 9 MPa using 28% hydrogene peroxide as an oxidant, acetonitrile as a sacrificing agent and *tert*-butanol as a solvent.

3 Results and discussion

Nitrogen adsorption measurements for both as-synthesized SBA-15 support and material modified by phenylation and then acylation showed the noticeable decrease of surface area and mean pore size which suggests the anchoring of TFAP catalytic species to the pore walls. The TFAP surface centers were successfully quantified by using ^{19}F NMR technique. The catalytic tests showed that the heterogeneous organocatalyst exhibits selectivity of propene conversion into propylene oxide of 100% with peroxide efficiency of 20%. What is the most important, this hybrid catalyst prepared by such a way could be easily separated from the reaction media by filtration and reused without any loss in activity.

4 Conclusions

The hybrid catalyst prepared by surface assembling of 2.2.2-trifluoroacetophenone molecules from their constituents using SBA-15 mesoporous silica as a support allows, for propene epoxidation with H_2O_2 at ambient temperature, to produce propylene oxide with selectivity of 100% and peroxide efficiency of 20%.

Selective Photo-Oxidation of α-pinene with Dioxo-Mo(VI) Complex /TiO_2 with Different Textural Properties

Martínez H.*, Páez E.A., Martínez F.

Cicat, Escuela de Química, UIS, Bucaramanga, Colombia

* hmartinezquinonez@gmail.com

Keywords: dioxoMo complex titania, nanotubes, surface, functionalization, selective photo-oxidation

1 Introduction

Dioxomolybdenum complexes anchored on TiO_2 are active on the selective photo-oxidation of hydrocarbons with O_2, but the concentration of the Mo complex tend to be low, affecting its activity [1,2]. Anchoring is carried out through on the surface hydroxyl groups. The amount of Mo complex depends on the concentration and accessibility of the OH groups. The concentration, distribution and accessibility of OH groups influence the chemical reactivity of the support [1] which depends on the preparation method. In the present work the photo-assisted oxygen transfer to α-pinene with O_2 with dioxo-dichloro-(4,4'-dicarboxylic acid-2,2'-bipyridine) Mo (IV) anchored on TiO_2: a- commercial Degussa P-25, b- Aldrich nanopowder and c- synthetized TiO_2 nanotubes (with different textural properties and different amounts of hydroxyl groups on the surface) was evaluated.

2 Experimental/methodology

TiO_2 nanotubes were synthesized by the hydrothermal method [3]. A solution of hexamethyldisilazane (HMDS) (Aldrich) in toluene (40 mL) was added to TiO_2 (1g), previously dehydrated. The mixture was stirred under N_2 flow for 24 hours. The amount of functionalized OH groups was determined collecting the released NH_3 on a solution of 2% H_3BO_3 and titrated (0.1N HCl). The nature of the OH groups (bridge, isolated and germinal) was observed by IR-PAS: the TiO_2 samples were heated (100 °C for 48 h) and stored under vacuum before taking the spectra. The amount of OH groups was determined by TGA: the TiO_2 samples were heated under N_2 from 25 °C to 120 °C at 10 °C/min, maintaining 120º during 10 min (adsorbed H_2O elimination), and then heated at 20 °C/min, from 120 º to 500 °C (OH elimination).
Silylated TiO_2 samples were suspended in toluene then a solution of 2,2'-bipyridine-4,4'-dicarboxylic acid was added. A toluene solution MoO_2Cl_2 was added to a toluene suspension of the previously obtained solid. α-pinene epoxidation was carried out in a 15-mL batch microreactor (Hg lamp, λ= 360 nm) at 19 °C in oxygen. α-pinene (10^{-2} M) in CH_3CN was thoroughly deoxygenated by bubbling N_2 before the addition of the catalyst (15 mg).

3 Results and discussion

TiO_2 textural properties were determined by N_2 adsorption-desorption and the surface OH density on TiO_2 was evaluated by HMDS titulation, IR and TGA (see Table 1).

Table 1. Textural properties and density of surface OH groups of the TiO_2 supports

TiO_2 Support	S BET (m^2g^{-1})	Total OH's/nm^2 [a*]	Reactive OH's/nm^2 [b*]	DioxoMo (mmol g^{-1})[a]
Degussa P-25	50	5,4	4,8	0,15
nanopowder	200	27,5	22,8	0,72
Nanotubular	330	31,6	26,3	0,81

[a] Calculated by TGA [b] Calculated by NH_3 titulation in HMDS sililation. [*] Average value of three measurements (+ 0,1)

Functionalization degree of the OH groups was followed by IR-spectroscopy PAS. The intensity of signals at 3555, 3745 and 3750 cm^{-1} are associated with the Ti-OH groups with a hydrogen type interactions, -OH isolated and geminal groups $Ti(OH)_2$ respectively [4] (see fig. 1-a,b), and confirm that the increase in surface area, like as it observed in the nanopowder and nanotubes samples leads to an increase in the number of hydroxyl groups prone to functionalize. This same intensity ratio is maintained in the subsequent steps of silylation and functionalization (fig. 1-c, d), that confirming that nanotubular TiO_2 (with a greater number of -OH susceptible to functionalize) has the highest amount of complex anchored.

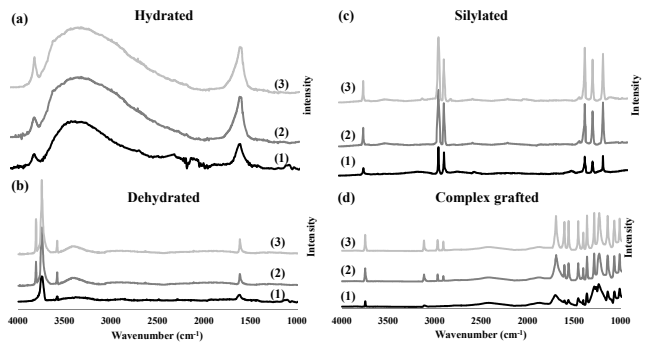

Fig. 1. IR-PAS TiO_2 monitoring (1)- P25, (2)-Aldrich nanopowder, (3)-nanotubes.

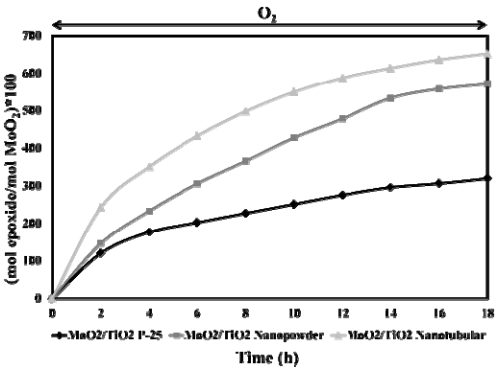

Fig. 2. Oxide α-pinene formation under molecular oxygen with various MoO_2/TiO_2

Figure 2 shows oxide α-pinene formation in the presence of the different dioxo-molybdenum(VI)/TiO_2 catalysts. It appears that there is a strong influence of hybrid MoO_2/TiO_2 catalysts on the α-pinene conversion. The MoO_2/TiO_2 nanotubes system is the most active with respect to the other catalysts based on the commercial TiO_2 (P-25) and Aldrich nanopowder supports. Such behavior could be related to an increased amount of dioxo-Mo(VI) species grafted over the surface of the nanotubular TiO_2 (see Table 1). MoO_2/TiO_2 (nanotubular) shows the highest surface density of hydroxyl groups required for the anchoring of the Mo(VI) complex, and hence the highest content of dioxo-Mo(VI) complex covalently anchored.

4 Conclusions

Dioxo-Mo(VI)-dichloro[4,4'-dicarboxylate-2,2'-bipyridine] complex anchored on various TiO_2 is active, selective and stable for the photo-assisted epoxidation of α-pinene. The textural properties of the TiO_2 support and the density of surface hydroxyl groups have a strong impact on the amount of the Mo complex grafted on the surface and hence on the catalytic properties.

Study on Kinetics of Liquid Phase Photocatalytic Oxidation of Dibutyl Sulfide over Fullerenes

Arsentyev A.V.[1,2*], Vorontsov A.V.[1,2]

1 - Novosibirsk State University, Novosibirsk, Russia,
2 - Boreskov Institute of Catalysis SB RAS, Novosibirsk, Russia

* alexars.92@mail.ru

Keywords: photocatalysis, C70, C60, visible light, selectivity

1 Introduction

Fullerenes represent a relatively new allotropic modification of carbon that was discovered in 1985 by Kroto et al. after vaporization of carbon species from the surface of a solid disk of graphite using a focused pulsed laser [1]. The discovery made a revolution in molecular design and it leads to obtaining other novel structures such as graphene and carbon nanotubes. Afterwards photochemical reactivity of fullerene was proved: quantum yield of singlet oxygen production in toluene solution of fullerene C_{60} is almost 100% [2]. Photoexcited fullerene transfers electron leading to generation reduced oxygen species ($O_2^{-\bullet}$ and $^{\bullet}OH$) [3]. Information on photocatalytic activity of fullerenes is available in the literature. However, kinetic studies were never undertaken. In the present work, the influence of several parameters on the rate and selectivity of dibutyl sulfide (DBS) photooxidation on C_{70} is investigated.

2 Experimental/methodology

Fullerene C_{70} (99%, Aldrich), dibutil sulfide (96%, Aldrich), toluene (99.5%, Reachim) were used in the experiments. Solution of fullerene C_{70} in toluene was prepared with necessary concentration and after addition of DBS was irradiated with visible LED lamp (10 W) in a batch reactor under continuous stirring and air bubbling. Naphthalene was used as internal standard. Spectral effects of light were studied using cut-off filters. Spectrum of light was measured with spectroradiometer ILT950. Products were identified with GC-MS (CP-3800 + Saturn 2000). Quantitative analyses of reaction mixture were carried on with gas chromatography (Hewlett Packard 5890, capillary column CP-Sil 8 CB and flame ionization detector).

3 Results and discussion

With the help of GC-MS we found that the major products of photooxidation of DBS (Bu_2S) are dibutil sulfoxide Bu_2SO, dibutil sulfone Bu_2SO_2, and dibutil disulfide Bu_2S_2.

The influence of spectral composition of irradiating light is illustrated in Fig. 1 and 2. Filters were selected to study the influence of wavelength on activity of fullerene C_{70}. Linear dependence of DBS consumption rate on photon flux with various wavelengths indicates that fullerene C_{70} has an equal activity in whole visible light range (Fig. 2). However, selectivity to products changed and dibutyl sulfone Bu_2SO_2 appears to form in larger quantities in reaction at lower irradiance (Fig. 1). Generation of dibutyl sulphide Bu_2S_2 is accelerated at higher irradiance.

In another experiment irradiation intensity was varied. It was shown that selectivity of oxidation depends on irradiation intensity. The ratio Bu_2SO:Bu_2SO_2 decreases when the intensity decreases. So it is possible to control selectivity for this reaction by changing light intensity. The influence of reagent Bu_2S and fullerene C_{70} concentration was also studied. Both experiments showed quite weak dependence of rate and selectivity of reaction in a wide range of parameters varied.

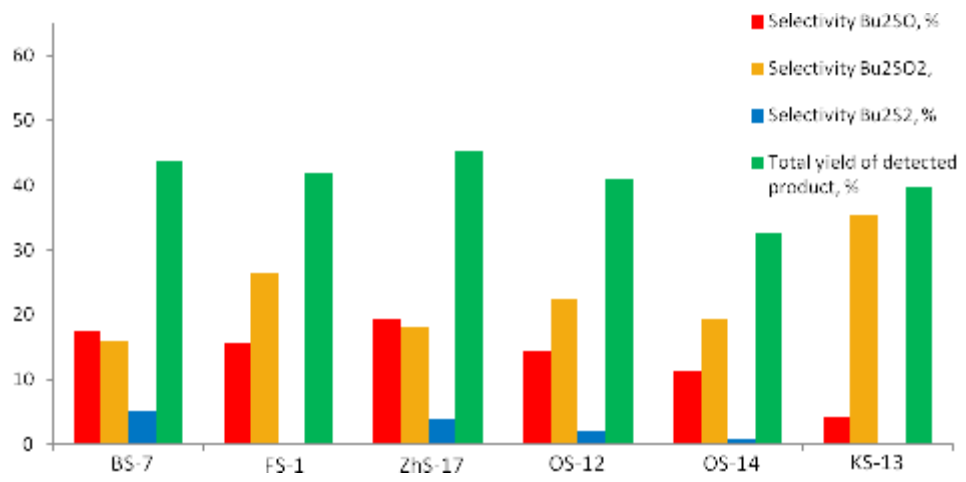

Fig. 1. Comparison of Bu_2S oxidation selectivity on fullerene C_{70} after 18 min of irradiation.

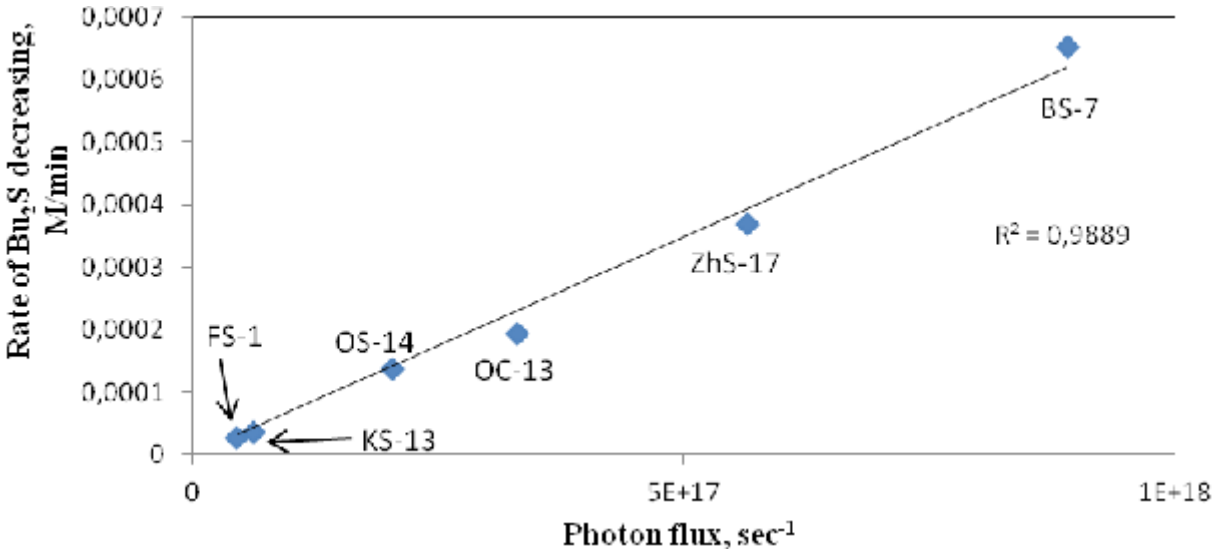

Fig. 2. Correlation between rate of reaction and photon flux; different filters were used as marked.

3 Conclusions

The kinetics of organic sulphide Bu_2S photooxidation with fullerene C_{70} as catalyst was studied under visible light. Intensity of irradiation affects on the rate and selectivity. Fullerene C_{70} has equal activity in whole visible light range.

Keywords: oxidation, L-sorbose, ascorbic, acid nanoparticles, hypercross-linked polystyrene

1 Introduction

The oxidation of monosaccharides is of great scientific and practical importance because compounds containing carboxyl groups are intermediates for several valuable fine chemicals such as pharmaceuticals and biologically active substances.

The oxidation reactions are often carried out with expensive and toxic stoichiometric oxidants. This way offers a direct route to the target products; however, the reaction frequently affords non negligible amounts of the side-products and requires additional purification as well as neutralization of the waste. The principles of "green" chemistry are based on the respect for the environment, therefore the task is to develop catalysts which should be easily removed from the reaction medium and reused with high efficiency. It is known that supported transition metal nanoparticles are highly active as heterogeneous catalysts in alcohols and monosaccharides oxidation with molecular oxygen or air [1-3]. Hypercross-linked polystyrene was chosen for the present study. Such structure combines both micropores and macropores and can be considered for regulated nanoparticle growth. This research focuses on the oxidation process of L-sorbose with synthesis of commercially interesting target product 2-keto-L-gulonic acid (ascorbic acid production).

2 Experimental/methodology

The monometallic and bimetallic nanosized catalysts were synthesized by the sorption of the precursors ($H_2PtCl_6 \cdot 6H_2O$, $Pd(CH_3COO)_2$, $HAuCl_4 \cdot 2H_2O$) from THF in the hypercross-linked polystyrene (HPS) matrix. In case of Pt-Au catalyst it was followed by sodium bicarbonate treatment for the precipitation of metal oxides.

The experimental set-up for oxidation at atmospheric pressure was a four necked glass flask (total volume 100 ml) for feeding the catalyst, the solvent, the reactant and cooling with a condenser. The constant heating was organized with a thermostat. Stirring speed during the reaction was 1000 rpm and furthermore, the catalyst particle size below 0.71 μm was used in order to perform the processes under kinetic regime. Evaluation of catalytic properties in L-sorbose oxidation was done with mass of 1 g of the reactant and the catalyst in 10 ml of water with adding NaOH as alkaline agent at 70°C.

The identification of the reaction mixture composition was performed with a mass spectrometer – gas chromatograph. The column used was Reprogel-H, Dr. Maicsh Gmbh, Germany, 500 mm × 8 mm.

3 Results and discussion

The next nanostructured catalytic systems (as the carrier and stabilizer HPS was used) were synthesized: 1%Pd/ HPS, 1%Pd-0.3%Pt/ HPS, 1%Pd-1%Pt/ HPS, 3%Pt/ HPS, 3%Pt –2%Au/ HPS. Selectivity to 2-keto-L-gulonic acid and conversion of L-sorbose after 6 h for tested

catalysts are given in Table 1.

Table 1. Selectivity to 2-keto-L-gulonic acid and conversion after 6 h.

Catalyst	Selectivity	Conversion
1%Pd/ HPS	8	21
1%Pd-0.3%Pt/ HPS	11	38
1%Pd-1%Pt/ HPS	10	44
3%Pt/ HPS	46	31
3%Pt –2%Au/ HPS	41	88

The most active catalyst was 3%Pt –2%Au/ HPS, showing the selectivity of 41% at conversion of 88% after 6 hours of the reaction. It is seen from the graph (Fig.1) that the selectivity to the target product 2-keto-L-gulonic acid increases with increasing conversion, and the selectivity to the side-product 5-keto-D-glukonic acid goes through the maximum and after it gives new products of overoxidation.

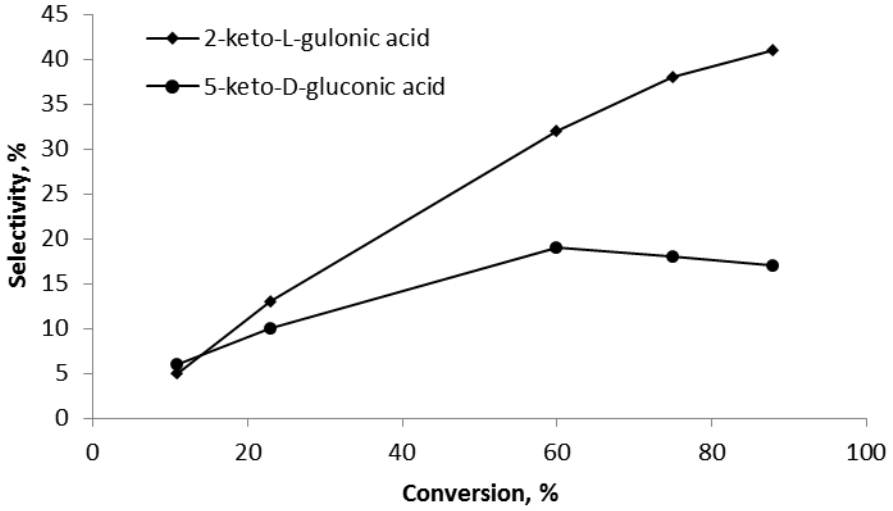

Fig. 1. Selectivity to 2-keto-L-gulonic acid (target product) and 5-keto-D-glukonic acid (side-product) as a function of conversion

Increasing the experiment time to 8 hours selectivity decreases as the target product is overoxidized and gives new side-products.

4 Conclusions

The unique features of HPS facilitate incorporation of various compounds into the nanostructured HPS matrix and, thus, nanoparticle formation. Such hybrid materials give the opportunity to prevent the agglomeration of nanoparticles and do not require ligands for stabilizing, that makes nanoparticles more active in catalytic processes. It can be stated that in this limited experimental series the highest selectivity achieved for the target compound, 2-keto-L-gulonic acid was 41 % at 88 % of L-sorbose conversion over 3%Pt –2%Au/ HPS in water with NaOH as alkaline agent at 70°C. The reaction network is complex and further studies are required to optimize the formation of the target product.

Keywords: propylene glycol, metal-organic framework, selective oxidation, hydroxyacetone

1 Introduction

Oxidation of alcohols to corresponding carbonyl compounds plays a key role in organic synthesis. In particular, the selective oxidation of vicinal diols is a challenging goal because these compounds are prone to C-C fission. Traditional methods for such transformations are based on the use of inorganic oxidants, e.g., chromium (VI) reagents. However, from both economic and environmental viewpoints, there is a growing demand for atom efficient catalytic methods employing environmentally benign oxidants [1].

Conversion of biomass-derived feedstocks to valuable products remains a formidable challenge. Propylene glycol (PG) can be produced from glycerol, which is a low-cost by-product in transesterification of triglycerides for biodiesel production [2]. A number of valuable products that find application in the production of fine chemicals and pharmaceutics can be obtained through oxidation of PG. Generally, PG is oxidized to methyl glyoxal in the gas phase [3]. However, thus far, publications in the field of catalytic liquid phase oxidation of propylene glycol are scarce.

Metal-organic frameworks (MOFs) have attracted great attention as heterogeneous catalysts thanks to a unique combination of properties, such as crystalline open structures, extremely high surface areas, tunable pore size and functionality, and large fraction of accessible metal centers [4]. In this work, we explored the potential of the chromium terephthalate Cr-MIL-101 in the selective oxidation of PG using *tert*-butyl hydroperoxide (TBHP) as oxidant. The effects of reaction conditions (temperature, concentrations, solvent nature) on this reaction were evaluated.

2 Experimental/methodology

Cr-MIL-101 was prepared according to the literature [5] and activated in vacuum prior to use. Catalytic oxidations were carried out in thermostated glass vessels at 40-70 °C under vigorous stirring (500 rpm). Typically, the reaction was initiated by the addition of TBHP (0.125 or 0.25 mmol) to a mixture containing PG (0.5 mmol), 1 ml of solvent (methanol, ethyl acetate or acetonitrile) and 3 mg of the catalyst. Aliquots of the reaction mixture were withdrawn periodically by a syringe through a septum and analyzed by GC (30 m ZB-WAX capillary column) using chlorobenzene as internal standard. Methyl glyoxal and formaldehyde were determined as ortho-phenylenediamine derivatives.

3 Results and discussion

The oxidation of PG over MIL-101 with TBHP leads to hydroxyacetone (HA) as the main product (Figure 1). Products derived from the oxidative cleavage of C-C bond (acetic acid and formaldehyde) were not detected. Moreover, HA overoxidation products, methyl glyoxal (MGO) and pyruvic acid, were not found. However, an experiment with MGO as substrate

demonstrated an unexpectedly high conversion (75 % versus 25 % theoretically predicted), which allowed us to suggest that MGO could undergo non-oxidative transformations under the reaction conditions. The increase in temperature accelerated the PG oxidation process. At 40 °C, substrate conversion did not exceed 4 % after 8.5 h while at 50 and 70 °C it attained 18 % ([TBHP]/[PG] = 0.25). HA selectivity was practically unaffected by the reaction temperature in the range of 50-70 °C and remained at the level of 60 %. Thus the efficiency of the oxidant utilization was ca. 70 %. Similar results were obtained using acetonitrile and ethyl acetate as solvents whereas in methanol the reaction stopped in 2 h and produced only 5% conversion. In ethyl acetate, increasing TBHP/PG molar ratio from 0.25 to 0.5 allowed enlargement of PG conversion up to 30 % but reduced HA selectivity from 60 to 30%. Nevertheless, no acetic acid and formaldehyde were detected. The mass balance between the reactants converted and products detected, especially for enhanced TBHP/PG molar ratio, was not complete. One of possible reasons for that could be non-oxidative transformations of the oxidation products (for example, MGO). Further work is in progress to clarify this matter.

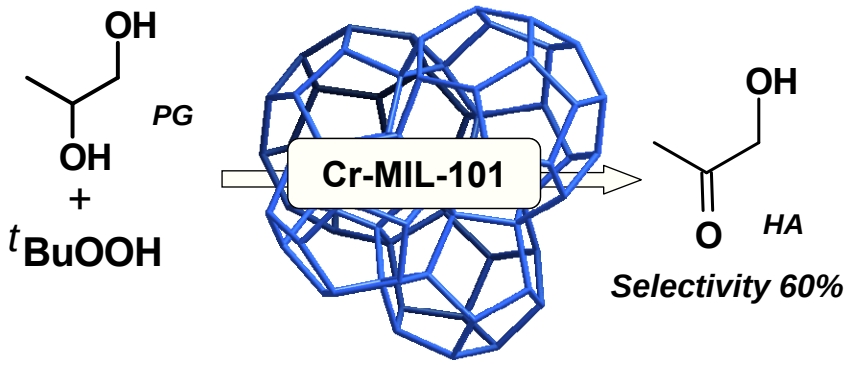

Figure 1. PG oxidation with TBHP over MIL-101

4 Conclusion

Hydroxyacetone was shown to be the predominant product of PG oxidation with TBHP over Cr-MIL-101 under mild conditions (50-70 °C). C-C cleavage, which is typical of PG oxidation [2], did not take place in the catalytic system studied.

Influence of Pre-Treatment on the Oxidative Coupling of Methane over MgO Catalysts

Schwach P., Tarasov A., Willinger M., Schlögl R., Trunschke A.*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin, Germany

* trunschke@fhi-berlin.mpg.de

Keywords: OCM, MgO, methane activation

1 Introduction

The functionalization of methane remains a challenging target from an academic as well as an industrial point of view. New concepts for the catalytic activation of C-H bonds in oxidation reactions are needed to overcome the current limitations in selectivity, which hamper broad utilization of, for example, the oxidative coupling of methane (OCM) for production of olefins from natural gas.

In a previous work on OCM over model MgO catalysts [1, 2], we found that the initial performance of freshly calcined MgO is governed by a surface-mediated coupling mechanism involving direct electron transfer between methane and oxygen. The abundance of structural defects, in particular mono-atomic steps and Lewis acid/base pairs, correlate with the initial rates of both methane consumption and C_{2+} hydrocarbon formation. During time on stream MgO sinters and loses activity in the steam-containing atmosphere at the high reaction temperatures of OCM. The deactivation process involves the depletion of mono-atomic steps and the reconstruction of the MgO termination under formation of polar and faceted surfaces.

In this work, the impact of pre-treatment of MgO with N_2, CO_2, O_2, H_2 and H_2O on the reactivity of the resulting catalysts in OCM is studied. CO_2, O_2, H_2 or H_2O are either reactive gases or formed during the OCM reaction. Analysis of their influence on the catalyst is of main importance to understand the deactivation mechanism in OCM over alkaline earth oxides and to develop alternative strategies and stabilization concepts.

2 Experimental/methodology

Magnesium oxide (Puratronic®, 99.998 % m. b., Alfa Aesar) served as model catalyst in this work. Prior to catalytic testing, the catalyst was treated in the reactor in 20 % O_2, CO_2, H_2 or H_2O in N_2 or in pure N_2 feed for 1 hour at reaction temperature (1023 K) before switching to the feed (90 mL·min^{-1}, $CH_4/O_2/N_2$=3/1/1). The first GC measurement was taken less than 2 minutes after switching.

Changes of the MgO surfaces due to pre-treatment were characterized by IR spectroscopy of adsorbed probe molecules (CO and CH_4), electron microscopy, UV-vis spectroscopy, and thermal gravimetric (TG) analysis. Paramagnetic defects were studied by EPR spectroscopy.

Figure 1 **Results and discussion**

Figure 1 shows the influence of the pre-treatment of MgO with N_2, CO_2, O_2, H_2 or H_2O on the yield of C_{2+} hydrocarbons and on the C_2H_4/C_2H_6 ratio in the product mixture. The catalysts pre-treated in N_2, CO_2, and O_2 show almost no difference. Treatment in N_2 or vacuum is used as reference in this work. Comparison between O_2 and N_2 treatment indicates that the partial pressure of oxygen has no significant effect in the range of the chosen conditions. CO_2 has been considered as a poison in the OCM reaction over Li/MgO [3], however, over pure MgO, CO_2 has no effect. This is in agreement with the fact that $Mg(CO_3)_2$ decomposes at a temperature below the reaction temperature.

Pre-treatment with H_2O considerably lowers the C_{2+} yield as well as the C_2H_4/C_2H_6 ratio. In the presence of steam, the MgO primary particle sinter and the active sites responsible for high methane conversion and high selectivity (i.e. mono-atomic steps), vanish at the same time. These results directly proof the detrimental effect of steam on OCM activity over MgO and explain self-poisening of MgO in OCM by the unavoidable reaction product water. Pre-treatment of MgO with steam at 1023 K can be used as accelerated procedure in deactivation studies, since few hours pre-treatment results in a similar low activity as 300 hours time on stream in OCM. After 48 hours treatment in steam at 1023 K, bulk paramagnetic defects have been observed by EPR spectroscopy. The defects are most-likely V^{-}like centers formed due to the incorporation of OH-groups in the MgO matrix [4].

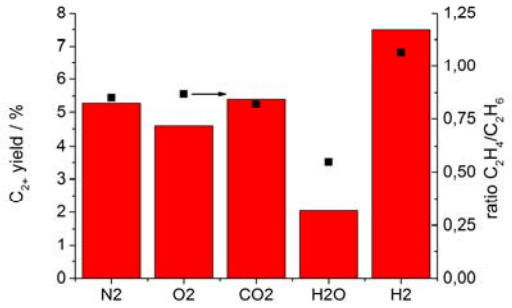

Fig. 1 Influence of pre-treatment in the OCM at T=1023 K, $CH_4/O_2/N_2$=3/1/1, W/F= 0.033 g·s·ml^{-1}

Surprisingly, pre-treatment in H_2 improves the performance in the OCM reaction in terms of C_{2+} yield. The C_2H_4/C_2H_6 and CO_2/CO ratios are also affected. IR spectroscopy of adsorbed CH_4 provides an explanation. The amount of adsorbed CH_4 increases on MgO treated by H_2 by a factor of 3 in comparison to MgO treated in vacuum. This indicates that H_2 treatment considerably increases the amount of active sites. To understand the effect of hydrogen better, H_2 pulsed TG experiments have been performed. Since MgO is an irreducible oxide, mass losses observed upon H_2-pulses at 1023 K indicate a restructuration of the MgO surface.

4 Conclusions

The pre-treatment of a nanostructured MgO catalyst with N_2, CO_2, O_2, H_2 and H_2O and the analysis of the changes in reactivity helped to interpret the deactivation mechanism of MgO in OCM [1, 2]. CO_2 and O_2, have no (or minor) effects on the OCM reactivity. H_2O has a detrimental influence due to sintering of the primary particles, while H_2 pre-treatment increases the concentration of active sites for CH_4 adsorption and activation.

New Insights in the Catalytic Oxidation of Levulinic Acid to Succinic Acid

Podolean I., Papuc B., Parvulescu V.I., Coman S.M.*

University of Bucharest, Faculty of Chemistry, Bucharest, Romania

* simona.coman@g.unibuc.ro

Keywords: ruthenium, magnetic nanoparticles, oxidation, levulinic acid, glucose, succinic acid

1 Introduction

Nowadays, due to the increasing environmental concerns, many efforts have been made to develop oxidation systems using environmentally-benign molecular oxygen as a sole oxidant. In this respect, Ru-based oxidation catalysis was rapidly developed being envisaged to play a major role in the renewable sources capitalization [1]. On the other hand, magnetic materials have attracted special attention because the magnetic properties make possible the complete recovery of the catalyst by means of an external magnetic field [2].

Based on the present state-of-the art and our interest in biomass capitalization to value-added chemicals, not long ago we developed a Ru(III)/functionalized silica-coated magnetic nanoparticles catalyst which was proven to be highly active, selective and easily recoverable catalyst for the oxidation of levulinic acid (LA) to succinic acid (SA) under green conditions [3]. Encouraged by these initially promising results, here we report the optimization of the former MNP-NH_2/Ru^{III} catalyst in order to further improve its catalytic performances in the LA oxidation to SA. In this scope the loading of the ruthenium species was varied (1-5wt.%) keeping constant the content of $–NH_2$ linker moieties. To extent the catalyst utility, LA was replaced with glucose as raw material.

2 Experimental/methodology

The catalysts were prepared in several steps, involving: a) the magnetite synthesis; b) its coating with silica, c) APTES functionalisation by silanisation, and d) ruthenium deposition by wet impregnation. The obtained catalysts were characterized by XRD, Mossbauer spectroscopy, magnetic measurements, EXAFS, DLS and DRIFT spectroscopy and tested in the LA oxidation using molecular oxygen as oxidation agent.

3 Results and discussion

The characterization of the former MNP-NH_2/Ru^{III} catalyst and correlation with catalytic performances indicated a certain cooperation of the acid/base sites as responsible for the LA oxidation to SA. For the new synthesised catalytic systems the base co-catalyst seem to be successfully supplied by the free $–NH_2$ moieties, while the acidity was ensured by the existing $Ru(OH)_xCl_{3-x}$ and $[Ru(H_2O)_5OH]^{2+}$ species [3] docked through hydrochloride -C-$NH_3^+Cl^-$ species on the surface of the magnetic nanoparticles. An additional variation of the NH_2/Ru atomic ratio can be made when the content in -NH_2 moieties is kept at the same level but the loading of ruthenium is varied. Therefore, catalysts with 1, 3 and 5% Ru were prepared and tested in the LA oxidation to SA (Figure 1). As Figure 1 shows, the concentration of ruthenium influences not only the catalytic activity but also the selectivity to SA. The optimum of ruthenium loading seems to be 4wt.%, a higher amount leading to a strong degrease not only of the LA conversion but also of the SA selectivity. However, when we express the catalytic activity by TOF (moles of transformed LA/[moles of catalytic active phase x time]) or by TON (moles of transformed LA/moles of catalytic active phase) the most performing catalytic sample

seems to be, in fact the MNP-NH_2-Ru(1wt.%) sample (Figure 2). The obtained catalytic results suggest that an important feature of the highly active and selective catalysts is the high dispersion of catalytic active sites.

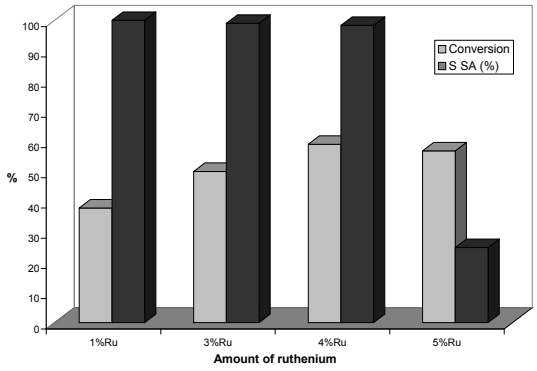

Fig. 1. The LA oxidation in the presence of MNP-NH_2/Ru^{III} with different amounts of ruthenium (180°C, 6h)

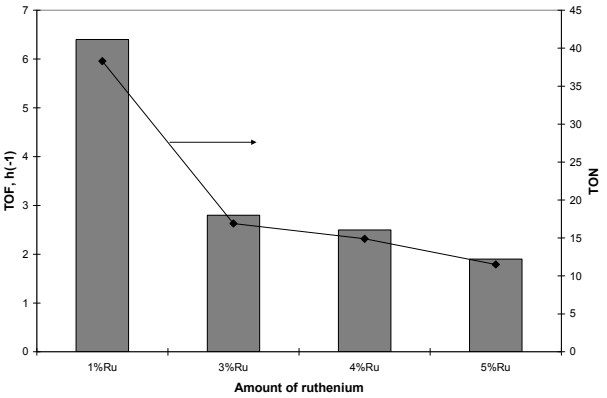

Fig. 2. The TOF and TON variation as a function of the ruthenium amount

As expected, the absence of intraparticle mass-transfer limitations and the improved Ru dispersion on silica-coated magnetite nanoparticles (MNP-NH_2/Ru^{III}) compared to the micrometer-sized commercial silica powder (SiO_2-NH_2/Ru^{III}) led to significant differences in the catalytic behaviour of the samples. In the presence of ruthenium based silica (SiO_2-NH_2/Ru^{III}) the conversion of LA was lower than 5% with a selectivity to SA of 92%. In the presence of MNP-NH_2/Ru^{III} (4 wt.%Ru) the efficient synthesis of SA from glucose by one-pot hydrogenolysis/oxidation concept was also possible at 150°C and 10 atm O_2. The gluconic acid was not detected in the reaction products, the main product of the oxidation reaction being SA. The selectivity was of 76.7% for a total conversion, after 11 h. Many other products as glycolic acid, glyceric acid, 3-hydroxybutanoic acid, ethylene glycol or lactones were also detected but in low amounts. Increasing the temperature at 180°C, glucose was totally converted with a yield to SA of 86.7%, in only 6 h.

4 Conclusions

The oxidation of LA and glucose to SA requires catalysts with both acid-base properties. The optimization of the MNP-NH_2/Ru^{III} showed that the optimum composition to achieve the highest catalytic performances comprises an excess of basic sites, ie a ratio NH_2/Ru >1 and 1wt.% Ru. These catalysts exhibit activity not only in the oxidation of LA but also of glucose. In this case the best results corresponded to C_{LA} = 59%, S_{SA} = 98.3%; $C_{glucose}$ = 100%, and S_{SA} = 62.7%.

Keywords: vanadates, ethanol, acidity, dehydrogenation, catalysts

1 Introduction

Transition metal Vanadates are widely studied as catalysts for methanol oxidation to formaldehyde[1,2]. Conversely, there are few information in literature regarding the catalytic properties of these materials in the transformation of ethanol, which is of interest nowadays in the context of the production of high added value chemicals starting from bio-alcohols. The aim of this work was to investigate ethanol transformation over V/Fe and V/Cu mixed oxides, under both aerobic and anaerobic conditions, and correlate catalyst behaviour with chemical-physical characteristics.

2 Experimental/methodology

The catalysts were synthesized adding either $Fe(NO_3)_3 \cdot 9H_2O$ or $CuCl_2 \cdot 2H_2O$ aqueous solution to a solution containing NH_4VO_3 and $H_2C_2O_4$, at controlled pH; the obtained precipitates were dried and then calcined at 650°C for 3 hours. Catalysts were tested in a fixed-bed gas-phase glass rector. Catalytic activity experiments were carried out feeding either ethanol or ethanol and oxygen. The reaction products were analysed by means of on-line GC and the catalysts were characterized both before and after reaction by means of SEM, XRD, Raman and FT-IR spectroscopy. Operando DRIFT experiments were carried out with ethanol continuous feeding at 573 K.

3 Results and discussion

Figure 1 and 2 show the trend of ethanol conversion and products yields plotted in function of time-on-stream at 573 K, with Fe/V/O and Cu/V/O catalysts, respectively, under anaerobic conditions.

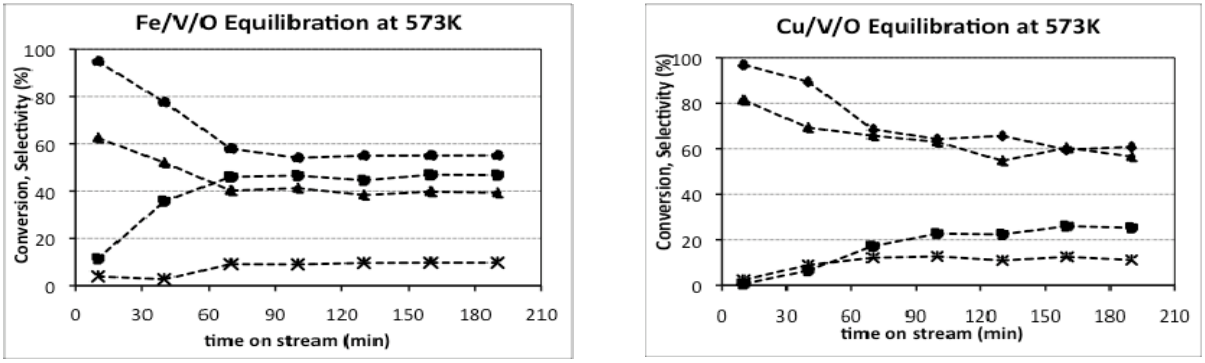

Fig. 1: Ethanol conversion and products selectivity as function of time-on-stream with Fe/V/O (left) and Cu/V/O (right) catalysts: ●: Ethanol conversion; ■: Ethylene selectivity; ▲: Acetaldehyde selectivity; ×: C3/C4 selectivity.

Both catalysts showed an "equilibration time" during which the behaviour was not stable, and metal oxides were progressively reduced. Besides acetaldehyde and ethylene, also C_3/C_4 compounds, such as ethylacetate, crotonaldehyde, crotyl alcohol, and acetone, were formed. The C_4 compounds are formed by consecutive reactions on acetaldehyde, via either Tishchenko dimerization to ethylacetate or aldol condensation and dehydration [3,4]. The relative contribution of the acid-catalysed dehydration to ethylene and the dehydrogenative/condensation pathway leading to acetaldehyde and C_3/C_4 compounds changed in function of catalyst structure and composition, as highlighted by characterisation of both fresh and equilibrated (reduced) catalysts. XRD and SEM characterization showed that in the case of Fe/V/O catalyst, the iron vanadate compound was progressively reduced into a spinel mixed oxide, which showed relevant acid properties. The latter were confirmed by means of operando DRIFT/MS experiments. Therefore, a high ethylene/(acetaldehyde + C_4) selectivity ratio was finally observed. In the case of the Cu/V/O system, instead, metallic Cu formed during catalytic test with ethanol feeding; the catalyst finally showed a much lower ethylene/(acetaldehyde + C_4) selectivity ratio, because of its lower catalyst acidity and because of the presence of Cu^0, which enhanced the dehydrogenative properties.

Co-feeding of oxygen at 573 K hindered catalyst reduction and led to higher activity in oxidative dehydrogenation. For example, Fe/V/O was stable in its oxidized form under aerobic conditions, and showed the preferred formation of acetaldehyde and CO_x to the detriment of ethylene. Conversely, Cu/V/O showed less Cu^0 formation than without oxygen in feed, and acetaldehyde and CO_x were the main products.

4 Conclusions

Fe/V and Cu/V mixed oxides were tested as catalysts for ethanol transformation under both aerobic and anaerobic conditions and were characterized before and after catalytic tests. Results showed that product distributions changed depending on the grade of catalysts reduction, highlighting the relationship between products distribution and the characteristics of the mixed oxides. For both catalysts, the presence of reduced phases contributed to increase catalyst acidity, shifting the products distribution from acetaldehyde to ethylene. However, this phenomenon was less evident in the case of Cu/V/O, because of the segregation of metallic Cu.

Keywords: MnO_x catalysts, promoters, selective oxidation, benzyl alcohol, mechanism kinetics

1 Introduction

The selective oxidation of alcohols is a very important class of industrial synthesis reactions to obtain a variety of chemicals used for manufacturing high added-value products like drugs, vitamins, fragrances and innovative materials [1]. However, the use of special and expensive precursors and reagents raises significant environmental and economic concerns due to poor *atom economy* and high *E-factor* [2]. Then, the discovery of eco-friendly catalytic technologies for the selective oxidation of alcohols with oxygen has been recently designated as a major *Green Chemistry* topic. Although noble-metal catalysts drive the oxidation of many alcoholic substrates under mild conditions, high cost, deactivation phenomena and safety issues hinder their industrial applications [1,3]. Despite a lower activity, bare and promoted MnO_x catalysts exhibit a highly selective activity pattern in the liquid phase aerobic oxidation of alcohols, rendering them a viable alternative to noble-metal catalysts [3]. However, decay phenomena and the need for regeneration-rejuvenation steps have also been documented [4,5].

Therefore, this work is aimed at highlighting the mechanistic issues of the reactivity pattern of bare and promoted (Ce, Fe) MnO_x catalysts in the aerobic liquid phase oxidation of benzyl alcohol to benzaldehyde. A systematic analysis of activity data sheds lights onto the factors controlling the functionality of MnO_x catalysts, while a simple kinetic model allows predicting their activity-stability pattern over a wide range of experimental conditions.

2 Experimental/methodology

Cerium and iron promoted MnO_x catalysts with different atomic ratios were prepared via the redox-precipitation route and characterized by XRF, N_2-physical adsorption, XRD, CO-TPR and DRIFT analyses [4,5]. Catalytic tests in the aerobic liquid phase oxidation of benzyl alcohol with O_2 were carried out into a 3-necked pyrex glass flask reactor containing a solution (50 mL) of benzyl alcohol (0.1 mol/L), toluene (solvent) and ethyl benzoate (int. std). The solution was heated at 343K under stirring and O_2 flow, adding, then, 0.45 g of powdered catalyst (t_0).

3 Results and discussion

Table 1 shows a good agreement between design and experimental Mn/Ce/Fe atomic ratios along with the presence of significant amounts of potassium, resulting in an asymptotic growth of the K/Mn ratio with MnO_x loading [4]. Promoters addition has a positive impact on surface texture, indicated by systematically larger surface area values of the composite catalysts than bare oxides. This has been ascribed to the fact that the redox-precipitation route promotes a *quasi-molecular* dispersion of the oxide phases, hindering any long-range ordered structure [4].

Both C and F systems are not active under std reaction conditions, while the MnO_x material exhibits a remarkable performance leading to a complete conversion of alcohol to benzaldehyde (S>99%) in 3h.

A direct relationship between activity and reducibility suggests that MnO_x plays the role of active phase, while minor is the contribution of promoters to the functionality of composite catalysts [6]. Despite no effects on selectivity (S>99%), promoters influence the reactivity of the MnO_x phase (Fig. 1A). Among Ce-based catalysts, M1C1 shows the poorest activity with a final conversion of 50%, while a complete alcohol conversion signals that the reactivity of M3C1, M5C1 and M9C1 samples compares to the bare M system. Replacement of Ce with Fe enhances the activity as M6C1F1 and M3F1 catalysts show conversion rates higher than M3C1 (Fig. 1B).

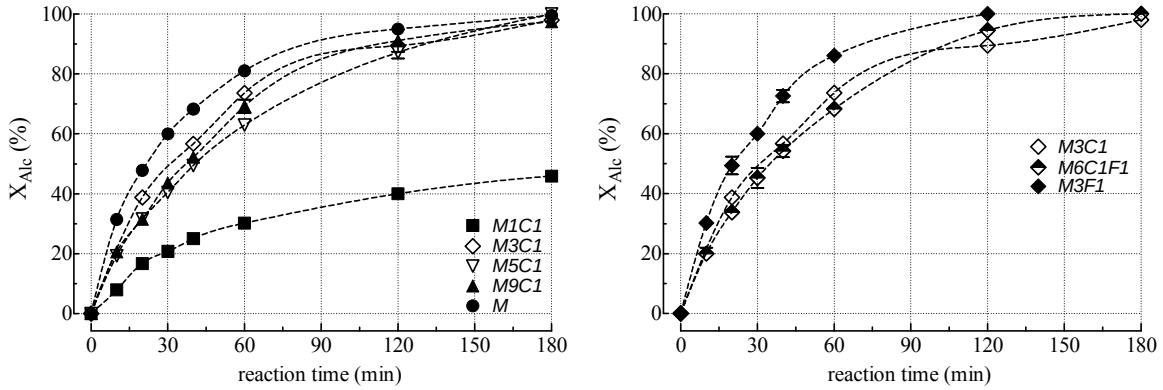

Fig. 1. Activity of catalysts in the selective oxidation of benzyl alcohol with O_2 at 343K.

The initial reaction rate values signal that the reactivity of Ce-promoted systems lowers with the Mn/Ce ratio, despite a fairly constant MnO_x rate rules out significant *electronic effects* [4]. The substitution of Ce with Fe has a positive influence on activity, while a constant MnO_x rate indicates the absence of significant chemical effects also in Fe-promoted catalysts [4].

4 Conclusions

The reactivity of bare and promoted (Ce, Fe) MnO_x catalysts is assessed [4].
Remarkable deactivation phenomena disguise 0^{th}-order reaction kinetics [4,5].
The activity-stability pattern is determined by strong adsorption phenomena [5].

Structural Peculiarities and Catalytic Properties of Supported Vanadium Oxide Catalysts for Oxidative Dehydrogenation

Sushchenko E.*, Kharlamova T.

Tomsk State University, Chemistry Faculty, Tomsk, Russia

* konfetty13@mail.ru

Keywords: vanadium oxide, oxidative dehydrogenation

1 Introduction

Propylene and styrene are important monomers for polymeric industry. Propane and ethylbenzene dehydrogenation (DH) over Cr_2O_3/Al_2O_3 and Fe_2O_3 catalysts, respectively, are conventional ways to produce the said compounds. However, DH of saturated hydrocarbons has many disadvantages. Therefore, the oxidative dehydrogenation (ODH) was suggested as an alternative way to produce propylene and styrene. Catalysts based on supported vanadium oxide demonstrated promising results in ODH of hydrocarbons [1]. Activity and selectivity of supported vanadium oxide catalysts depend on support nature and vanadium content, determining oxidation state, coordination number, aggregation state, and structure of vanadium oxide species on the support surface [1]. This work is devoted to the study of the structural peculiarities and catalytic properties in ODH reactions of vanadium species at the surface of different supports.

2 Experimental

VO_x/SiO_2, VO_x/TiO_2, VO_x/Al_2O_3, VO_x/AlC catalysts (Table 1) were synthesized by wetness impregnation using aqueous solution of NH_4VO_3. SiO_2, TiO_2, γ-Al_2O_3 and carbon-modified γ-Al_2O_3 (AlC) were used as catalyst supports. The nominal V_2O_5 content was 12 or 3.5 %wt. to ensure 0.2-0.25 monolayer coverage. The catalysts were characterized by low temperature N_2 adsorption, XRD, IR and Raman spectroscopy, UV-Vis DRS and H_2-TPR. Catalytic activity of the samples in ODH reactions was determined using flow catalytic unit with online chromatographic analysis of the products.

Table 1. Sample characteristics.

Sample	V_2O_5, wt.%	V_2O_5, monolayer	SSA, m^2/g	D_{XRD}, nm
VO_x/Al_2O_3	12	0.25	183	8
VO_x/AlC	12	0.21	211	41
VO_x/SiO_2	12	0.2	289	19
VO_x/TiO_2(12)	12	>>1	10	38
VO_x/TiO_2(3.5)	3.5	0.24	59	-

3 Results and discussion

According to XRD data, VO_x/Al_2O_3, VO_x/SiO_2, VO_x/TiO_2(12) samples are composed of phases of the support (γ-Al_2O_3, amorphous SiO_2 or anatase) and V_2O_5. The VO_x/AlC contains graphite phase along with γ-Al_2O_3 and V_2O_5. Only anatase phase was detected in VO_x/TiO_2(3.5). V_2O_5 was well crystallized in both VO_x/TiO_2 and VO_x/AlC with the mean crystallite size of ~40 nm. VO_x/SiO_2 and VO_x/Al_2O_3 samples contained V_2O_5 phase in dispersed state.

According to Raman spectroscopy data, VO_x/AlC, VO_x/SiO_2, VO_x/TiO_2(12) catalysts contained crystalline V_2O_5, whereas VO_x/TiO_2(3) did not contain one according to XRD data. The absence of V-O bands in the spectrum of VO_x/TiO_2(3) indicated the presence of vanadium

oxide mainly in the form of polymerized surface vanadium oxide species. However, in contrast to XRD data, there were no bands typical for crystalline V_2O_5 at 145, 196, 284, 404, 481, 550, 701, 994 cm^{-1} in the spectrum of VO_x/Al_2O_3, but only shifted peaks at 124, 187, 266, 379, 457, 538, 680, 978 cm^{-1} and new ones at 497, 620 cm^{-1}. This indicated the possible interaction of vanadium oxide with Al_2O_3 to form some surface vanadium oxide species.

According to UV-vis DRS, ligand-to-metal charge transfer bands of V^{5+} are present in the spectra of all samples, which are overlapped with those of support in the case of VO_x/TiO_2 and VO_x/Al_2O_3. The spectra of initial VO_x/SiO_2, $VO_x/TiO_2(12)$ and VO_x/AlC indicates the presence of V^{5+} in dispersed V_2O_5, with the spectra of VO_x/SiO_2, $VO_x/TiO_2(12\%)$ remaining practically unchanged before and after the catalyst testing. The spectra of VO_x/Al_2O_3 and $VO_x/TiO_2(3.5)$, in their turn, indicates the presence of V^{5+} in the form of polymerized surface vanadium oxide species. However, the presence of amorphous V_2O_5 phase is possible in VO_x/Al_2O_3 as well. The spectrum of VO_x/AlC was similar to that of VO_x/Al_2O_3 after the catalyst testing, indicating the interaction of VO_x with the support.

According to H_2-TPR data, $VO_x/TiO_2(12)$ reduction is characterized by two peaks of H_2 consumption, namely, weak peak at 360-530ºC corresponding to reduction of polymerized vanadium oxide species as well as intense peak above 550ºC corresponding to reduction of bulk V_2O_5. The TPR profile of $VO_x/TiO_2(3.5)$ is characterized by the H_2 consumption from 400 to up to 700ºC with maxima at 516 and 580ºC, which seems to be caused by the reduction of polymerized surface vanadium oxide species. The VO_x/SiO_2 profile contains weak peak at 200-450ºC attributed to amorphous vanadium oxide species, and intense peak above 450ºC attributed to dispersed V_2O_5 crystalline particles. The TPR profiles of VO_x/AlC and VO_x/Al_2O_3 are characterized by only one peak of H_2 consumption with maximum at 595ºC and 536ºC, respectively. The narrow instansive peak in the VO_x/AlC profile is caused by the reduction of V_2O_5 crystalline particles, while wide peak in the VO_x/A_2O_3 profile is caused by the reduction of polymerized surface vanadium oxide species as well as dispersed V_2O_5 particles of low crystallinity. Interestingly, the TPR profiles of VO_x/AlC and VO_x/Al_2O_3 after the catalyst testing are similar and characterized by a wide peak with maximum at 590ºC. This, in accordance with Raman and UV-vis DRS data, also indicates the interaction of VO_x with Al_2O_3 to form polymerized surface vanadium oxide species.

According to the catalytic data, $VO_x/TiO_2(3.5)$ showed the highest catalytic activity, but the main product of the propane conversion was CO_x. VO_x/Al_2O_3 showed propane conversion comparable to that of $VO_x/TiO_2(3.5)$, but the highest selectivity towards propene among samples studied. The VO_x/AlC and $VO_x/TiO_2(12)$ showed lower activity, with the selectivity towards propene being, respectively, comparable and lower to that of VO_x/Al_2O_3. The VO_x/SiO_2 showed low activity and selectivity towards pronene. Therefore, the interaction of VO_x with the support to form polymerized surface vanadium oxide species in VO_x/Al_2O_3 and $VO_x/TiO_2(3.5)$ results in the increase of catalyst activity, while selectivity depends on the strength and electron density change of V-O-support bond in the formed surface vanadium oxide species.

4 Conclusions

The interaction of vanadium oxide with the support to form polymerized surface vanadium oxide species was shown to result in increase of catalyst activity, while selectivity depends on the strength and electron density change of V-O-support bond in the formed surface vanadium oxide species.

Silica Supported Vanadia Catalysts for Selective Methane Oxidation: Impact of Morphology and Heteroatom Doping on Catalyst Performance

Wallis P.*, Schönborn E., Wohlrab S., Kalevaru N., Martin A.

Leibniz Institute for Catalysis, Rostock, Germany

* philipp.wallis@catalysis.de

Keywords: mesoporous, silica, vanadia, methane oxidation, formaldehyde

1 Introduction

At present, methane valorization is clearly dominated by energy production. Intense research efforts are directed towards broadening the scope of methane as feedstock. Areas of interest are dry reforming, selective oxidation of methane and oxidative coupling of methane [1]. Selective oxidation of methane to formaldehyde is investigated over supported vanadia catalysts [2]. Several approaches to improve the selectivity to formaldehyde (S_{HCHO}) are reported in literature: First, homogenous gas phase admixture like of carbon dioxide can be used to improve S_{HCHO} [3]. Second, textural properties of the support as pore diameter and surface fractality have been probed for reactivity tuning [4,5]. As Ti-doping of siliceous supports has also been observed to improve selectivity (V/Ti-MCM-41 [6]) but may alter pore size distribution in some cases, it is the aim of this study to put the effects of pore size distribution and heteroatom doping in perspective. This will be done by comparing Ti-doped and Ti-free silica supports of various pore size distributions and evaluate the effect on selectivity.

2 Experimental

SBA-15 synthesis was done according to a procedure by Zhao et al. [7] in a variant, where the batch was stirred at 35 °C for 12 h after addition of $Si(OEt)_4$; variation of pore size distribution was achieved by mesophase ageing at 80 °C (V/SBA-15-T1) and 90 °C (V/SBA-15-T2) [8]. Ti-SBA-15 was synthesized by dissolving 4.00 g Pluronic P123 in 125 mL 2M HCl at 40 °C. 0.51 g Cp_2TiCl_2 (Strem) were added and the resulting mixture stirred at 40 °C for 3 h. 9 mL $Si(OEt)_4$ was added and stirred together for 20 h at 40 °C. The obtained slurry was then kept at 100 °C for 24 h, filtered, washed and dried overnight to give a white powder. Template was removed via calcination. 2.27 g Ti-SBA-15 were obtained. During calcination, all supports were heated from RT with 1 K/min to 650 °C, kept at 650 °C for 16 h and then cooled to RT with 1 K/min. VO_x was grafted onto support by incipient wetness impregnation of aqueous NH_4VO_3 solution and subsequent calcination, nominal V content 2.8 wt% [9]. Catalytic tests in selective oxidation of methane to formaldehyde were carried out at T=550-690 °C; GHSV=94,000–360,000 L/kg_{cat}h; admixture: CH_4: O_2 = 7: 2: 1 where admixture was CO_2, N_2, Ar, CH_4. Product gas was kept at 180 °C for analysis and composition was determined using an infrared gas detector (Gasmet CX1000).

3 Results and discussion

Maximum achieved space-time-yield was 3.6 kg/kg_{cat}h (686 °C, 360,000 L/kg_{cat}h) over V/Ti-SBA-15 compared to 3.2 kg/kg_{cat}h over V/SBA-15-T1 (665 °C 360,000 L/kg_{cat}h). Catalytic tests showed S_{HCHO} = 50% at 1% methane conversion (X_{CH4}) over 0.2 wt% Ti containing V/Ti-SBA-15 (d_{pore} 6 nm), while S_{HCHO} of V/SBA-15-T1 and V/SBA-15-T2 (d_{pore} < 5 nm) was between 40 and 50% at comparable conversion (Fig. 1A). Over the range of conversion

observed, samples containing larger pores (see PSD in Fig. 1B) exhibit higher selectivity of formaldehyde formation.

If diffusion limitation and contribution of inner-pore gas phase reaction can be excluded, this trend may be due to altered equilibrium surface structure distribution of vanadia due to a change in support morphology [4]. As was shown by general support variation [10], V-O-Support bonds are important for methane activation. Surface density of V-O-Support moieties may decrease for identical V-loading as the ratio of monomeric $O=V(\text{-}O\text{-}Support)_3$ to polymeric $O=V(\text{-}OV)_n(\text{-}O\text{-}Support)_{3\text{-}n}$) decreases. For identical support morphology and extended time-on-stream, initially different distributions of V between monomeric and polymeric species are expected to equalize due to reaching thermodynamic equilibrium; hence exhibiting identical catalytic activity at this stage. However for support variation e.g. surface roughness, pore curvature or heteroatom doping, thermodynamic equilibrium distribution may differ yielding different catalytic activity.

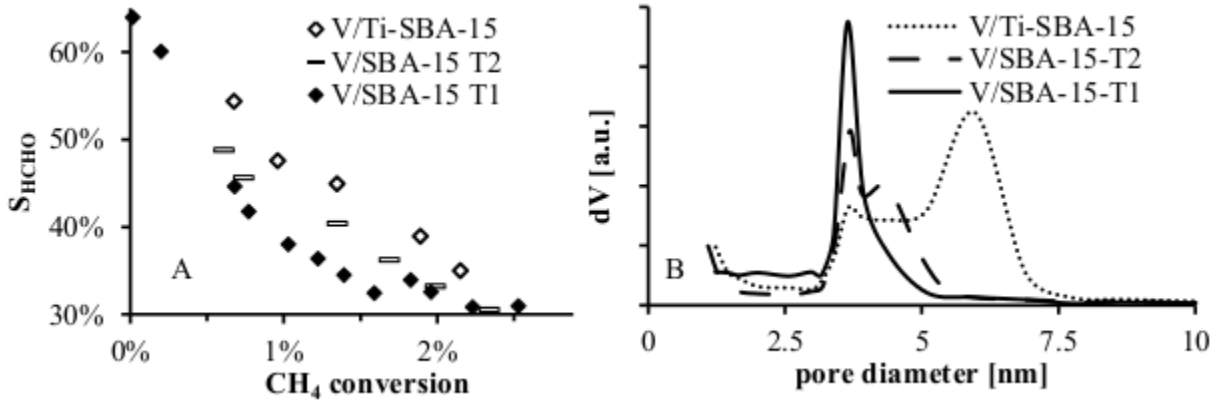

Fig. 1. X_{CH4} vs. S_{HCHO} plot (A) of supported VO_x catalysts and their different pore size distributions (B).

4 Conclusions

The results clearly show improved selectivity towards formaldehyde for Ti-modified samples. Further investigations will clarify the role of titanium as structural or electronic promoter by testing if a similar effect can also be achieved by application of Ti-free silica support of similar pore size distribution.

Selective Oxidation of Cyclic-Alkane, Catalyzed by Nano Size SWNTs Supported Pt and Pd Complexes Catalysts

Machado K., Mishra G.*

Universidade de Trás-os-Montes e Alto Douro (UTAD), Vila Real, Portugal

- mishrags@utad.pt

Keywords: heterogeneous catalysis, carbon nano-tubes, metal complexes, alkane, oxygen

1 Introduction

Single wall carbon nano-tubes (SWNTs) have used much broader applications such as catalysis, gas storage and separation, nanoprobes, chemical sensors and high strength composites [1]. Magnetic SWNTs have been used, either only Fe or Fe/Co, Co/Ni/Fe, Ni/Co in catalysis [2]. An application of supported metal complex over nano-size materials have combined advantages of homogeneous over heterogeneous in catalysis, such as tremendous catching power liquid wastes, easy magmatic separation, large surface area, less toxic and economical. Functionalized SWNTs have much attention, which allow covalent anchoring with a targeted metal complex. Particularly, pincer complexes, they are well known form long time but their appropriate application in heterogeneous catalysis is still untouched field of research.

Oxidation of cyclohexane (*Cy-hx*) is a key process because it's oxidized products which are use for the production of polyamide-6, nylon-6 and additives etc.. Earlier, precursors of Co have been used for *Cy-hx* oxidation with Air/O_2 mixture at above 150 ºC (*ca.* 4 % conv. With *ca.* 85 % selectivity) [3]. The prospect of operate with molecular O_2 as "*greener oxidant*" and cheaper oxidant with nanoparticles catalysts is constitute the selective product formation, reducing by-products and energy saving. Recently, di(ethylthio)alkanes Pd complexes over silica have also developed for the same reaction with O_2 and achieved 16 % conv. [4]. Hence, the main purpose of this work is to use *NH_2*-functionalized supramagnetic SWNTs as novel support Pd and Pt complexes as recyclable catalysts for the oxidation of *Cy-hx* with O_2 to achieve high turnover numbers (TONs) and selective product under solvent free condition.

2 Methodology

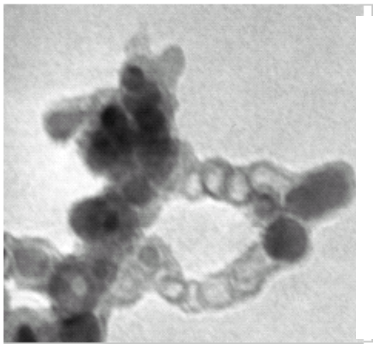
2.1 *Synthesis of Nano-Catalysts and Oxidation Technique:* The SWNTs have been prepared by the method [5]. Surface was modified by $[NH_2(CH_2)_3Si(OCH_3)_3$ in toluene, refluxed for 12 h and carefully washed with H_2O in order to obtained NH_2-functionalized magnetic SWNTs. Both $Pd^{(II)}$ and $Pt^{(II)}$ pincer complexes have been prepared [6] and bonded with *functionalized* SWNTs in presence of K_2CO_3 in dry toluene, refluxed overnight.

Teflon line reactor having a 22 mL capacity was used for the conducting all oxidation reactions. It was initially charged with substrate and catalyst and removed air and introduced O_2. After reaction, liquid mixture was injected in GC with pentanone as internal standard. The characterization TEM, FTIR, TGA, AAS and GC/MS have been performed at CQ-VR centre.

3 Results and discussion

The amino-functionalized magnetic SWNTs support have been used for anchoring of active species of $Pd^{(II)}$ and $Pt^{(II)}$ (pincer -*NNN* and –*SNS* ligands) complexes as selective catalysts for *Cy-hx* oxidation with cheaper and greener oxidant (molecular oxygen). Due to changing the electronic properties, these hetero-atoms in the side-arms complexes could be useful for the fine-tuning of high catalytic activity. Typical fiber like texture of SWNTs/Pd catalyst is seen in

TEM image *Fig.1* at 240 nm magnification. In *Fig.2*, the testimony of Pd complex over support was distinguished by the different peak positions by TEM-EDS *i.e.* Co at 0.9, 6.4 and Ni at 1.1, 6.6 of functionalized SWNTs and one additional Pd peak, after the anchoring at 2.4.



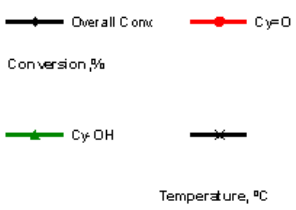


Fig.1 **Fig.2**

Novel magnetic SWNTs supported SWNTs/Pd and SWNTs/Pt catalysts have been applied for the oxidation reaction of *Cy-hx* hydrocarbon using molecular O_2 as oxidant in batch reactor. Notably high TONs 1946 were achieved with SWNTs/Pd and 1678 with SWNTs/Pt catalyst.

We have also run additional oxidation reaction with only SWNTs, to check the effect of support *i.e.* non-functionalized SWNTs (6 h at 150 ºC and $p(O_2)$ 10 bar). It was obtained not very low overall yield *i.e.* 11.6 % with *K/A* ratio1.5. It's reflects that SWNT is also taking part to improve the catalytic activity.

For ideal reaction condition of *Cy-hx* oxidation in respect of temperature was investigated between 100 to 225 ºC with SWNTs/Pd catalyst (*Fig.2*). Best Pd catalyst results have been obtained overall conversion 22.9 % (*Cy=O*, 12.01 % and *Cy-OH*, 9.35 %) with selectivity 93.3 %, under above condition. Other catalytic system SWNTs/Pt has also exhibits good catalytic activity, overall conversion 20.7 % but better *K+A* selectivity 95.2 % was obtained, in compression to Pd catalyst. Trash amount of some by-products were also observed. At 225 ºC, black unidentified oil material was observed. Free radicals *CyOOH* was also detected in the reaction solution with PPh_3 treatment. It is confirming the radical type mechanism.

4 Conclusion

Magnetic nano-catalysts give mainly *Cy=O* and *Cy-OH* products of the corresponding *Cy-hx* were obtained with very high TONs 1946 for Pd catalyst and 1678 for Pt catalyst. Highest 22.9 % conv. (93.3 selectivity %) is achieved by Pd catalyst. This magnetic nano-catalytic study is opening the gateway for the development of more sustainable catalyst for future easy magnetic separation process.

Catalytic Synthesis of 2-Methyl-1,4-Naphthoquinone in 1%Au/HPS Presence

Shimanskaya E.I.*, Doluda V.Yu., Sulman E.M.

Tver Technical University, Tver, Russia

* shimanskaya-tstu@yandex.ru

Keywords: 2-methyl-1,4-naphthoquinone, 2-methylnaphthalene, catalytic oxidation, gold

1 Introduction

Selective oxidation of aromatic compounds opens access to a great number of useful products. Quinones with various functional groups are important intermediate in fine organic synthesis as quinone fragments are part of difficult molecules of the substances used in manufacture of vitamins and medical products. An example of such compounds is 2-methylnaphthalene. The 2-methylnaphthalene oxidation stage has a low selectivity, and consequently a small target product yield. At oxidation 2-methylnaphthalene such products, as 2-methyl-1,4-naphthquinone, isomerous 6-methyl-1,4-naphthquinone, methyl groups oxidation products, dinaphthquinone, epoxiquinone and other products of deep oxidation are formed. It necessary to find the way of selective synthesis of menadione. There are a lot of catalysts described in literature which are applied in the menadione synthesis, however the majority of them gives low selectivity (<40%), is toxic, pollutes the prime product and gives a considerable quantity of by-products [1]. We decided to use the based on HPS catalyst, because of its properties. Hypercrosslinked polystyrene (HPS) is rigid polymeric network of polystyrene linked by methylene bridges [2].

2 Experimental

Synthesis of 1%Au/ HPS

The 5%Au/ HPS catalyst was prepared as follows: 3 g of polymer was impregnated with 0.086 g of Ph_3PAuCl in 8.5 mL of THF under stirring and dried at 70°C. Next the catalyst was treated with 0.5 g of Na_2CO_3 in 12 mL of H_2O. Then it was dried again and washed to a pH of 7.

Oxidation methodology

The oxidation reaction was conducted batchwise in a glass apparatus that permits independent control over parameters such as the substrate concentrations, temperature and the stirring rate. A solution of the substrate in the appropriate solvent (20 mL) prepared at a predetermined concentration was placed in the reactor. The high stirring rates employed here ensured good mixing without diffusion limitations. Samples of the reaction mixture were periodically removed for analysis. The oxidation process was carried out at the following reaction conditions: reaction temperature 80°C, substrate initial concentration 0.035 mol/L.

3 Results and discussion

At first industrial non-catalytic reaction of 2-methylnaphthalene oxidation by a H_2O_2 has been in vitro researched. Oxidation was conducted in the glass reactor within 2 hours at the temperature 80°C. Concentration of a 2-methylnaphthalene solution in acetic acid is 0.035 M. Samples were taken every 15 minutes during the reaction and analyzed using GC-MS. The yield of the process attained 43%.

2-methylnaphthalene catalytic oxidation was carried out with use of HPS-based Au-catalyst in H_2O_2 presence. Synthesis of such system was carried out by introduction of metal in a carrier

by impregnation on a moisture capacity of Wilkinson complex salt. The yield of the process attained 72%.

4 Conclusions

The yield of the non-catalytic process attained 43%. The yield of the catalytic process attained 72%.

Mo-Incorporated KIT-6 Mesoporous Silica Catalysts with High Performance for the Selective Oxidation of Propane to Acrolein

Liu Q.L., Li J.M., Zhao Z.*, Gao M.L., Liu J.

State Key Laboratory of Heavy Oil, College of Science, China University of Petroleum, Beijing, China

* zhenzhao@cup.edu.cn

Keywords: Mo-KIT-6 catalyst, framework-incorporation, highly dispersed active sites, propane selective oxidation, acrolein

1 Introduction

The selective oxidation of alkanes is of fundamental and industrial significance because it provides a potential route to effectively transform alkanes instead of olefins to value-added chemicals for effective utilization of abundant natural gas and shale gas resources. The 3D interconnected mesoporous silica KIT-6 with large pores and thick pore walls, high hydrothermal stability, high specific surface area and large pore volume has attracted much attention for potential applications in catalysis[1-3]. Molybdenum-based catalysts are one of the most efficient catalysts employed in the selective oxidation of alkanes[4-6]. The performance of these catalysts is strongly related to the nature of the active species. This kind of framework-incorporated catalysts is different from supported catalysts. The framework-incorporation contributes to achieving high concentrations of highly dispersed active sites and high stability of catalysts which may have high activity for selective oxidation[7,8]. In this work, we synthesized the Mo-KIT-6 catalyst that gave good catalytic performance for the selective oxidation of propane to acrolein.

2 Experimental

Mo-incorporated mesoporous molecular sieves (Mo-KIT-6) were synthesized by one-pot co-assembly method using nonionic triblock copolymer surfactant Pluronic P123 ($EO_{20}PO_{70}EO_{20}$, MW=5800, Aldrich) and n-butanol (BuOH) as a structure-directing mixture, tetraethyl orthosilicate (TEOS) as silica source and ammonium heptamolybdate (AHM) as a molybdenum source in hydrochloric acid. A typical procedure was as follow: 2.0 g of Pluronic P123 was added into 4.0 g 35 wt % HCl with stirring at 308 K for 4h and the acquired amount of AHM was dissolved in 72 g water. Then, the two solutions were mixed. 2.0 g of BuOH was added and the stirring was continued for 1 h. Subsequently, 4.3 g of TEOS was added to the homogeneously clear solution. The subsequent step was similar to the literature[9]. In the filtration and washing processes, the Mo species that is not incorporated into the catalysts would be washed away. The samples were labeled as xMo-KIT-6, x denotes Mo content in recipe (Mo:Si=X:100, molar ratio). The final Mo contents in Mo-KIT-6 samples were determined by inductively coupled plasma (ICP) measurement.

3 Results and discussion

Figure 1 exhibits the several characterization results of Mo-KIT-6 catalysts. It can be seen that the materials are well ordered mesostructure similar to that of KIT-6. However, it is notable that the diffraction peak shifts to low angle and peak intensity decreases with the increase of Mo contents. This can be attributed to the incorporation of Mo species into framework of molecular sieves. The wide-angle XRD pattern and Raman spectra indicate that the catalysts mainly contain highly dispersed MoO_x species. The results of catalytic activity show 8Mo-KIT-6 sample is the best catalyst and its catalytic activity results are illustrated in Table 1.

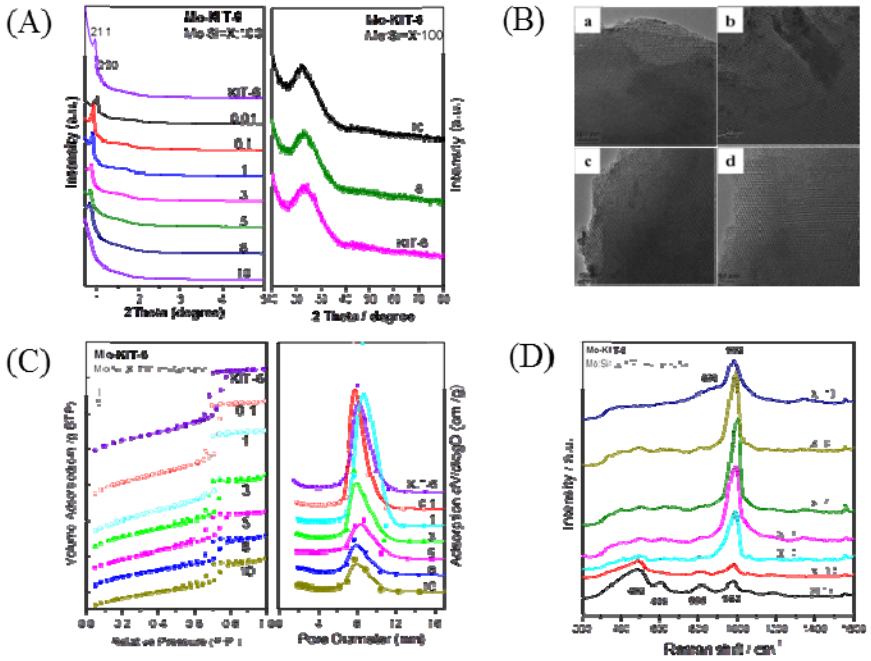

Fig. 1. The characterisations of Mo-KIT-6 catalysts: (A) Low-angle and wide-angle XRD patterns; (B) TEM images, a)0.1Mo-KIT-6, b)5Mo-KIT-6, c)8Mo-KIT-6, d)10Mo-KIT-6; (C) The N_2 adsorption-desorption isotherms and pore-size distribution; (D) Raman spectra

Table 1. The catalytic performances of Mo-KIT-6 catalysts for the selective oxidation of propane

Conv., %	Temp., K	Selectivity [a], %							Yield, %	
		Oxy.			C_3H_6	HC	CO	CO_2	Acr	Olefins+Acr
		Acr	C2	Ace						
76.5	873	25.4	0.9	0.9	20.4	20.4	23.0	7.8	19.4	46.0

[a] Oxy.: oxygenated chemicals; Acr: acrolein; C2: acetaldehyde; Ace: acetone, HC: ethylene and methane

4 Conclusions

A kind of framework-incorporated Mo-KIT-6 mesoporous molecular sieve catalysts with different Mo contents were successfully synthesized by one-spot co-assembly method. It was found that the catalyst was effective for the oxidative conversion of propane to acrolein. Detailed characterizations and catalytic behavior showed that highly dispersed MoO_x species were predominant in the catalysts and the high concentrations of highly dispersed active sites are favorable for enhancing the activity of selective oxidation of propane to acrolein.

Keywords: ethane, ethylene, nickel oxide, pillared clay, dehydrogenation

1 Introduction

Ethylene is the most important raw material in Petrochemistry. It is industrially obtained through a very inefficient process from an energetic viewpoint, which is called "steam reforming". The oxidative dehydrogenation (ODH) of ethane is considered as a viable alternative to "steam reforming" for the industrial manufacture of ethylene. Currently, two catalytic systems are the most promising in the ODH of ethane, those based on MoV oxides and those based in nickel oxide [1]. Nickel oxide alone is highly active but presents a low selectivity towards ethylene. However the addition of an appropriate either support or promoter leads to an enhanced formation of ethylene [2,3]. At the present work, the use of a silica with a pillared structure as support for nickel oxide will be studied for the ODH of ethane and its performance will be compared to that of conventional silica.

2 Experimental/methodology

Supported NiO catalysts were prepared through the evaporation at 60 ºC of a stirred ethanolic solution of nickel(II) nitrate, $Ni(NO_3)_2 \cdot 6H_2O$ (Sigma-Aldrich) and oxalic acid to which the corresponding support (conventional silica, pillared clay silica with columns of silica or silica/titania 5/1) was added. The solids obtained were dried overnight at 120 ºC and calcined for 2 h at 500 ºC. Pillared clays were synthesized according to reference [4].

The catalysts have been characterized by several techniques: XRD, XPS, Nitrogen adsorption, SAED-EDX, TEM, HR-TEM, TPR and Oxygen isotopic-exchange. The catalytic tests for the ODH of ethane were carried using a mixture of ethane/O_2/He with a molar ratio of 3/1/29. The temperature used varied from 300 to 500 ºC. The catalyst weight and total flow was varied to get different pairs selectivity-conversion at a given temperature. Blank runs showed no conversion in the range of reaction temperatures employed. Reactant and products were analyzed by gas chromatography using two packed columns [2].

3 Results and discussion

Table 1 summarizes some catalytic properties in the oxidative dehydrogenation of ethane of NiO based catalysts. NiO supported on conventional silica (5 and 10 wt.% NiO) show low selectivity to ethylene (i.e. 20-30%). A drastic improvement in the catalytic performance takes place for catalysts with the same NiO loading but supported on pillared silica, presenting also higher selectivity to ethylene (i.e. 55-60%). A further increase is also observed for NiO supported on silica/titania pillared material. The use of pillared silica instead of conventional silica has meant a decrease in the NiO crystallite size but also a lower reducibility of Ni-species.

Table 1. Catalytic properties of the catalysts synthesized.[a]

Catalyst	NiO wt.%	Support	Ethane conversion (%)	Selectivity to ethylene (%)	Ethylene productivity[b]
5NiSi	5	SiO_2	4.1	20	27
10NiSi	10	SiO_2	11.2	29	111
5NiPCH	5	PCH-SiO_2	8.1	55	152
10NiPCH	10	PCH-SiO_2	15.4	56	295
5NiPCHTi	5	PCH-TiO_2	10.2	60	210
10NiPCHTi	10	PCH-TiO_2	13.1	64	577

[a] Reaction Temperature = 450ºC and W/F = 8 g_{cat} h / $molC_2$; [b] in g_{C2H4} kg_{cat}^{-1} h^{-1}.

The use of pillared silica with titania columns has led to a further decrease of reducibility. Therefore, the catalytic performance has been inversely related to the reducibility of the nickel species (Figure 1).

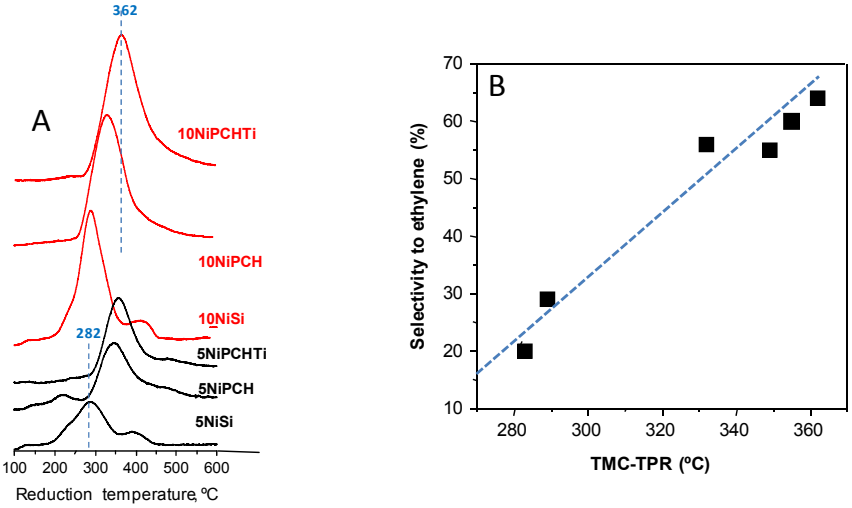

Fig. 1. TPR profiles for supported NiO catalysts (a) and the relationship of the temperature of maximum reductions and the selectivity to ethylene in ethane ODH (b). Note: Selectivity to ethylene at 10% conversion and 450ºC. TMC is the temperature of maximum hydrogen consumption in the TPR experiments.

Accordingly, it can be proposed that highly reducible species activate ethane to give carbon dioxide whereas those less reducible selectively activate ethane. However, no correlation can be established between catalyst reducibility and catalytic activity for ethane conversion.

4 Conclusions

Pillared clays, especially if columns are SiO_2/TiO_2-made, are excellent supports for NiO for the oxidative dehydrogenation of ethane. Selective Ni-species with low reducibility are likely involved in the high ethylene formation.

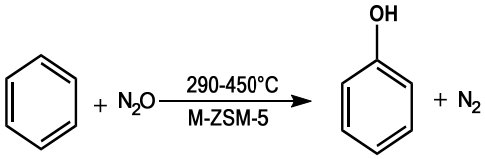
Keywords: benzene hydroxylation, phenol, N_2O, M/ZSM-5 catalysts

1 Introduction

Phenol is very important in chemical industry due to its prevalent use in the fields of agrochemicals, pharmaceuticals etc. It is used for the synthesis of various commercially important chemicals such as caprolactam, bisphenol, chlorophenol [1-2]. Phenol is conventionally produced by a three step processes. A representative example is the cumene process that produces acetone as a major by-product in addition to the desired phenol. In addition, this process also produces an explosive intermediate cumene hydroperoxide. These are some of the drawbacks of this commercial process [3]. On the other hand, direct conversion of benzene to phenol in one step is indeed an attractive alternative method also from the economic and environmental viewpoints. To date, many efforts have been made to synthesise phenol using green oxidising agents such as nitrous oxide, oxygen, and hydrogen peroxide to produce phenol from benzene by means of a gas phase oxidation [e.g. 4]. Fe/ZSM-5 catalysts are widely used for direct synthesis of phenol from benzene [5-6]. In this contribution, we describe the synthesis, characterisation and application of various transition metal doped (e.g. Co, Ni, Cu, Zn) ZSM-5 catalysts towards gas phase hydroxylation of benzene to phenol.



Scheme1. Reaction scheme for benzene to phenol

2 Experimental

Various transition metal doped ZSM-5 catalysts were prepared by impregnation method. A commercial ZSM-5 sample supplied by Zeochem, Germany was used as support for preparing the present catalysts. Required quantities of suitable metal precursors were dissolved in distilled water and then impregnated on to the support. Then the catalysts were dried first and then calcined in a furnace at 500 °C for 6 h in air. The transition metals used were Co, Ni, Cu and Zn and their contents were kept constant at 1 wt% in every case. The solids were characterized by ICP, XRD, N_2 adsorption (BET-SA) etc. Catalytic tests were carried out in a fixed bed stainless steel tubular reactor in the temperature range from 290 to 430 °C. N_2O was used as an oxidant and the catalytic tests were performed under varying reaction conditions. The reactor was filled with 2.0 g of catalyst particles (1-1.25 mm fraction) that were diluted with an equivalent weight of quartz beads of the same size to achieve isothermal operation. The reactant feed mixture was then introduced into the reactor and the reaction was performed at a residence time of 0.9 s (in general). Liquid products were collected for every half-an-hour in an ice-cooled trap and analysed by off-line GC equipped with FID, while gaseous products were detected by TCD.

3 Results and discussion

The BET-surface areas and pore volumes of the catalysts depend upon the nature of the transition metal doped. In general, they varied in the range from 353 to 391 m^2/g and 0.126 to 0.325 cm^3/g, respectively. The metal contents estimated from ICP are in good agreement with those of nominal values (~1 wt%). These materials were also characterised by XRD, but we could not see any crystalline phases corresponding to any of the metals doped. This is due to small loadings of metal and probably their X-ray amorphous nature. Fig. 1 illustrates the catalytic performance of M/ZSM-5 catalysts tested at 410 °C. It is evident from the figure that the yield of phenol obtained is the highest for Zn doped catalysts compared to all others. Among them, Cu-doping gave the lowest yield. Zn/ZSM-5 exhibit acceptably good yield of nearly 9% at a benzene conversion of ca. 20%. The remaining proportion is from the formation of by-products such as catechol, CO, CO_2 etc. Moreover, the catalysts are observed to deactivate gradually with time due to coking.

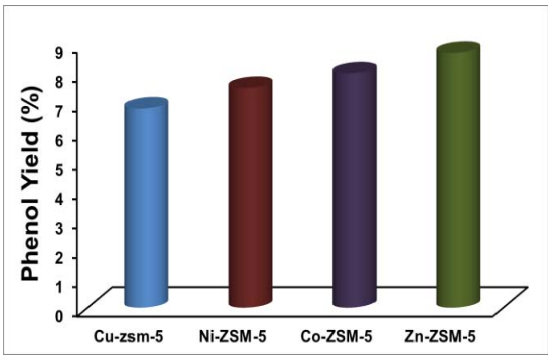


Fig. 1. Phenol yield obtained over different transition metal loaded on ZSM-5 (T=410°C, Benzene: N_2O: N_2 = 1.0: 1.5: 82, 3 Cat: 2 g; GHSV4000 h^{-1})

4 Conclusions

Results revealed that the nature of transition metal has shown considerable influence on the catalytic performance. Among the four different transition metals used, Zn displayed the best performance giving ca. 9% yield of phenol. Coking of catalyst seems to be an important problem of this reaction, which needs to be considered in the future catalyst compositions and catalytic tests.

DFT Study of the Interaction of CO and O_2 with Gold-Copper Tetrahedral Bimetallic Clusters

Gogol V.V.*, Pichugina D.A., Ku'zmenko N.E.

M.V. Lomonosov Moscow State University, Moscow, Russia

1 Introduction

The properties of nanoscale materials are usually very different from those of the corresponding bulk materials. The high surface to volume ratio of nanomaterials causes such materials to have frequent contact with the reactants of a targeted chemical reaction and to enhance the catalytic activity. Furthermore, nanoscale materials have a large number of low-coordinated atoms at the surface, which also leads to a high reactivity [1].

The oxidation of carbon monoxide (CO) to carbon dioxide (CO_2) has attracted great interest in recent years because the reaction has many industrial applications such as in catalytic conversion of automobile exhaust and in fuel cells. As we all know, noble metals such as Pt are used as a catalyst for CO oxidation in environment purification and the ORR in fuel cells [2]. However, the high cost of Pt has sparked a search for a Pt substitute or new ways of reducing the quantity of Pt required. For example, in contrast to Au bulk materials, Au nanoparticles can be used in many selective oxidation reactions, particularly in CO oxidation [3]. Also it has been shown that the sub-nano atomic Au_n clusters (n = 2–20) supported on magnesia are the active in CO oxidation [4]. At the same time, some alloyed nanoparticles, including Au–Pd nanoalloys, $MeAu_n$ (Me = W, Pb, Zr, Sc and n = 12–17), Cu-doped Au nanoparticles [5], are more active than pure gold clusters.

In this study we have investigate the CO and O_2 adsorption both on neutral, positively and negatively charged $Au_{20-x}Cu_x$ clusters having the heteroatom on the top, the edge, and the facet of the tetrahedral cluster. The detailed investigation of the cluster structure and electronic properties as well as the possible orientations and activation of the molecular oxygen and carbon monoxide on their surface would allow the further design and modification of the nanoparticles and their application in various processes.

2 Computational methods

Geometry optimizations were performed within the spin-polarized relativistic density functional theory approach using the PBE functional. The Priroda program was used for the all electron calculations within the scalar-relativistic approach, which was based on the full four-component one-electron Dirac equation with separation of the spin–orbit effects. The structures with a Cu atom located on the apex, on the edge and on the facet were obtained by substituting one Au atom with a Cu atom in Au_{20} cluster. Mono-doped copper-rich clusters $Cu_{19}Au$ were constructed from Cu_{20} the same way. The geometries of all generated clusters $Au_{20-x}Cu_x$ were fully optimize in the singlet spin state.

The adsorption energies of CO (or O_2) on the gold-copper clusters are calculated according to the formula:

$$\Delta E_{ad} = E(Cluster - CO) - E(Cluster) - E(CO);$$

where ΔE_{ad} is the CO (or O_2) adsorption energy on cluster; *E(Cluster-CO)* is the total energy of cluster with CO (or O_2) molecule adsorbed, *E(Cluster)* is the total energy of bare cluster and

E(CO) is the total energy of CO (or O_2) free molecule.

3 Results and discussion

The bimetallic clusters are relatively stable and maintained the tetrahedral structure of Au_{20} with slight distortion in the structure. As was expected, Au_{20} weakly interacts with oxygen: O-O bond length changes faintly upon adsorption on Au_{20}. That fact indicates weak oxygen activation. It should be noted, O_2 interacts much easier with negatively charged Au_{20} cluster. The O_2 dissociation is more favourable process on $Au_{20-x}Cu_x$, both molecular and dissociative adsorption take place. For molecular adsorption oxygen prefers bonding on the apex Cu atoms, than both on the edge and facet atoms. In different orientations on $Au_{20-x}Cu_x$ clusters O_2 prefers bonding to copper instead of gold atoms. The same situation we can see in the case of CO adsorption. Compared to the neutral clusters, a charge (negative or positive) on the clusters enhances CO adsorption. Compared with CO reaction on Au_{20} clusters, CO reaction on Cu-doping Au takes place easily, also.

4 Conclusions

To understand how Cu-doping in Au nanoparticles affects atomic-catalytic reactivity, we performed DFT calculations for the CO and O_2 adsorption on Cu-doped tetrahedral Au cluster. These calculations indicate several conclusions, as shown below: (1) CO and/or O_2 molecules are easily adsorbed on $Au_{20-x}Cu_x$ clusters. (2) The charging of $Au_{20-x}Cu_x$ can improve not only O_2 adsorption, but also CO adsorption. (3) The apex atoms in the clusters are more active in the binding of O_2 and CO. The Cu-doped Au nanoparticles are comparable with Au nanoparticles. The $Au_{20-x}Cu_x$ appears to be a good candidate for a CO oxidation catalyst.

Keywords: oxidation, carbon nanotubes, palladium catalyst, isopropyl alcohol

1 Introduction :

In this study, amphiphilic magnetic hybrid carbon nanotubes (CNTs) are synthesized and used as supports of (2% w/w) ruthenium and palladium supported catalysts, and evaluated for the reaction of decomposition of isopropyl alcohol as probe reaction. These hybrids CNTs interact very well with aqueous media due to the hydrophilic nitrogen doped section, while the undoped hydrophobic part has strong affinity for organic molecules [1].

2 Experimental :

The hybrid carbon nanotubes were synthesized by a catalytic CVD process in a fluidized bed reactor using ethylene as carbon source and acetonitrile as carbon/nitrogen source. Four samples of carbon nanotubes were produced: (a) ethylene alone for 30 min, (b) acetonitrile/N_2 for 30 min, (c) ethylene for 10 min, followed by acetonitrile/N_2 for 20 min, and (d) acetonitrile/N_2 for 20 min followed, by ethylene alone for10 min. The CNTs were purified by a solution of H_2SO_4 (50 vol.%) under reflux for 3 h for the elimination of catalyst particles contained in the nanotubes.

After that, the desired amounts of Pd and Ru precursors were added to an acetone solution containing 0.5 g of the carbon nanotubes supports. After stirring overnight at ambient temperature, the catalysts were filtered, washed with acetone and dried in an oven at 120°C. The catalysts were then reduced at 300°C for 2 hours in a horizontal oven under an Ar-H_2 flow (20 vol% H_2).

3 Results and discussion :

The presence of nitrogen functionalities (pyrrolic, pyridinic and quaternary nitrogen) on the nitrogen doped support induces a high metal dispersion. Figure 1 shows TEM micrographs and particle size distribution for the palladium and shows that the Pd dispersion increases with the nitrogen content in the CNTs for which the mean Pd particle size was 4.4 nm (Pd/CNT) > 1.4 nm (Pd/Amphiphilic-CNT) > 1.2 nm (Pd/N-CNT). For the hybrid structure, for which the nucleation should arise preferentially on the N-doped sections, a much higher density of metallic nanoparticles is noticed on the hydrophilic sections.

Decomposition of isopropyl alcohol on the CNT supports, leads to acetone by dehydrogenation and propene by dehydration. Thus, on hybrid N-CNT, at 210°C as reaction temperature, and in the presence of air as carrier gas, the conversion was higher than on the CNT and nitrogen doped CNT samples. As far as the supported catalysts are concerned, the Pd ones were more active and more selective than the Ru ones. From 90°C, the Pd over hybrid CNT catalysts was 100% selective towards acetone for a conversion of 100%, whereas Ru

catalysts lead to dehydration and dehydrogenation products. The nitrogen doping induces the appearance of redox properties, which appear when oxygen is present in the reaction mixture.

Table 1. Surface and structural characterization of the hybrids CNTs.

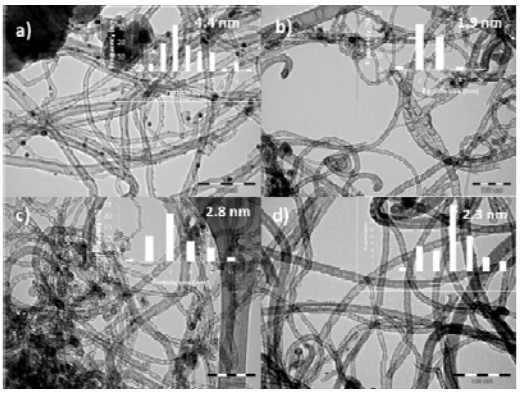

Fig. 1. TEM micrographs and Pd particle size distribution of the fresh Pd catalysts: a) Pd/E30; b) Pd/A30; c) Pd/E10A20; and d) Pd/A20E10.

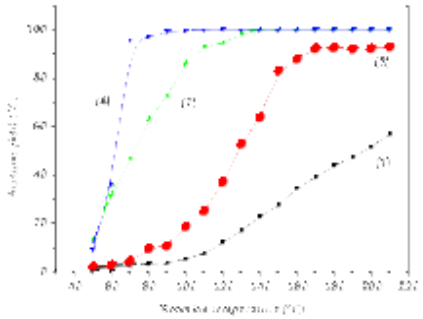

Fig. 2. Acetone yield over Pd/E10A20 catalysts versus reaction temperature in absence (1) and presence (2) of air, and over Pd/A20E10 in absence (3) and in presence (4) of air.

4 Conclusions :

The hybrid carbon nanotubes are very promising for the development of many different applications in catalysis and biphasic processes, other investigations for the recovery of these hybrid nano-structures are in course.

Keywords: zirconium phosphate, copper, phosphate, ethanol, oxidation, dehydrogenation

1 Introduction

Acetaldehyde is used as a raw material for production of many important organic compounds such as acetic acid, acetic anhydride, ethyl acetate, ethylene, crotonaldehyde, etc. As a rule, IB-group metals and transition metal oxides are active towards the oxidation of alcohols to aldehydes [1, 2, 3]. Metal phosphates are considered as catalysts for oxidation, dehydration and dehydrogenation of alcohols [4, 5, 6]. The attention to double metal phosphates is connected with their flexible structure and composition.

In the present work peculiarities of formation of Cu^0 particles in the structure of double copper-zirconium phosphates as well as activity of zirconium phosphate and copper-zirconium phosphate in ethanol transformation were studied.

2 Experimental

The samples of zirconium phosphate (ZP) and copper-zirconium phosphate (CZP) were prepared as previously described [6]. Sols were dried and calcined in air at 700-1000 ^oC during at least 10 h. The CZP sample was pretreated by a flow of H_2/N_2 mixture at 600 ^oC prior to catalytic experiments (CZP-H_2).

The structure of samples was characterized by X-ray diffraction and transmission electron microscopy with high resolution (HRTEM). The interaction of copper cations with the reducing agent was studied by a temperature-programmed reduction-oxidation (TPR/TPO) technique.

The temperature-programmed gas-phase ethanol oxidation reactions were carried out in a quartz tube flow reactor with an internal diameter of 6 mm. The reactor containing the catalyst was fed with the reactive gas mixture EtOH/O_2/He (ODE) or EtOH/He (DE), operating at atmospheric pressure. During the catalytic runs, gas samples were analyzed periodically by integrated online GC with a flame-ionization detector and a thermal conductivity detector.

3 Results and discussion

According to the X-ray phase analysis data of CZP samples calcined at different temperatures, the amount of phases of double copper-zirconium phosphates increased with a rise of sintering temperature, while the amount of pyrophosphate ZrP_2O_7 decreased. Only $Zr_{2.25}(PO_4)_3$ phase was detected for ZP sample. The CZP(700) sample consisted of morphologically homogeneous faceted crystals of $Cu_xZr_y(PO_4)_z$ with sizes about 50 nm. These crystals were combined into mesoporous aggregates with sizes about 100 nm. TEM HR observations of crystal structure showed interplanar distance equal to ≈ 0.7 nm, which related to the frame structure.

TPR profiles of cyclic experiments TPR1/TPO/TPR2 showed thermal instability of double phosphates towards reduction of atmosphere and destruction of original compounds. Treatment of Cu-containing samples (CZP-H_2) by a flow H_2/N_2 mixture at 600 °C led to reduction of copper ions to form Cu^0 (CSR 34 nm) and accompanied by destruction of original double metal phosphates $Cu_{0.5}Zr_2(PO_4)_3$, $CuZr_4(PO_4)_6$. The distribution of Cu^0 particle sizes was in the range from 2 nm to ~1 μm.

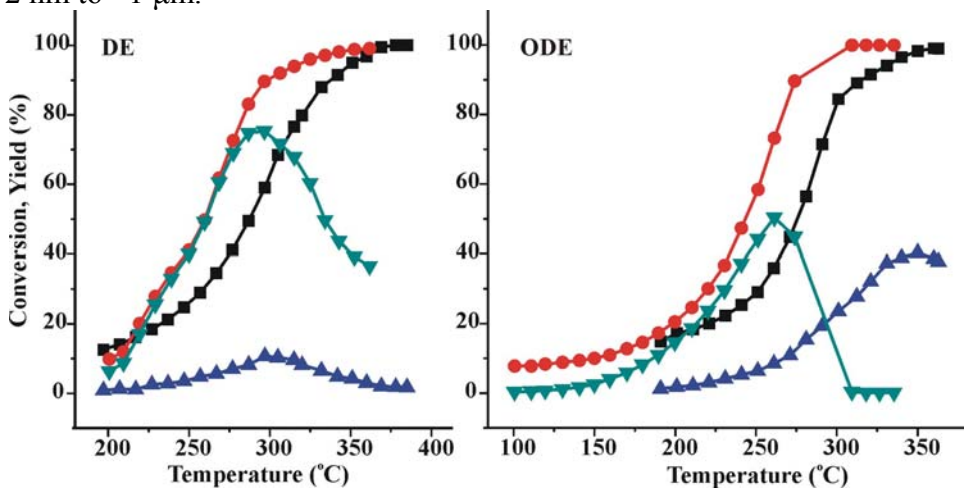

Fig. 1. Catalytic performance of ZP and CZP-H_2 in dehydrogenation (DE) and oxidative dehydrogenation (ODE) of ethanol. Conversion of ethanol over ■ – ZP and ● - CZP-H_2; yields of acetaldehyde over ▲– ZP, ▼ – CZP-H_2.

For both samples conversion of ethanol reached 100% under DE and ODE conditions. Ethanol transformations over the samples led to formation of acetaldehyde, ethylene, COx, diethyl ether and unidentified product. Acetaldehyde was the main product for CZP-H_2 sample in the absence of oxygen (Fig. 1, DE ▼, yield 75 %), while ethylene was the one for ZP sample. Formation of acetaldehyde was also observed over zirconium phosphate in a small amount, 11 % (Fig. 1, DE ▲). The ZP sample was an acid catalyst, and dehydration products were produced above 270 °C resulting in shifting of ethanol conversion curve to higher temperatures (Fig. 1, DE ■).

When oxygen was in the initial feed, the yield of acetaldehyde reached 50 % for CZP-H_2 sample at 260 °C (Fig. 1, ODE ▼). Deep oxidation of ethanol occurred above 260 °C. This was due to formation of Cu_2O on the surface of Cu^0 particles. Ethanol oxidized to acetaldehyde over zirconium phosphate ZP (Fig. 1, ODE ▲) under similar conditions, which can be connected with interaction of oxygen with coordination unsaturated Zr^{4+}.

4 Conclusions

The study on structure, phase composition and catalytic properties of Cu-containing zirconium phosphate and zirconium phosphate in ethanol transformation was carried out. The absence of oxygen in the feed gas favored for dehydrogenation of ethanol to form acetaldehyde over Cu-containing zirconium phosphate: acetaldehyde yield was 75%. Acetaldehyde yield about 40 % was reached for zirconium phosphate in oxygen-containing atmosphere.

Keywords: oxidative coupling of methane, C_1-C_2-hydrocarbon oxidation, heterogeneous-homogeneous processes, kinetic conjugation

1 Introduction

The oxidative coupling of methane (OCM) is a promising one-step process for producing ethylene from methane. One of the factors that hamper its practical implementation is a relatively low per-pass yield of the target products (ethane and ethylene) that is due to their high reactivity as compared to methane. Consequently, the OCM reaction conditions are the subject for optimization based on the reliable kinetic information about the secondary reactions of C_2-hydrocarbons. This work is focused on the detailed study of C_2-hydrocarbon oxidation including the possible reciprocal influence of C_1-C_2 hydrocarbons during their simultaneous oxidation in the presence of OCM catalysts (kinetic conjugation). Some literature data indicate that the presence of methane in the reaction mixture inhibits both ethane and ethylene oxidation in the gas phase [1]. Since all hydrocarbon molecules may undergo activation of the same type via C-H bond capture over typical OCM catalysts, one may expect even more complex conjugation in the conditions of their catalytic oxidation.

2 Experimental/methodology

Separate methane, ethane and ethylene oxidation are studied both in the presence and in the absence of OCM catalyst ($NaWMn/SiO_2$) in a conventional quartz flow micro-reactor at atmospheric pressure with on-line GC analysis. In typical experiments, methane, ethane, ethylene and oxygen partial pressures were 0.5, 0.05, 0.05, and 0.15 atm., respectively (balance – nitrogen). To reveal the reciprocal influence of C_1-C_2 hydrocarbons, we compared the sum of concentrations of different components in the reaction mixture obtained during the oxidation of individual hydrocarbons and their mixtures in the same conditions.

3 Results and discussion

The experimental results demonstrate that in a blank reactor C_2-hydrocarbon oxidation proceeds with a high rate at temperatures above 760°C. Almost total conversion of ethane and ethylene mainly to CO_X is observed at temperature around 840°C (see Fig. 1). In the reactor filled with quartz chips and $NaWMn/SiO_2$ catalyst the rate of conversion of both hydrocarbons significantly drops; in the presence of the catalyst ethane oxidation shifts from non-selective oxidation to oxidative dehydrogenation and ethylene oxidation – from CO to CO_2 formation. These observations suggest that the OCM catalyst surface substantially changes the hydrocarbon transformation pathways and efficiently inhibits unselective gas phase oxidation. The observed inhibitory effect is likely due to the interaction of free radicals responsible for chain branching and propagation with the catalyst active sites. Such radicals can be both generated and captured by the catalysts surface that leads to substantial changes of absolute and relative concentrations of species responsible for the development of chains and formation of different products.

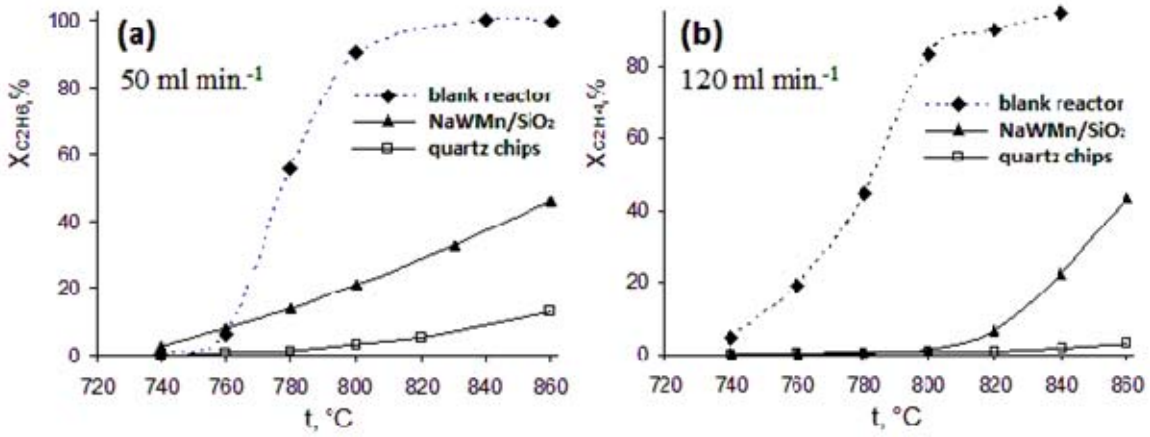

Fig. 1. Ethane (a) and ethylene (b) oxidation in blank reactor and in reactor filled with quartz chips and $NaWMn/SiO_2$ catalyst.

The presence of methane in the initial mixture strongly affects the C_2 hydrocarbon oxidation. In case of ethylene, strong inhibition of its oxidation is observed both in blank reactor and over $NaWMn/SiO_2$ catalyst; the addition of methane also leads to a drastic drop of CO_X concentration and noticeable increase of propylene formation in a good agreement with [1,2]. Based on the results of detailed kinetic modeling of gas phase C_1-C_2 hydrocarbon oxidation [1] it was proposed that high concentrations of methane greatly reduce chain-branching reactions. The newly obtained results demonstrate that such inhibitory effect takes place not only in case of gas phase ethylene oxidation, but in presence of OCM catalysts as well. It is likely that in both cases the observed effects can be explained in the same manner.

A more complex kinetic conjugation is observed during ethane oxidation in presence of methane. In blank reactor, methane acts as the gas-phase oxidation inhibitor (similar to ethylene oxidation). On the contrary, during the methane-ethane mixture oxidation over $NaWMn/SiO_2$ catalyst a strong increase of conversion rates of them both is observed. A possible explanation of observed effect can be likely obtained from the process simulation based on the detailed heterogeneous-homogeneous model [3].

4 Conclusion

C_1-C_2-hydrocarbon oxidation has been studied in conditions of methane oxidative coupling. It is demonstrated that gas phase oxidation of ethane and ethylene proceeds with a high rates at typical OCM temperatures. $NaWMn/SiO_2$ catalyst acts as an efficient inhibitor of gas phase oxidation of C_2-hydrocarbons and substantially changes their reaction pathways. A complex reciprocal influence of C_1-C_2 hydrocarbons during their simultaneous oxidation is demonstrated. Unlike the process in the gas phase, methane and ethane strongly increase the reactivity of each other while oxidized over the OCM catalyst.

Keywords: electrooxidation, metal-catalysis phosphonation, azoles, dialkylphosphites

1 Introduction

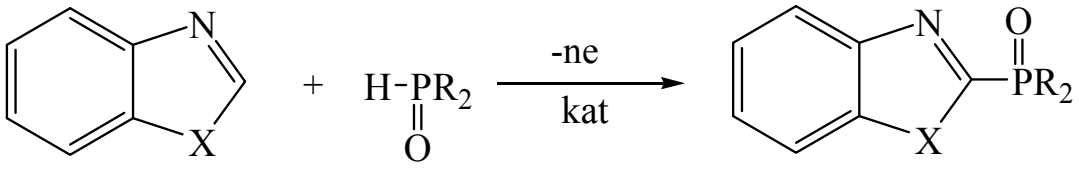
Aryl phosphonates and their derivatives have found a wide range of applications in medicinal chemistry, catalysis and organic synthesis. Phosphorylated azoles play important role in this field. The first phosphonate derivatives of benzoxazoles were obtained in the 60-s of the last century by Razumov A.I. by heating of o-aminophenol with diethyl diethoxymethyl phosphonate with the distillation of alcohol [1, 2]. Recently, transition metal catalyzed aromatic C–H functionalizations have found increasing applications in the formation of C–heteroatom bonds including scarce catalytic examples of C(sp2)–P bond formation. The first Pd-catalyzed direct phosphonation of azoles with dialkylphosphites has been achieved without addition of base or acid. This method involves the oxidative cleavage of C–H and P(O)–H bonds and represents an atom-efficiency alternative to the classical phosphonation of Ar–X [3]. Electrochemical approach has several advantages over conventional organic synthesis allowing reactions to be carried out under mild conditions without any oxidizing agents. The development of new approaches for selective C-H-functionalization (phosphorylation) of different heteroaromatic substrates under conditions of electrocatalytic generation of palladium or nickel catalysts in high oxidation states is important.

2 Experimental/methodology

Electrochemical approach, which has several advantages over conventional organic synthesis allowing reactions to be carried out under mild conditions without any oxidizing agents, was used. The latter is important for oxidative M(II)-M(III)/M(IV) catalysis that is sensitive to the choice of an oxidant.

3 Results and discussion

The metal-catalyzed electrochemical oxidation (phosphonation) of heteroarylazoles (benzoxazoles, benzothiazole and other) with dialkylphosphite was developed. Palladium and nickel complexes were tested as catalysts.The joint electrochemical oxidation of a mixture of azoles and dialkylphosphite in the presence of palladium acetate Pd(OAc)2 (10 mol %) or (bpy)NiBF4 at room temperature affords the desired ortho C-H substitution product, 2-substituted azoles.



X = O, S, N

R = AlkO, Ph

The structure of the obtained heteroaryl azoles was confirmed by NMR spectroscopy, mass-spectral analysis. To optimize electrochemical synthesis experiments were carried out in different conditions. Metal-catalyzed electrochemical oxidation studied and its mechanism was proposed.

4 Conclusions

Thus a new electrocatalitic approach to C-H phosphonation of heteroarylazoles was developed.

Keywords: petrochemistry, oil refining, catalysis, technology, training, personnel

1 Introduction

The priority fields of the economic development of Russia include the sustainable use of energy and natural resources in oil-and-gas production, oil-and-gas processing, and petrochemistry. Their development is supported by solving the problems of effective using and providing the sustainable replenishment of resources for oil producing and processing industries; reducing losses at all stages of operating procedures in oil-and-gas treatment, production, transportation, and processing; deepening oil-and-gas processing; integrated extracting and using all valuable associated and dissolved components, upgrading the existing oil-and-gas processing and petrochemical industries, as well as developing and implementing new technology [1].The efficient solving of the above tasks using catalytic techniques creates a need for highly qualified personnel trained on an advanced basis.

2 Experiment / Methodology

Thus, the primary purpose of the advanced training of catalysis experts in petrochemical and refining industries is educating competent, perspective/innovative-oriented personnel capable of working in the existing productions using known catalytic techniques, as well as in would-be implemented ones, and focusing on the development and research of new catalysts, engineering-ready catalytic productions and their efficient management.

Within the Federal State Budgetary Educational Institution of Higher Professional Education "Kazan National Research Technological University" (FSBEIHPE "KNRTU"), advanced professional training is implemented as an innovative educational process. Its efficiency is determined by integrating science, education and production, by developing and implementing multilevel educational programs, by arranging the professional development of teaching personnel, by developing technical infrastructure, and by developing the methodological support of education.

Integration of science, education and production is promoted within an industry-specific research and education cluster. Within the cluster, the key partners of FSBEIHPE "KNRTU" are:JSCTatneft, JSCKazanorgsintez, OJSCAmmoni, JSCTaneco, and PJSCNizhnekamskneftekhim. Interaction with key employers allows organizing the study of catalytic technology by students in the conditions of real plants: Arranging and equipping catalytic processes, the special features and opportunities of catalysis, analysis of changes in catalysts activity, and the methods of catalyst recovery.

Advanced training in the field of catalysis is supported by implementing the educational programs of multidisciplinary masters course. Within a research masters course, our graduates study advanced catalytic systems, catalytic process chemistry and technology, chemical reaction mechanisms and kinetic models, catalysts manufacturing techniques and research methods, and facilities equipment.

The intensive development of catalytic techniques and their implementation in production create the need for training design engineers. Implementing design engineering master programs covers the need of the complex for catalytic production 3D design experts.

Within a management masters course, future experts are trained to manage chemical and technological processes under the conditions of high integration of modern productions.

Educationis also provided with its advanced nature due to internationally integrated catalysis research and practical studies at Aristotle University of Thessaloniki, Greece, the University of Chemical Technology and Metallurgy – Sofia, Bulgaria, and the Technical University of Denmark, as well as to practical studies at leading companies developing catalytic technologies, such as Hempel Group or HaldorTopsoe (Denmark).

3 Results and discussion

Within the cluster, the key partners of FSBEIHPE "KNRTU" in implementing the advanced training are:JSCTatneft, JSCKazanorgsintez, OJSCAmmoni, JSCTaneco, and PJSCNizhnekamskneftekhim.

When organizing the advanced training, the following programs have been developed and are implemented: In the research masters course – Chemistry and Technology of Basic Organic and Petrochemical Synthesis Products, Chemical Engineering of Manufacturing the Reactants for Oil Extracting/Processing Industries, Catalytic Techniques in Petrochemistry and Oil Processing; in the design masters course – Innovative Petrochemical Synthesis Technology Design, Theoretical Bases and Design of Prospective Chemical Techniques; and in the management masters course – Petrochemical Enterprise Lifecycle Management.

The efficiency of advanced training is confirmed by the increased being in demand of the university's graduates in the industry labor market; professional growth of graduates within 2-3 years on innovative petrochemical enterprises; the students' interest in studying the programs of multidisciplinary masters course; growth in the students' research activities and their participation in innovative project competitions.

4 Conclusions

In training the experts, advanced education, unlike the conventional one, focuses on developing the readiness to get new knowledge and acquire multifunctional skills rather than on a certain professional activity, and enables the professional mobility and competitiveness of a graduate conforming with the demands of the modern and challenging labor market [2].

Keywords: catalysis, quantum chemistry, catalytic processes, mechanism and kinetics

1 Introduction

Various traditional courses on catalysis mainly based on available experimental data and consider experimental methods. In addition to these classes, theoretical course "Catalysis and mechanisms of chemical reactions" have been taught in KNRTU over the past five years. This course considers employing of theoretical methods of quantum chemistry, statistical thermodynamics, reactions rate theory for exploration of mechanism and kinetics of the complex multi-stage chemical processes, including catalytic reactions.

2 Methodology

Some methodological features of the course are discussed in this report. First of all, authors believe that gaining skills of using quantum-chemical calculations for exploration of the mechanisms of catalytic reactions is the task of highest priority.

3 Results and discussion

Therefore, the ratio of the time course of lectures and laboratory classes is 1: 3. This course is taught in KNRTU to the students of basic chemical specialties with different level of knowledge and experience in the field of physical chemistry and physics. Hence, it is necessary to spend some time during lectures and laboratory classes for introduction to elements of quantum mechanics and statistical thermodynamics.

The course is taught for bachelors and masters. Classes of chemical compounds and chemical reactions are usually chosen for the undergraduate courses in accordance with students' specialty. Undergraduate students develop skills and acquire basic knowledge for modeling of chemical compounds and determination of the properties of the simulated material. As for the graduated students, selected tasks are usually overlapped with the subject of their master theses. Visiting http://nano-portal.ru/ and www.rusnano.com/ websites is practiced during classes with the purpose to introduce students to latest achievements in the field of catalytic processes.

4 Conclusions

Considerable part of the course and laboratory classes is devoted to the study of the structure of nanocatalysts and their role in catalytic processes at molecular level.

Textbooks and manuals designed and published by the staff of the Department of Catalysis KNRTU are widely used during the course together with existing textbooks.
